Nasal regurgitation of liquids or solids is the result of an incompetent velopharyngeal mechanism and can be observed in patients with palatal or tonsillar fossa resection, or cranial nerve or muscular dysfunction. Cranial nerve dysfunction can be the result of, for example, ALS, skull base tumor, or cerebral or brainstem stroke (Fig. 32-13). The increased pressure by the tongue to propel the bolus into the pharynx causes the bolus to take the path of least resistance, resulting in nasal regurgitation when there is reduced nasopharyngeal closure during swallowing. Nasal regurgitation is usually more pronounced with liquid boluses or when the patient's chin is tucked in. Patients may control their nasopharyngeal incompetence by adopting a head upright posture or by swallowing consistencies of higher viscosity than liquids.

Palatal obturators or palatal lifts are dental appliances constructed to reduce nasal regurgitation, increasing the integrity of the velopharyngeal port. In cases of severe incompetence when an appliance is not available, these patients can be instructed to hold the nose closed with their fingers in an attempt to improve the seal and increase pressure on the bolus without leakage into the nasopharynx.

Epiglottis

Downfolding of the epiglottis is frequently a focus in VFSS interpretation. It is important to bear in mind, though,

FIGURE 32-13 Nasopharyngeal regurgitation (*arrow*).

VIEW IMAGE

that the epiglottis is a cartilage with attachments to the hyoid bone, tongue base, and larynx. Since the epiglottis is a ''passive performer,''[24] its inversion depends on adequate function of these attached structures, which are most often implicated in impaired epiglottic movement. Biomechanical movements of structures attached to the epiglottis should receive attention when therapeutic maneuvers are selected for evaluation during the VFSS.

Prior to the onset of the pharyngeal swallow, the epiglottis deflects advancing secretions or boluses around the laryngeal inlet.[39] The laryngeal vestibule is shielded by the movement of the epiglottis from the upright to the horizontal position by thyrohyoid shortening and is clearly visualized on fluoroscopy, particularly in the lateral view.

FIGURE 32-15 Laryngeal penetration (*arrow*) during the swallow to the level of the true vocal folds in a patient with a supraglottic laryngectomy. In this procedure the hyoid bone, epiglottis, and supraglottis are resected. Aspiration is prevented by forceful adduction of the true vocal folds during the swallow.

VIEW IMAGE

Inversion of the epiglottis can also be visualized in the AP projection, appearing as a slit-like opacity within the column of barium (Fig. 32-14).

In the standard supraglottic laryngectomy procedure, the entire epiglottis is resected together with the carcinoma of the supraglottis, making the laryngeal vestibule vulnerable to penetration or aspiration of oral secretions, liquid materials, and solid materials (Fig. 32-15). Patients are

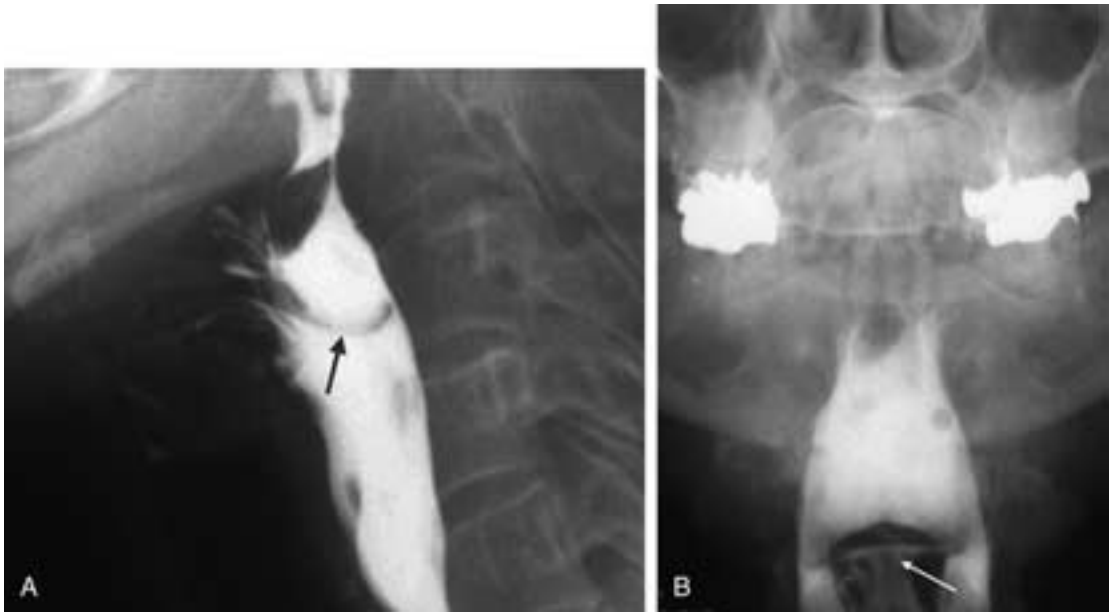

FIGURE 32-14 Normal epiglottic (*arrow*) deflection during swallowing in the lateral (**A**) and AP (**B**) views.

taught voluntary airway protection techniques, enabling them to swallow in most cases.

Thickening and fibrosis of the epiglottic mucosa and attached supporting structures occur after radiation therapy, affecting the extent of downfolding even if hyolaryngeal excursion is spared. An edematous epiglottis may attach to the tongue base and appear blunted in the lateral radiographic view, restricting the guarding function of the epiglottis and obliterating the valleculae.[39]

Impaired laryngeal excursion or tongue base retraction has the effect of maintaining vallecular continence, in contrast to the ''flattening out'' of the valleculae that occurs in normal epiglottic deflection, and stasis is observed in the valleculae after the swallow. Furthermore, transient penetration can occur along the laryngeal surface of the epiglottis during the pharyngeal swallow, which may or may not be extruded from the laryngeal vestibule, depending on the competence of hyolaryngeal excursion.

The danger of impaired epiglottic downfolding lies in the amount of residue remaining in the valleculae after the swallow. The greater the stasis, the greater the risk that material (liquid or solid) will spill over the tip of the epiglottis or over the aryepiglottic folds and penetrate the airway.[45]

Hyoid and Larynx

The radiodensity of the hyoid bone makes its movement trajectory quite easy to track during swallowing on VFSS. The hyoid bone is suspended by muscular attachments extending from the tongue and mandible to the larynx. Contractions of the geniohyoid, mylohyoid, and anterior belly of the digastric muscles are primarily responsible for superior and anterior movement of the hyoid bone.[15] The hyoid bone is attached along its inferior border to the thyroid cartilage by the thyrohyoid ligament, which is shortened during hyolaryngeal excursion. These movements are clearly viewed in the lateral radiographic projection. In the normal individual, the hyolaryngeal complex moves an average of 2 cm anteriorly and 2 to 2.5 cm superiorly from rest to maximal excursion (Fig. 32-12).[25, 34, 46] Increased bolus volume affects the duration and extent of maximal hyolaryngeal excursion.

The primary function of hyolaryngeal excursion is to pull the entire larynx away from the posterior pharyngeal wall, thus creating a continuous conduit for the advancing bolus from the hypopharynx through the cervical esophagus. This has the dual effect of opening the upper esophageal segment while simultaneously protecting the laryngeal vestibule as the epiglottis deflects. As the larynx elevates, the arytenoid cartilages rock and tilt anteriorly to contact the base of the epiglottis, closing the entrance to the airway.[12]

Impairment of hyolaryngeal excursion results therefore in stasis in the pyriform sinuses after the swallow or in penetration of the laryngeal vestibule during the swallow resulting from incomplete closure of the supraglottic entrance. While transglottic aspiration may not occur immediately, the presence of material in the larynx may make it more likely. Since pyriform sinus stasis can also result from impaired pharyngeal clearance or inadequate intrinsic relaxation of the cricopharyngeus muscles, all possibilities must be probed before reduced laryngeal excursion is held primarily responsible.

In most cases, anterior and superior movement coexist; however, it is possible to observe increased impact in one or the other movement plane. For example, it is possible for patients to present with reduced anterior excursion while superior movement is preserved. In reality, safe and efficient swallowing demands sufficient superior and anterior excursion.

Pharyngeal Wall

The pharyngeal constrictors move the pharyngeal wall anteriorly during the pharyngeal swallow to function as a surface that the tongue base can contact to drive the bolus into the hypopharynx. In addition, contraction of the constrictors and the longitudinal pharyngeal musculature (salpingopharyngeus, palatopharyngeus, and stylopharyngeus) shortens the pharynx, clearing the bolus from the pharyngeal recesses and propelling it into the cervical esophagus. In the lateral projection, pharyngeal contraction is seen as a progressive anterior bulge from superior to inferior along the posterior wall. Propagation in the pharynx is very rapid, 12 to 25 cm/sec, compared with 1 to 4 cm/sec in the esophageal phase.[26, 27] In the AP projection, medial excursion of the lateral pharyngeal walls is seen bilaterally in the normal individual, but in up to 20% of normal subjects, swallowing can occur down only one side.[47] The term *pharyngeal contraction wave* is preferable to *pharyngeal peristalsis*, as peristalsis applies to a circumferential muscular tube such as exists in the esophagus and does not pertain to the pharynx, as the anterior pharyngeal wall is composed of the tongue base, laryngeal vestibule, and larynx[12] (Fig. 32-12).

The effect of impaired pharyngeal wall motion is residue along its length or in the pharyngeal recesses. In unilateral impairment, the residue is located along the weak side and is best viewed in the AP projection. Usually the stronger side pushes the bolus over to the weaker side, which has increased flaccidity; hence the unilateral retention. However, in the AP plane, unilateral pharyngeal wall weakness is visualized as residue in one of the pyriform sinuses or in one side of the vallecula (Fig. 32-16). Double or multiple swallows per bolus may indicate pharyngeal weakness. The patient may also report the failure of bolus clearance.

Bilateral pharyngeal weakness can be seen in patients suffering from progressive neurologic disease, deconditioning, sarcopenia of the oropharyngeal musculature, and radiation fibrosis. Patients with pharyngectomy extending across the midline experience severe stasis even when tongue base retraction is relatively spared. Postural therapeutic maneuvers to be discussed later, which alter the dimensions of the pharynx, are sometimes helpful.

Weak pharyngeal contraction is difficult to separate from weak tongue base retraction. Each biomechanical movement must be inspected for its contribution in the event that pharyngeal residue is observed. Furthermore, impaired laryngeal elevation can affect epiglottic deflection and may erroneously implicate the pharyngeal constrictors.

Transient pharyngeal outpouchings may be observed during swallows of liquid boluses larger than 7 to 12 cc.[48] These outpouchings are the result of pharyngeal mucosa herniating through focal weakness in the thyrohyoid membrane anterior to the thyrohyoid ligament and are believed to occur due to dyssynchronous contraction of the

Copyright © 2003, Mosby, Inc. All rights reserved.

VIEW IMAGE

FIGURE 32-16 Unilateral weakness of the right pharyngeal wall resulting in stasis on that side. Contraction of the left lateral pharyngeal wall, indicated by the arrow, moves the bolus over to the weaker right side.

oblique and longitudinally oriented pharyngeal muscles[48] in the context of increased intrapharyngeal pressures (Fig. 32-17). While these outpouchings have been considered a normal variant, Curtis et al.[48] observed that they become symptomatic when the bolus arrival coincides with the appearance of the pharyngocele. When the bolus is in the esophagus once the outpouching occurs, the patient is asymptomatic.

Glottic Closure

Protection of the airway involves numerous biomechanical movements that change the aerodigestive tract from a respiratory to an alimentary system.[49] Epiglottic inversion and hyolaryngeal excursion close the airway in a vertical plane. Closure of the laryngeal vestibule in the horizontal plane is made possible by adduction of the true and vestibular vocal folds and can be first detected during the oral stage of swallowing. Respiration ceases at this point, increasing the subglottic pressure and helping to keep boluses from entering the airway. The airway remains closed for 0.6 to 0.7 second and opens again once the larynx descends and the epiglottis is in the resting position.[22, 50]

Glottic closure is not clearly observed with videofluoroscopy, and inferences about its integrity are based on the presence or absence of barium flow. In the lateral view, closure of the laryngeal vestibule is inferred when the air column disappears. Through frame-by-frame analysis of the video recording, it is possible to visualize rocking of the arytenoid cartilages anteriorly to appose the base of the epiglottis. In the AP projection, normal glottic closure is usually superimposed on the bony spine, compromising detection of midline vocal fold adduction. However, when aspiration occurs, an outline of the true and vestibular vocal folds and the laryngeal ventricle is clearly visible.

Laryngeal penetration and/or aspiration are the primary consequences of impaired closure of the glottis. Incoordinated timing of laryngeal closure is one of the major culprits and is discussed in a later section. Neuromuscular or structural defects can impair laryngeal closure, can occur unilaterally or bilaterally, and can involve small or large

VIEW IMAGE

sections of the larynx. Vocal fold paralysis can result from disease processes such as brainstem stroke, progressive motor neuron disease, skull base tumors, or infection. In addition, iatrogenic vocal fold paralysis is a well-documented risk in patients who have undergone thyroidectomy, cardiac surgery, carotid endarterectomy, or various thoracic surgical procedures. Some patients with injury to the recurrent laryngeal nerve resulting in unilateral vocal fold paralysis may, but do not always, demonstrate penetration of the airway during swallowing of liquids. Similarly, wide surgical resection of the larynx, as seen in supraglottic laryngectomy or hemilaryngectomy, affects closure of the airway in the horizontal or vertical plane. Since many of these patients also undergo pre- or postoperative radiation therapy, fibrosis of the laryngeal structures further compromises airway closure. Patients who have recently required endotracheal intubation may exhibit impaired laryngeal adduction as a result of trauma to the vocal folds. Patients who demonstrate aspiration during the swallow as a result of impaired airway closure are excellent candidates for using postural strategies such as rotation of the head to the affected side or compensatory maneuvers such as the supraglottic swallow technique described in a later section.

When glottic closure is impaired during the swallow, it is likely that the protective or reflexive cough in response to aspiration will also be involved. This increases the patient's risk of developing pulmonary compromise since they will be unable to clear material from the airway either reflexively or upon instruction.

Cricopharyngeus/Pharyngoesophageal Segment

The pharyngoesophageal region is located ''beneath the pharyngeal air column and posterior to the arytenoid cartilages'' (Murray,[39] p. 126) and is approximately 3 to 4 cm in length, with the cricopharyngeus muscle comprising 1 cm of this length.[51] It is difficult to identify precisely the high-pressure zone of the pharyngoesophageal segment because of the tight contact of the mucosal walls. Cook[52] suggested that its location corresponds to the middle and lower third of the cricoid cartilage.

Opening of the pharyngoesophageal segment occurs as a function of three factors: intrinsic relaxation of the cricopharyngeus muscle, intrabolus pressure, and, most importantly, anterosuperior distraction of the hyolaryngeal complex away from the posterior pharyngeal wall, as discussed above. Only the last can be reliably observed on VFSS, but all factors may be involved in failure of opening. In the normal condition, the cricopharyngeus muscle complex does not indent the barium column, and increased bolus volume increases the duration and diameter of opening of the pharyngoesophageal segment[25, 52] (Fig. 32-12).

Functional failure of opening of the pharyngoesophageal segment may be the result of failure of or incoordinated cricopharyngeal relaxation, as occurs in patients with oculopharyngeal muscular dystrophy, lateral medullary syndrome, and Parkinson's disease.[53] Impaired hyolaryngeal elevation may also affect opening of the pharyngoesophageal segment, as has been described, resulting in postswallow retention in the pyriform sinuses.

Structural pharyngoesophageal abnormalities are numerous. The most common, cricopharyngeal prominence (also

FIGURE 32-18 Lateral view of a cricopharyngeal prominence (*arrow*).

VIEW IMAGE

referred to as a cricopharyngeal bar, cricopharyngeal achalasia, or cricopharyngeal hypertrophy) is a controversial entity in terms of its role in dysphagia (see Fig. 32-20). It appears as a shelf in the posterior barium column at the level of the cricoid cartilage and can be reproducible or inconsistent. Its location can be variable in relation to the cervical vertebrae because of the superior excursion of the larynx during the swallow. The presence of a cricopharyngeal bar increases with age, with 6.3% to 22% of elderly normal persons displaying this phenomenon.[32, 54, 55]

Abnormal contraction (or lack of relaxation) of the cricopharyngeus muscle is visible only during swallowing. It may occur as a function of uncoordinated timing or may be the result of intrinsic muscle fibrosis, for example in postradiation stricture. In either case, the muscle contraction appears as an indentation in the barium column, which, if severe, can obstruct the lumen, and is particularly troublesome during swallows of solid food and pills. It is sometimes seen in primary muscle disease such as polymyositis, peripheral or central cranial nerve palsy, brainstem stroke, or pharyngeal paresis.[15] Radiographic imaging of the cricopharyngeal prominence is best visualized during swallowing of large mouthfuls of barium (Fig. 32-18). It is important to remember that fluoroscopic imaging only provides information about the degree of opening or obstruction of the bolus flow. It does not document the extent of spasm or pressure, which is measured by manometric recordings. If cricopharyngeal achalasia is suspected, manometric investigation may be necessary.

The functional significance of a cricopharyngeal prominence increases in the context of coexisting pharyngeal problems such as reduced pharyngeal contractions. In fact, there are instances when the pharyngoesophageal segment

Copyright © 2003, Mosby, Inc. All rights reserved.

only appears to be prominent in relation to absent or weak pharyngeal contraction forces. Careful evaluation of pharyngeal contractility independent of the cricopharyngeus muscle complex is necessary to determine the underlying etiology of reduced bolus flow through the pharyngoesophageal segment. Dynamic fluoroscopic imaging is necessary to make this distinction. Cricopharyngeal myotomy may be recommended as the treatment of impaired opening of the cricopharyngeal muscle complex. Recent studies have shown that this procedure has limited value in patients with abnormal laryngeal excursion. Without the mechanical traction of the larynx away from the posterior pharyngeal wall, bolus flow through the segment is markedly restricted even after myotomy.[56, 57] Ergun and Kahrilas[58] state that cricopharyngeal myotomy is indicated only when there is complete obstruction of bolus flow, with increased intrabolus pressure and a decreased transsphincteric flow rate, as seen on manometric study as well as fluoroscopic imaging.

Zenker's diverticulum represents an abnormality of the opening of the pharyngoesophageal segment and, if large, can affect swallowing of solids and liquids. A Zenker's diverticulum is defined as ''a mucosal outpouching of the hypopharyngeal wall located in Killian's triangle between the upper border of the cricopharyngeus and inferior pharyngeal constrictor muscles''[59] (p. 1229). Figure 32-19 presents images of a Zenker's diverticulum in the lateral and AP projections. The cricopharyngeus is described as fibrotic and stiff and reduces the opening of the lumen in the context of normal laryngeal excursion. During VFSS, contrast fills the pouch, and as the larynx descends and pressure is placed on the pouch, its contents are emptied and some of the regurgitated material may fall into the airway. Surgical correction is the appropriate treatment, with pexy or resection of the pouch and concurrent cricopharyngeal myotomy necessary to avoid formation of recurrent diverticula.[60]

Occasionally, a small irregularity is noted on the anterior wall of the hypopharynx that corresponds to the postcricoid region. This indentation has been attributed to a submucous venous plexus and/or redundant mucosa.[61] This irregularity is often pliable and not fixed, as in the case of a tumor, which can be confirmed if necessary with a CT scan or endoscopic evaluation. Table 32-4 provides a summary of impaired biomechanical movements in oropharyngeal swallowing and their related radiographic findings.

Esophagus

Propagation of boluses through the esophagus is the result of primary and secondary peristalsis lasting for approximately 8 seconds.[1] While a discussion of esophageal motility is beyond the scope of this chapter, it is important to emphasize the need to observe contrast moving through the entire lumen of the esophagus in patients who complain of solid food dysphagia and who present with normal oropharyngeal swallowing of semisolid and even textured boluses. Obstruction of the lower esophageal segment by a 13 mm barium tablet or failure to pass the tablet in these cases may support the need for further radiographic or endoscopic evaluation.

Temporal Coordination of Biomechanical Events in Relation to Bolus Flow

Up to this point, the focus of interpretation of VFSS has been on displacement of the bolus as a result of

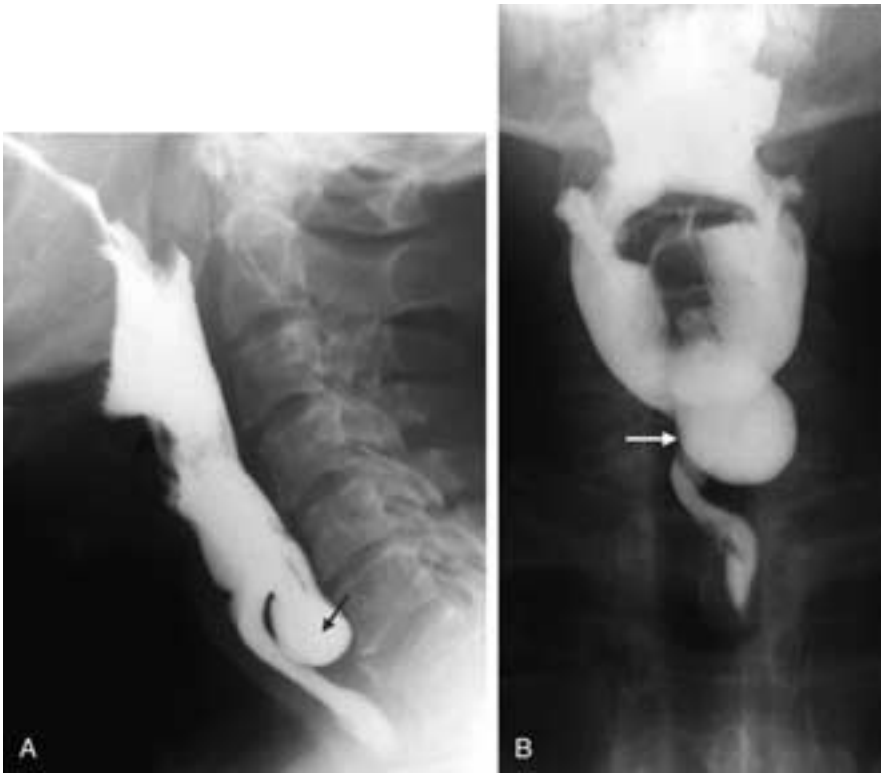

FIGURE 32-19 Lateral (**A**) and AP (**B**) views of a Zenker's diverticulum (*arrows*).

Table 32-4
COMMON OROPHARYNGEAL BIOMECHANICAL IMPAIRMENTS AND THEIR RELATED RADIOGRAPHIC FINDINGS

Biomechanical Impairment	Radiographic Findings
Reduced lip closure	Barium spills out from the lips
Reduced range of coordination of tongue movement	Bolus coats tongue diffusely
Reduced tongue lateralization	Bolus is not deformed promptly during chewing
Impaired cognitive function, neural function, or oral sensation	Hesitancy initiating swallowing
Reduced labial or buccal tension	Stasis in buccal sulci
Reduced tongue shaping	Stasis in floor of mouth
Impaired tongue motion	Abnormal AP lingual movements
Reduced tongue elevation	Poor tongue-to-palate contact
Parkinson's disease	Repetitive tongue rolling
Reduced tongue or palatal control	Premature spillage of bolus
	Penetration and/or aspiration before the swallow
Dry oral cavity	Diffuse coating of barium over tongue and pharynx
Impaired tongue movement	Slow oral transit time
Delayed onset of pharyngeal swallow	Bolus fills valleculae and/or pyriform sinuses before swallow is activated
Velopharyngeal insufficiency	Nasal regurgitation
Impaired tongue base retraction	Residue in valleculae and on pharyngeal wall
Reduced hyolaryngeal excursion	Residue in pyriform sinuses
	Incomplete epiglottic deflection
	Aspiration during and after the swallow
Hypertonic cricopharyngeus muscle	Reduced opening of the pharyngoesophageal segment
	Increased pyriform sinus residue
Large cervical osteophyte	Incomplete epiglottic deflection
Diminished pharyngeal wall contractions (unilateral or bilateral)	Stasis along pharyngeal wall
	Residue in valleculae and/or pyriform sinus
	Laryngeal penetration and/or aspiration after the swallow
Reduced hyolaryngeal excursion	Impaired epiglottic downfolding
	Impaired tongue base retraction
	Laryngeal penetration and/or aspiration
Incomplete laryngeal closure	Laryngeal penetration/aspiration during the swallow
Zenker's diverticulum	Regurgitation after swallow from pouch in cervical esophagus
Impaired vocal fold adduction	Laryngeal penetration and/or aspiration during the swallow

movements of the structures of the oral cavity, larynx, pharynx, and pharyngoesophageal segment as isolated events. It is the sequenced coordination of these events, many of which overlap temporally, that affects the direction or misdirection of the bolus through the upper aerodigestive tract.

Timeliness of Onset of Pharyngeal Swallow

Timing of onset of the pharyngeal swallow is important in determining the interaction between bolus flow in relation to airway protection. Delayed onset of the pharyngeal swallow response is also referred to as *pharyngeal delay*,[62] *duration of stage transition*,[63, 64] *stage transition duration*,[39] *delayed swallow* reflex,[65] or *delayed pharyngeal swallow*[12] (Fig. 32-20). It is affected by a number of conditions including stroke, Parkinson's disease, ALS, prior radiation therapy, postendotracheal intubation/tracheostomy, or oral cavity resection affecting laryngopharyngeal sensation. The longer the delay in initiating the pharyngeal swallow response after the bolus is in the pharynx, the greater the risk of latent material spilling into the airway.[45] Thin liquids travel rapidly through the oral cavity and pharynx, and an unprotected airway is vulnerable to an advancing bolus if the pharyngeal response is not elicited promptly. More viscous substances such as solids and semisolids travel more slowly and cohesively and allow the sensory system more time to respond with respect to initiating the motor responses for airway protection and opening of the pharyngoesophageal segment.

In the most extreme case, the pharyngeal response, with its sequence of events for driving the bolus through the oral pharynx and hypopharynx, can be absent. Fortunately, this is a relatively uncommon occurrence, but it can be seen in patients with lateral medullary syndrome where there is injury to the central swallowing pattern generator. In moderate brainstem dysfunction it may be possible to observe the onset of components of the pharyngeal swallow response, but these may be uncoordinated and may lack the correct sequence. For example, in the lateral projection, it may be possible to observe aspiration before the swallow

FIGURE 32-20 Pharyngeal delay with coating of the valleculae (*arrows*).

VIEW IMAGE

Copyright © 2003, Mosby, Inc. All rights reserved.

response is elicited, and/or mistimed tongue propulsion and pharyngeal clearance with failure of the bolus to enter the esophagus.[66, 67]

Bolus characteristics of volume and viscosity modulate the timing of the onset of the pharyngeal swallow with the beginning of vocal cord adduction and airway closure. Research in normal adults has shown that vocal cord adduction and the onset of hyolaryngeal elevation begins when large liquid boluses are placed in the oral cavity.[25, 26, 28] Radiographically, this is most easily observed in the lateral plane. The laryngeal vestibule narrows as the arytenoid cartilages rock and tilt toward the base of the epiglottis and the glottis closes. This results in a negative onset time in that the liquid bolus has not exited the oral cavity and yet the pharyngeal swallow response has begun. For example, Lazarus et al.[68] found that an average normal pharyngeal delay time for a 5 ml liquid bolus was -0.6 second in adults aged 18 to 80 years.

Different anatomic landmarks are used by different researchers in calculating pharyngeal delay in relation to bolus flow. In the most commonly used definition, the onset of the pharyngeal swallow occurs as the head of the bolus crosses the intersection of the ramus of the mandible and the tongue base.[13, 39] Pharyngeal delay time has been observed to increase with age,[28] in which a large portion of the bolus reaches the vallecular space before the onset of airway closure and hyolaryngeal elevation. This is thought to be the result of reduced sensory awareness of the bolus but is also considered a normal variant in older individuals (>70 years of age).

Purees and solid boluses have increased viscosity and therefore travel more slowly, presenting less of a threat to an open airway. During normal mastication, boluses move in small amounts over the tongue base and into the valleculae in the presence of an open airway, and the pharyngeal swallow response may not be triggered until the material reaches the pyriform sinuses or touches the aryepiglottic folds. This phenomenon is not considered abnormal in the case of solid bolus swallowing and does not necessarily increase the relative risk of laryngeal penetration or aspiration. Perlman et al.[69] suggested that only when the boluses remain in the pharynx longer than 1 second but less than 2 seconds before the beginning of laryngeal closure is the pharyngeal swallow onset considered mildly delayed. A delay of 5 seconds or more is considered severe.

Duration of Oral and Pharyngeal Transit

Swallowing efficiency is estimated by determining the duration of transit of the bolus through the oral cavity and pharynx. Counting the number of swallows required to clear a liquid or solid bolus provides a rough guide of swallow efficiency. Usually a 5 to 30 ml bolus is cleared in a single swallow and may be followed by a second clearing swallow. There is greater variability in solid boluses, particularly those that require longer mastication. Several swallows are required to clear boluses with hard textures.[70]

A more precise assessment of oropharyngeal swallow efficiency is described by Rademaker et al.[71] This measure depicts the interaction between the speed of bolus flow and the efficiency with which the material is cleared from the oropharynx, taking aspiration into account. The numerical value provided by this measure may be particularly helpful when determining change in function after treatment.

FIGURE 32-21 High laryngeal penetration (*arrow*) without aspiration.

VIEW IMAGE

Laryngeal Penetration and Transglottic Aspiration

Identification of material in the airway has traditionally been the key abnormal finding on a VFSS and is often the catalyst for terminating the study for fear of airway compromise. Aspiration or laryngeal penetration is not a binary event, and the physiologic circumstances surrounding its occurrence must be described to determine the full implications. The first challenge is definition. The literature is replete with ambiguous terminology to describe the entrance of barium contrast into the laryngeal vestibule, larynx or trachea. For purposes of this chapter the following definitions are used: Laryngeal penetration refers to the presence of barium contrast in the laryngeal vestibule that does not pass below the level of the true vocal folds into the trachea (Fig. 32-21). Aspiration refers to the presence of barium contrast below the level of the true vocal folds in the subglottis or trachea.

The most clinically useful way of resolving the confusion is to describe the amount and viscosity of barium in the airway, its lowest location, the timing of its occurrence in the airway, and the patient's response to its presence. Detection of silent aspiration, defined as aspiration in the absence of a reflexive patient response, is a distinct advantage provided by the VFSS and assists in prognostication. Rosenbek et al.[64] describe an 8-point penetration-aspiration scale based on videofluoroscopic data that fulfils this purpose (Table 32-5).

Copyright © 2003, Mosby, Inc. All rights reserved.

Table 32-5
EIGHT-POINT PENETRATION-ASPIRATION SCALE

Score	Description of Events
1	Material does not enter the airway
2	Material enters the airway, remains above the vocal folds, and is ejected from the airway
3	Material enters the airway, remains above the vocal folds, and is not ejected from the airway
4	Material enters the airway, contacts the vocal folds, and is ejected from the airway
5	Material enters the airway, contacts the vocal folds, and is not ejected from the airway
6	Material enters the airway, passes below the vocal folds, and is ejected from the airway
7	Material enters the airway, passes below the vocal folds, and is not ejected from the airway
8	Material enters the airway, passes below the vocal folds, and no effort is made to eject

From Rosenbek JC, Robbins J, Roecker EV, Coyle JL, Woods JL. A penetration-aspiration scale. Dysphagia 1996;11:93-98.

It is instructive to note that laryngeal penetration is not uncommon in normal healthy adults. Robbins et al.[28] found that 20% of their adult subjects showed high laryngeal penetration during the swallow and received a score of 2 on the penetration-aspiration scale, indicating that the material was ejected from the larynx before the swallow was completed. Given its occurrence in normal patients, it would be unnecessary to terminate the VFSS on the basis of laryngeal penetration alone, particularly if the patient senses the material in the airway.

In addition to defining the nature of the penetration or aspiration, it is necessary to understand the physiologic basis for its occurrence, particularly when therapeutic strategies are to be evaluated. Laryngeal penetration or aspiration can occur before, during, or after the pharyngeal swallow response is activated. Aspiration *before* the swallow usually is due to impaired tongue movement for bolus control, resulting in premature spillage into the pharynx and/or delayed onset of the pharyngeal swallow. Aspiration *during* the swallow implies that the swallow response has been initiated but laryngeal closure is incomplete, resulting in penetration or aspiration (Fig. 32-22). Any of the multiple airway protective forces such as true and vestibular vocal fold closure or hyolaryngeal elevation with epiglottic inversion may be impaired, resulting in an exposed laryngeal inlet. Aspiration *after* the swallow is usually the result of retention in the pharyngeal recesses from an impaired pharyngeal contraction clearing force, reduced hyolaryngeal elevation with a reduction in opening of the pharyngoesophageal segment, or hypertonicity of the cricopharyngeal region (Fig. 32-23). Residue may also appear in the pyriform sinuses after the swallow as a result of emptying of a Zenker's diverticulum or cervical esophageal dysmotility.

Commonly, if the penetration or aspiration occurs during the initial descent of the bolus during the swallow, it is referred to as primary penetration or aspiration. If the penetration or aspiration occurs after the initial descent of the bolus, from residual bolus in the valleculae or more commonly in the pyriform sinuses, it is referred to as secondary penetration or secondary aspiration.

FIGURE 32-22 Aspiration during the swallow.

VIEW IMAGE

Evaluation of Therapeutic Strategies

One of the major advantages of the VFSS is that it provides an opportunity to assess the value of therapeutic

FIGURE 32-24 Aspiration (**A**) (*arrow*) eliminated by the chin-down posture (**B**), indicating increased narrowing of the laryngeal vestibule and greater tongue base retraction.

strategies. Appropriate selection of these strategies as isolated maneuvers or in combination depends on the precise characterization of the biomechanical and temporal events of the swallow resulting in impairment. Therapeutic procedures are either compensatory or rehabilitative in nature.[12] Compensatory strategies are designed to alter the bolus flow in an attempt to eliminate the patient's disordered symptoms. Postural changes involve changing the position of the head in order to alter the geometry of the oral, pharyngeal, and laryngeal systems. Individual techniques can reduce the angle of opening of the upper airway, as occurs in the chin-down (chin tuck) posture[72, 73] (Fig. 32-24), or can improve hyolaryngeal excursion and increase the propulsive force on the bolus by obstructing paretic pharyngeal musculature, as in head rotation[74, 75] (Fig. 32-25). Correct performance of these postural changes requires minimal cooperation from the patient since the instructions are single step and simple, for example, ''Put your chin on your chest.'' Matching the physiologic outcome of the postural change with the patient's swallowing problem increases the likelihood of the effectiveness of the technique. The frequently employed chin-down posture does not assist all patients. In fact, if contrast fills the pyriform sinus prior to the onset of the pharyngeal swallow, there is an increased risk of aspiration as the larynx elevates and the pyriform sinuses empty.

Other compensatory techniques involve manipulating bolus viscosity and volume and increasing sensory input. Changing bolus viscosity is a powerful tool in assisting patients with dysphagia, and a wide range of options is available, from thin liquids to textured solids.[13, 68] Increasing the bolus volume for liquids may be helpful in patients with incomplete oral or pharyngeal contraction, such as those with total glossectomy.[12, 25, 75] Smaller volumes of liquids may be indicated in patients with reduced laryngeal closure. The effectiveness of these trials can be evaluated by videofluoroscopy. Table 32-6 lists the most common compensations and their physiologic indications.

Rehabilitative therapy procedures place aspects of the patient's swallow under voluntary control and alter the physiology of the swallow[12]; they are listed in Table 32-7. These maneuvers require sophisticated cooperation by the patient, with the ability to understand, learn, and apply the treatment strategy. For example, the super-supraglottic swallow requires the patient to perform a Valsalva maneuver while swallowing a bolus and to cough after the swallow in an effort to invoke voluntary airway protection.[76] Since these therapeutic maneuvers take some time for the patient to learn, it is fitting for the speech pathologist to anticipate

FIGURE 32-25 Head rotation to the right in this patient with right-sided pharyngeal weakness obstructs bolus flow on the affected side, causing the bolus to flow down the left side of the pharynx.

Table 32-6
COMPENSATORY SWALLOWING STRATEGIES AND THEIR IMPACT ON SWALLOWING PHYSIOLOGY

	Functional Impairment	Physiologic Impact
Changes in Bolus Viscosity		
Increase bolus viscosity	Impaired tongue control	Reduces rate of liquid bolus flow
	Aspiration before the swallow	Allows improved lingual control
	Impaired laryngeal closure	Bolus remains cohesive
	No response to bolus placement	Increased sensory stimulation activates bolus manipulation (e.g., chewing of solids)
Decrease bolus viscosity	Impaired anterior posterior bolus propulsion	Reduced resistance to bolus flow
	Weak pharyngeal contraction	
Changes in Bolus Volume		
Increase bolus size	Delayed onset of pharyngeal swallow	Increases stimulation of sensory receptors to activate swallow response
Decrease bolus volume	Severe tongue weakness	Increased control
Postural Changes		
Chin down	Delayed onset of pharyngeal swallow	Widens vallecular space
	Reduced tongue drive on bolus	Displaces tongue posteriorly
	Aspiration before the swallow	Narrows angle of laryngeal vestibule
Head rotation to affected side	Unilateral pharyngeal weakness	Isolates damaged side from bolus flow
	Reduced laryngeal excursion and opening of pharyngoesophageal segment	Reduces pressure of pharyngoesophageal segment
	Unilateral vocal fold paralysis	Increases vocal fold adduction
Head tilt to unaffected side	Unilateral oral or pharyngeal weakness	Redirects bolus flow down unaffected side
Head extended	Reduced tongue propulsion	Gravitational forces assist bolus flow
	Velopharyngeal incompetence	Reduces nasal regurgitation

which therapeutic maneuvers may require assessment and to teach them to the patient before the study. The VFSS can be used to determine how accurately the patient has performed the maneuver and can be shown to the patient after completion of the study to assist with treatment recommendations.

Compensatory and rehabilitative procedures can be used in isolation or in combination. For example, a patient who presents with unilateral impaired pharyngeal weakness and weak tongue base retraction, resulting in pharyngeal retention and aspiration of residue after the swallow, may benefit from head rotation to the impaired side (to close off the weaker pharynx) together with a chin tuck (reducing the laryngeal opening size and increasing drive on the bolus) and an effortful swallow maneuver (to increase force on the bolus). Assessment of therapeutic maneuvers is conducted in the lateral and anterior projections, using several trials to ensure the reliability of the findings.

OVERVIEW OF A NORMAL VFSS

Although much detail regarding the normal swallow has been presented, it is useful to summarize the main points to observe on a normal VFSS. On the lateral view, there should be coordinated tongue movements and, in general, the bolus should remain on the upper surface of the tongue. The soft palate should be caudal, against the tongue base prior to initiation of the pharyngeal phase of the swallow. As the tongue thrusts dorsally, the soft palate should touch the

Table 32-7
REHABILITATIVE MANEUVERS THAT ALTER THE PHYSIOLOGY OF THE SWALLOW

	Indication	Physiologic Effect
Super supraglottic swallow instruction: ″Bear down, swallow, cough, and swallow again″	Aspiration before, during, and after the swallow	Improved airway protection with decreased amount of laryngeal penetration or aspiration
Effortful swallow instruction: ″Swallow as hard as you can″	Weak tongue base and pharyngeal wall contractions	Improved clearance of pharyngeal recesses
Mendelsohn maneuver instruction: ″Swallow and keep your larynx elevated until you have completed the swallow″	Poor coordination of tongue base movement to the posterior pharyngeal wall	Sustains laryngeal elevation during swallow
	Increased pharyngeal retention in the pyriform sinuses	Sustains opening of pharyngoesophageal segment

Copyright © 2003, Mosby, Inc. All rights reserved.

posterior pharyngeal wall, effectively closing off the nasopharynx. The posterior tongue may be seen to first descend slightly and then the tongue base should move dorsally, touching the posterior pharyngeal wall. The pharyngeal phase should normally initiate as the bolus reaches the upper posterior aspect of the tongue. The hyoid, and thus the larynx, should then move forward and upward, while the epiglottis should be seen to tilt passively downward, resting upon the arytenoid cartilages and muscles. Forward movement of the posterior pharyngeal wall should occur, signaling pharyngeal contraction, and as the bolus reaches the lower hypopharynx, the cricopharyngeus should open, with no posterior cricopharyngeal indentation being seen on the barium column. The cricopharyngeus should then close as cervical esophageal primary and secondary contractions are initiated. There should be no residual contrast in the vallecula or pyriform sinuses with liquids. Some residua may be seen with purees and solids; however, this should be cleared on subsequent swallows of saliva. Similarly, tongue or pharyngeal coating should be rapidly cleared on the next swallow of saliva.

In the AP or frontal projection, the lateral pharyngeal walls should be filled symmetrically by the bolus, bulging outward without any ''dog ears'' (pharyngoceles). The vocal folds may be seen to adduct fully, and the barium column should smoothly enter the cervical esophagus.

CONCLUSION

Diagnosis of oropharyngeal swallowing disorders demands an understanding of the complex normal and abnormal biomechanical events that drive boluses from the oral cavity through the hypopharynx and into the esophagus. The VFSS provides information about the physiologic substrates underlying the swallowing process that extends beyond the simple detection of aspiration. Thoughtfully executed studies that draw on the expertise of the radiologist and speech pathologist in understanding the problem permit evaluation of therapeutic strategies aimed at improving the chance that the patient can eat safely and efficiently by mouth.

ACKNOWLEDGMENTS

The author wishes to thank the following individuals:Cary Crehan, R.T., M.B.A., for his assistance in printing the images used in this chapter; Sandy Martin, M.S., C.C.C., Joanne Gutek, M.A., C.C.C., and Suzanne Danforth, M.S., C.C.C., for their invaluable editorial comments; and Hugh Curtin, M.D., for his generosity of spirit and knowledge.

DIFFERENTIAL DIAGNOSIS

INTRODUCTION

Many of the structures in the head and neck are intimately related to the embryogenesis of the branchial apparatus (i.e., branchial arches, pharyngeal pouches, branchial grooves, and branchial membranes). These branchial structures are transient and undergo such substantial remodeling that their original embryonic form is unrecognizable in the adult. Nonetheless, knowledge of their development provides a basis for understanding how their derivatives acquire their adult forms, and it provides an understanding of the pathogenesis of the variety of congenital anomalies that may result from abnormal branchial apparatus development (Chapter 35). This chapter gives an overview of the early stages of head and neck embryology (the somatomere and somite phase of development) and reviews all of the branchial arches, with particular focus on the derivatives of the third through sixth arches.[1–7] A detailed discussion of the first and second arches and their contributions to the formation of the face, sinonasal cavities, and oral cavity appears in Chapter 1. The embryology of the eye and orbit is discussed in Chapters 8 and 9 and that of the skull base is described in Chapter 12, while the embryology of the temporal bone is discussed in Chapter 19. In addition, this chapter reviews the development of the aortic arches and arteries, the veins, and the lymphatics of the head and neck. The embryology of the larynx and the salivary glands is also discussed. Finally, the anatomy of the neck in the adult is described, and differential diagnosis based on anatomic location is reviewed.

BASIC TERMINOLOGY OF HEAD AND NECK DEVELOPMENT

General Terminology

As differing terms are often applied to the development of head and neck structures and the time frames within which this development occurs, it is important to establish briefly those terms that will be used in this chapter. First, the term *embryo* or *embryogenesis* is properly used to refer to the first 8 weeks of development in humans. This period largely corresponds to the appearance of organs and organ systems. The term *organogenesis* thus is largely equatable with the embryonic period.

Following the embryonic period is the *fetal* period. This is largely the time of growth and differentiation as opposed to the appearance of structures. Accordingly, one should not refer to an individual before the end of the eighth week as a fetus or after the ninth week as an embryo. It should be noted that these demarcations, terms, and time frames are based on humans. Other animals have different gestational periods from humans, and so the periods and terminology may not mirror those of humans. This is important to keep in mind in studies on comparative embryology in general, in which a number of mouse, rat, or avian species are used as experimental models.

Branchial Arches

The branchial arches are the main component of the branchial *apparatus*, which includes the branchial arches, pharyngeal pouches, branchial grooves, and branchial membranes. Branchial arches are transient embryonic structures from which will arise many of the adult structures of the head and neck. The word *branchial* derives from the Greek *branchia*, meaning ''gill.'' Early in development, the cranial region of an embryo has marked arch-like regions with intervening clefts. To early anatomists, this condition resembled the gills of a fish (they are, in fact, homologous to the precursors of gills in fish and immature amphibians), and hence the term *branchial* came into common use. As humans never develop gills, the term *pharyngeal arch* is frequently used. The term *branchial arch* will be used throughout this chapter, as it is the more commonly used term and is also used in discussing vertebrates.

Basic Terminology of *Hox* Genes

Over the last few years, a great deal has been learned about the establishment of the overall body plan, and much of this has come from our understanding of the genes involved. For example, the basic body plan—from *Drosophila* through humans—is highly conserved and follows the blueprints laid out by some basic genes. These basic genes, known collectively as homeotic genes, share a highly conserved 180 base pair sequence known as the homeobox.[8, 9] In vertebrates, specific homeotic genes are referred to as *Hox* genes. The positional commitment of head and neck structures may be the result of the specific overlapping expression of these *Hox* genes. Studies exploring these features of head and neck development will be referenced throughout this chapter.

EARLY EMBRYOLOGY OF THE HEAD AND NECK

Mesodermal Layers, Somitomeres, and Somites

Prior to the full appearance of the branchial arches, the somitomere and somite period of intrauterine development occurs. In fact, it is not until the late somite stage (fourth intrauterine week) that the branchial arches can be clearly seen. Starting at about the twenty-first gestational day, and lasting for approximately 10 days, the major event in embryonic development is the folding of the neural plate, from which the brain and spine will develop. Following this, the mesoderm differentiates into three aggregations: a lateral mesoderm, an intermediate mesoderm, and a paraxial mesoderm. The lateral mesoderm contributes to the development of the walls of the embryonic coelom, and from this will arise the pleural, pericardial, and peritoneal cavities.[10] In the head and neck, the lateral mesoderm has been described as forming considerable portions of the throat and larynx, such as the tracheal cartilages and connective tissues, as well as forming angiogenic precursors that may seed distant parts of the head.

The intermediate mesoderm is not present in the head and contributes to the formation of the gonads, kidney, and adrenal cortex. The paraxial mesoderm, which is alongside the notochord, gives rise to all striated voluntary muscles in the body. In the head and neck, the paraxial mesoderm develops seven rostral condensations of incompletely segmented *somitomeres* and a series of 42 to 44 paired more caudal segmented *somites*. Overall, there are 7 somitomeres and 4 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 8 to 10 coccygeal somites (Fig. 33-1).[10]

Each somite differentiates into three parts. The ventromedial part, or *sclerotome*, contributes to the development of the vertebral column and accounts for its segmental nature. As a result of notochordal secretion of procollagen and collagen, some of the sclerotomal cells are induced to convert into cartilage. The lateral part of the somite, or *dermatome,* gives rise to the development of the dermis and skin. With reference to muscular development, it is the intermediate part of the somite, or *myotome,* that eventually differentiates into the muscles of the trunk and limbs, as well as some of the orofacial muscles. The *somitomeres* are not as clearly delineated as the somites; nevertheless, their muscular derivatives arise from a somewhat comparable region known as the myomere.

It is the myomeres and the myotomes that form the primitive muscle cells, or *myoblasts*, which then divide and fuse to form *myotubes*. The myotubes, in turn, halt subsequent mitosis and become *myocytes*, or muscle fibers.[11] Although most muscle fibers develop prior to birth, they continue to increase in size during early infancy. It is motor innervation that stimulates muscle activity and further growth by hypertrophy. The craniofacial muscles develop

initially from paraxial mesoderm that transiently resides in seven somitomeres and the five most rostral somites. The resultant muscles obtain their innervation, in a sequential manner, from the cranial nerves. Thus, four of the extraocular muscles (the superior rectus, medial rectus, inferior rectus, and inferior oblique) arise from the first two somitomeres and are supplied by the third cranial nerve (oculomotor, CN III) (note: the first two cranial nerves, the olfactory and optic, are not true nerves, but rather brain tracts historically called nerves). The superior oblique muscle develops from the third somitomere and is innervated by the fourth cranial nerve (trochlear, CN IV). The myomere of the fourth somitomere invades the first branchial arch and develops into the muscles of mastication (the masseter, medial pterygoid, lateral pterygoid, and temporalis) supplied by the fifth cranial nerve (trigeminal, CN V). The lateral rectus muscle comes from the fifth somitomere and is supplied by the sixth cranial nerve (abducent, CN VI). The myomere of the sixth somitomere invades the second branchial arch to form the facial muscles that are supplied by the seventh cranial nerve (facial, CN VII). The seventh somitomere forms the stylopharyngeus muscle of the third branchial arch, which is supplied by the ninth cranial nerve (glossopharyngeal, CN IX).[11, 12]

The development of the caudal arches (fourth to sixth) is much less clear than that of the rostral arches (9). Nevertheless, it appears that the myotomes of the first four (occipital) somites invade the fourth, (fifth?), and sixth branchial arches, bringing the tenth cranial nerve (vagus, CN X) and the eleventh cranial nerve (the cranial ''root'' portion of the spinal accessory, CN XI) to the extrinsic and intrinsic laryngeal muscles. The precursors of the tongue muscles are probably derived from occipital somites 2 to 4 and supplied by the twelfth cranial nerve (hypoglossal, CN XII), which migrates into the tongue to form the intrinsic and extrinsic tongue muscles. The derivatives of the third through seventh somites, innervated by the spinal root of CN XI (with initial cell bodies in the accessory, or spinal, nucleus in the spinal cord rather than in the nucleus ambiguus), form the sternocleidomastoid and trapezius muscles.[12] Overall, there is a cephalocaudal sequence of development so that the orofacial muscles are the first to develop. As the muscles form, their nerve and blood supplies also develop, and these are maintained as the muscles migrate from their sites of origin. As the muscle fibers differentiate, they gain their attachments to bone; this process is related to periosteal growth.[12]

NORMAL EMBRYOLOGY OF THE BRANCHIAL APPARATUS

General Embryology

The branchial apparatus is first identified at about the fourth week of development and is complete by the sixth to seventh week. Initially, ventrally migrating neural crest cells

Copyright © 2003, Mosby, Inc. All rights reserved.

interact with lateral extensions of the ventral pharyngeal endoderm that surrounds the six aortic arch arteries. This appears to initiate branchial arch development and results in the segmentation of the mesoderm lateral to the ventral foregut to form a series of five distinct bilateral mesenchymal swellings referred to as the branchial arches. The initial mesodermal core of each arch is then augmented by migrating neural crest cells that surround the mesodermal elements. This mesoderm will give rise to muscle myoblasts, while the neural crest cells will give rise to skeletal and connective tissues.

Externally, the ectodermally covered branchial arches are separated by branchial clefts or grooves, which correspond to five internal outpouchings of the endodermally lined foregut, referred to as the branchial pouches (Fig. 33-2A,B). The fifth arch does not appear on the surface but lies buried about the site of origin of the laryngotracheal outgrowth. Indeed, it is unclear whether or not the fifth arch ever develops in humans. For this reason, it is often placed together with the sixth arch and its derivatives, and is thus perhaps more conservatively described as originating from the *fifth-sixth* arches. This terminology will be used in this chapter. The branchial arches decrease in size from cranial to caudal, with each pair eventually merging midventrally.

Thus, there are five visible arches, which are numbered cranially to caudally as the first, second, third, fourth, and fifth-sixth branchial arches. These arches are prominent in a lateral profile of the embryo, and they are aligned transversely to the plane of the neck. Between each arch is a branchial cleft. The branchial cleft ectoderm forms a thin double-layered branchial or closing membrane where it transiently comes in contact with the endoderm of the primitive pharynx. However, mesoderm soon separates the ectodermal and endodermal layers of the membranes. The tympanic membrane, which is derived from the first branchial membrane, is the only branchial membrane structure to remain as such in the adult human. It should be noted that the clefts never communicate with the foregut lumen, as they do in the gill apparatus of the fish. The cleft and pouch (and thus the branchial membrane) of each arch are positioned caudally to the arch (mesoderm) of the same number. Each arch contains a central cartilaginous rod that is differentiated from neural crest tissue and forms the skeleton of the arch. This tissue is destined to become bone, cartilage, or ligamentous structures. There is also a muscular component, an aortic arch artery that runs around the developing pharynx from the ventral heart to the dorsal aorta, and a neural element that supplies the mucosa and muscles that will arise from that arch (Fig. 33-2C). These neural elements consist of sensory and specialized visceral motor fibers of one or more cranial nerves. It is the migrating cranial nerve fibers of each arch that initiate the development of that arch's muscles and, although some of these muscles may migrate from their sites of origin, these muscles retain their original arch nerve supply.[1, 4, 7, 13] It is also the migration of the muscles, which ''drag'' their neural supply with them, that accounts for the tortuous routes of many of the cranial nerves.

Shortly after the branchial arches appear, excessive mesodermal growth occurs in the first arch, the cranial portion of the second arch, obliterating the outer contour of the second through fourth grooves and forming the hyoid operculum. Overgrowth also occurs in the epipericardial ridge, which develops from the mesoderm lateral to the fifth-sixth arch. These accelerated growths result in a submerging of the intervening caudal portion of the second, third, and fourth arches into a shallow recessed ectodermal pit, the retrohyoid depression or the cervical sinus of His (Fig. 33-3).[14] Further growth about the cervical sinus results in narrowing of the external opening into a channel called the cervical duct. Soon the cervical duct is obliterated, as is the ectodermally lined cervical sinus, and eventually there is a smooth uniform contour to the external surface of the neck. In the adult, the site of the cervical sinus is located at the angle between the dorsal surface of the strap muscles and the anterior margin of the sternocleidomastoid muscle.[2]

The epipericardial ridge contains the rudiments of the sternocleidomastoid-trapezius muscle complex, the infrahyoid muscles, and the muscles of the floor of the mouth and tongue. Also contained within this mesodermal ridge are the spinal branches of the spinal accessory (XI) and hypoglossal (XII) cranial nerves. Based on this embryology, any communication persisting between the cervical sinus and the skin or the pharynx lies anterior to the derivatives of the epipericardial ridge and the hypoglossal nerve. Such developmental anomalies are discussed in Chapter 35.

The ganglia of cranial nerves V, VII, and IX and portions of the ganglia of cranial nerves VIII and X derive from neural crest cells. In addition, neuroblasts from superficial ectodermal thickenings, the epibranchial placodes, develop at the dorsal portions of the first through fourth branchial grooves and contribute to the ganglia of cranial nerves V, VII, IX, and X. Caudal to the region of the vagal ganglion, neural crest tissue in the occipital region contributes to the ganglia of cranial nerves XI and XII.[14]

Pouch Derivatives

There are four endothelially lined pouches that protrude laterally from the developing foregut. There is a rudimentary sixth pouch, but it is considered an appendage of the fourth pouch, as it has no independent communication with the pharyngeal lumen.[15] Later in development, as the pouches progressively extend away from the wall of the pharynx, their communication with the pharynx is maintained via an elongated pharyngobranchial duct.

The first and second pouches merge to form the tubotympanic recess, from which the middle ear and eustachian tube develop. Thus, the epithelial lining of the eustachian tube and the middle ear, including the inner lining of the tympanic membrane, is of endodermal origin. The ventral portion of the second pouch does not contribute to the tubotympanic recess, but rather eventually forms the palatine tonsillar fossa. The actual tonsillar tissue, however, comes from the underlying mesoderm of the second arch. The third, fourth, and sixth pouches give rise to glandular structures discussed below (Fig. 33-4).

The Thymus and Parathyroid Glands

FIGURE 33-3 Coronal diagram of a 6-week-old fetus shows that the second arch overgrows the third and fourth arches and the epicardial ridge develops to oppose it. This creates the cavity referred to as the cervical sinus of His, which covers the second, third, and fourth arches and clefts. It is the failure of the sinus of His to obliterate that is believed to be the cause of the development of branchial cleft cysts, fistulas, or sinuses. (From Langman J. Medical Embryology, 4th ed. Baltimore: Williams & Wilkins, 1981:274.)

sixth week of gestation. These outpouchings are initially hollow. Rarely, the ventral portion of the fourth pouch gives rise to a rudimentary thymus that lies near the superior parathyroid glands. These outpouchings undergo caudal elongation, being connected to the pharynx by tubular structures referred to as thymopharyngeal ducts. By the end of the sixth week, these connections of the thymic primordia have continued to migrate caudally and medially, their lumina have become obliterated by epithelial proliferation, and the glands have increased in bulk. By the middle of the seventh week, obliteration of the thymopharyngeal ducts is complete, and the two solid masses of primitive thymus approach each other in the midline just below the thyroid gland. At the beginning of the eighth week, the bilateral thymic primordia join in the midline, attach to the pericardium, and begin to descend into the superior mediastinum. By the ninth week of gestation, the thymus is in its final position in the anterior mediastinum, and the elongated stalks through which their descent occurred undergo atrophy and disappear. This is followed by eventual invasion of the thymus by mesenchymal cells, with subsequent degeneration of the primitive endodermal cells into Hassall corpuscles.

The inferior and superior parathyroid glands develop from dorsal portions of the third and fourth pharyngeal pouches, respectively, and are thus sometimes called the parathyroid-3 and parathyroid-4 glands. The inferior parathyroids migrate in either side of the neck along the course of the thymopharyngeal duct, thus following the same caudal elongation pattern as the thymus. Their thymic connection, however, is lost at the level of the thyroid gland, where they reach their final destination near the inferior dorsal aspect of the gland. The dorsal aspect of each fourth pouch forms the superior parathyroid glands. Once these cells lose their connection to the fourth pouch, they attach to the caudally migrating thyroid gland and assume their position near the superior dorsal aspect of the gland. Thus, the craniocaudal relationship between the inferior and superior parathyroid glands is *reversed* due to differential migration, placing the cells derived from pouch three caudal to those derived from pouch four.

The sixth pouch and a portion of the fourth pouch give rise to the ultimobranchial body, which differentiates into glandular tissue that resembles fetal thyroid. Its ultimate fate in the adult is still unclear. However, as noted in the following section on The Tongue and Thyroid Gland, the calcitonin-secreting cells, which are derived from neural crest tissue, are eventually incorporated into both the thyroid gland and the ultimobranchial body.[13]

The Tongue and Thyroid Gland

Development of the thyroid gland begins early in embryonic life, starting between the second and third weeks and virtually finishing by the eleventh week. The thyroid arises simultaneously from three bodies, one median anlage and two lateral anlagen (Fig. 33-5).[16, 17] Although a few embryologists believe that only the median anlage forms the gland, this discussion will assume the majority opinion that the lateral anlagen exist, for without them, it is difficult to reconcile many of the nonmidline ectopic locations of thyroid anomalies.

The first branchial arch is responsible for the formation of the anterior two thirds of the tongue in the form of two anterior lingual swellings that fuse with the median tuberculum impar, which is a more posterior midline swelling. The two lateral lingual swellings overgrow the tuberculum impar and merge to form the anterior two thirds

FIGURE 33-5 Axial diagram showing the position of the median and lateral thyroid primordia in relationship to the developing larynx.

of the tongue (Fig. 33-6). Since these are all first arch structures, the anterior portion of the tongue has its sensory innervation from the mandibular branch of the trigeminal nerve (V), the nerve of the first arch. The posterior third of the tongue is formed from the coalescence of the ventral aspects of the second and third branchial arches, as well as a lesser contribution from the fourth arch. The third arch is felt to be the major contributor to the posterior tongue since the glossopharyngeal nerve (IX), the nerve of the third arch, is responsible for sensory innervation of the posterior third of the tongue. The copula is a median elevation formed by the fusion of the ventromedial portion of the second branchial arch and the hypobranchial eminence, which develops from the mesoderm of the third and fourth branchial arches (Fig. 33-6). The large hypobranchial eminence overgrows the copula, which eventually disappears, and in the adult, the junction line between the ectoderm and endoderm is in front of the row of the vallate papillae. The anterior two thirds of the tongue is demarcated from the posterior one third of the tongue by a V-shaped groove, the terminal sulcus, which lies just behind the vallate papillae (Fig. 33-6).[15]

During the third week, the median thyroid anlage arises as an endodermal thickening, evaginating caudally from the ventral pharyngeal wall, in the midline between the first and second branchial arches, just caudal to the medial tongue swelling between the tuberculum impar and the copula. Thus, this evagination arises from the first pharyngeal pouch at the junction of the developing anterior and posterior portions of the tongue. In the adult, the site of this thickening is the foramen caecum. This thickening forms the thyroid diverticulum, which may start as a single diverticulum but divides very early into two lateral lobes.[16, 18] As the embryo grows, the thyroid diverticulum descends caudally in the neck, acquiring new cells from the surrounding endoderm. These existing cells then begin proliferating.[19] In the earliest stage of thyroid embryogenesis, the median thyroid diverticulum comes in contact with the aortic sac of the developing heart, located immediately below the pharynx. As the heart descends into the thorax, it pulls the median thyroid anlagen down, elongating its pharyngeal connection or stalk (Fig. 33-7). As the thyroid anlage descends, it interacts with the fourth and sixth pharyngeal arches, and by the end of the seventh week, the median thyroid anlage has reached its final position in front of the trachea, with a small median isthmus as well as two lateral lobes having been formed (Fig. 33-8). When the hyoid anlage rotates and fuses, the descending thyroid stalk can become adherent to its periosteum and a portion of the stalk can end up lying

posterior to the hyoid bone, after first passing anterior to and then underneath the hyoid body.[20, 21]

Though the median thyroid stalk can be a solid tract of epithelial cells, it usually has a lumen and is referred to as the thyroglossal duct.[16] In fact, it has been shown that the process of pharyngeal evagination, or duct formation, and epithelial proliferation, or obliteration of the duct to form a solid tract, are separate processes. As it descends, the gland expands dorsally and laterally while losing its connection with the foramen cecum (Fig. 33-9). Norris, in 1918, postulated variations in the early development of the median thyroid anlage.[22] He described a pre-anlage stage, which represents the time prior to the appearance of the thyroid anlage. The early anlage stage demonstrates the earliest thyroid primordia with endodermal proliferation and a shallow evagination. Although the early growth stage deals largely with growth of the thyroid primordia, three distinct anatomic variations in form can develop. The connection with the pharynx can be solid, cystic, or bilobed. At the beginning of the separation stage, these three types of connecting stalks lengthen. During the complete separation stage, the thyroid severs its connection with the pharynx in a variety of ways. The separation can occur anywhere along the descent of the thyroid, and at this time, the gland itself can also have wide variation in form.

As previously mentioned, the existence of the lateral thyroid anlagen remains controversial; however, many nonmidline ectopic thyroid anomalies are best explained by the existence of such structures. The lateral lobes of the thyroid are thought to receive contributions from the ventral portion of the fourth and sixth branchial pouches, also called the caudal pharyngeal complex. In mammals, this lateral pharyngeal diverticulum is called the ultimobranchial body. As the median thyroid descends and interacts with this portion of the branchial apparatus, it loses its attachment to the aortic root. As the lateral anlagen migrate anteriorly, they fuse with the median thyroid anlage and simultaneously, during the sixth week of gestation, detach from the pharynx (Fig. 33-10). The contribution to the adult thyroid gland from these lateral thyroid primordia varies from 0% to 33% of the total gland volume.[16, 23]

The calcitonin-producing parafollicular cells originate from neural crest cells, which are of ectodermal origin, adjacent to the fourth and sixth pharyngeal pouches. These cells migrate and eventually become incorporated into the lateral thyroid primordia to form the ultimobranchial bodies (Fig. 33-11).

The morphogenesis of the thyroid gland is characterized by a proliferation of cells in the rudimentary thyroid that is followed by organization into double cellular plates. By the

eighth week, these differentiate further into primary thyroid follicles, and secondary follicles result from further budding and subdivision.[24] Between the tenth and eleventh weeks of gestation, the fetal thyroid develops the ability to trap and organify iodine to form thyroxine.[25] The arterial blood supply for the developing thyroid anlage is acquired by the eighth week of gestation from the extensive fetal capillary network of the branchial arches supplied by the carotid and branchiocephalic systems.[16] The pathology of the thyroid gland is discussed in Chapters 37 and 40.

Pharynx, Larynx, and Trachea

The respiratory primordium begins at about the fourth week of gestation with the formation of the laryngotracheal groove, which extends lengthwise in the floor of the gut just caudal to the pharyngeal pouches (Fig. 33-12). This groove deepens into the laryngotracheal diverticulum, whose ventral endoderm will become the larynx and trachea, while the more caudal endoderm will give rise to the bronchi and lungs. Lateral furrows develop on either side of the laryngotracheal groove or diverticulum, at the level of the junction between the groove and the future esophagus. These furrows gradually deepen and extend cephalad, elongating this structure to form the primitive laryngotracheal tube. The lateral furrows join, splitting off first the lung bud and then the trachea. The upper end of this tube advances slightly cephalad until it lies between the fourth branchial arches, and this region will form the primitive laryngeal aditus. A tracheoesophageal septum develops caudally to cranially and separates the respiratory system from the esophagus.[26]

It is at the end of the fourth week of gestation that the single lung bud appears at the caudal end of the laryngotracheal tube (Fig. 33-13). This bud soon divides into right and left bronchial buds, and these grow caudally and laterally into the pericardioperitoneal cavities. The primitive lung buds then subdivide into secondary and tertiary bronchi. Throughout fetal development, the surrounding pulmogenic mesoderm continues to develop into the lung parenchyma.[27]

The larynx develops on the proximal end of the laryngotracheal groove between the fifth and sixth gestational weeks, as three swellings appear at the laryngeal aditus. The anterior swelling, which is the future epiglottis, may be a derivative of the hypobranchial eminence from the fourth arch, although its actual origin and relationships to the branchial arches remain unclear. It should be noted that in contrast to the first, second, and third arches, little is clearly known about the precise development of the *caudal* arches, the fourth through sixth arches.[9] The two lateral masses give rise to the future arytenoids, from the fourth or fifth-sixth arches. These two lateral swellings migrate cranially and

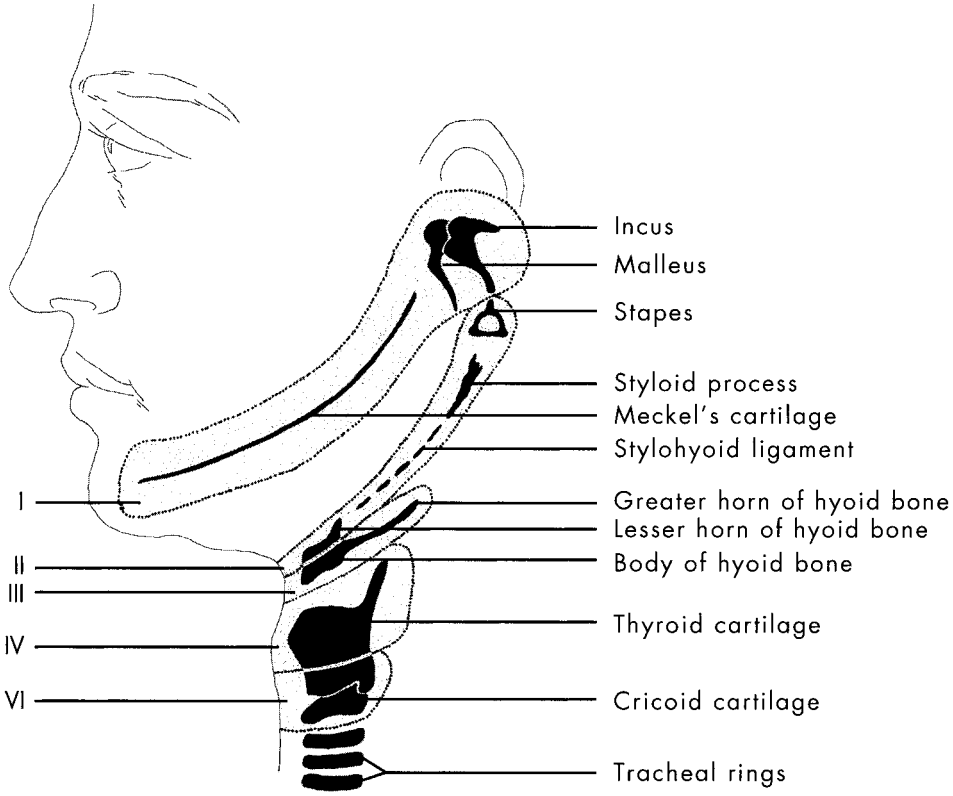
FIGURE 33-13 Development of the respiratory system. **A**, Drawing of a 4-week-old fetus shows the laryngotracheal groove developing from the ventral wall of the primitive pharynx. The proximal portion will be the future laryngeal aditus. **B**, Drawing of a 4- to 5-week-old fetus shows that the tracheoesophageal septum now separates the laryngotracheal tube from the primordium of the esophagus. The bronchial buds will become the bronchi. **C**, Drawing at a slightly later stage of development shows that the esophagus and the trachea are now completely separate. A tracheoesophageal fistula is an abnormal persistence of the original communication between the trachea and the esophagus (**A**). (From Moore KL, Persaud TVN. The Developing Human. 5th ed. Philadelphia: WB Saunders, 1993;227.)

medially to oppose each other and, together with the epiglottic swelling, surround a T-shaped laryngeal aditus.[28, 29] The laryngeal lumen becomes occluded at eight weeks of gestation due to epithelial proliferation. If normal recanalization does not occur during the tenth gestational week, a laryngeal web results. The formation of the vocal (true) and vestibular (false) folds (cords) is related to the condensation of mesenchyme and the outpouching of the laryngeal sinus or ventricle. The two vocal folds separate during the third gestational month, and failure of this recanalization process results in congenital atresia of the larynx.

The laryngeal cartilages develop from the branchial arches, with the more cranial cartilages possibly arising from the fourth arch and the more caudal ones from the sixth (with the caveat that the epiglottis may not be arch derived, as mentioned above) (Fig. 33-14). The thyroid cartilage develops from the fourth arch as two lateral plates that fuse in the midline. This process is almost completed by the ninth gestational week. The cricoid cartilage appears to begin as



VIEW IMAGE

FIGURE 33-14 Diagram of the lateral face and neck showing the cartilaginous derivatives of the branchial arches. (Modified from Langman J. Medical Embryology, 3rd ed. Baltimore: Williams & Wilkins, 1975.)

two cartilaginous centers of the sixth arch. First, the centers grow and unite in the ventral midline; then, by the seventh gestational week, they fuse dorsally. The rostral advancement of the tracheoesophageal septum results in the fusion of the dorsal cricoid lamina. Failure of advancement of this septum results in a fistula. At first, the cricoid lumen is slit-like in shape, but eventually the ventral and lateral walls of the cricoid cartilage condense and there is progressive enlargement of the lumen. Failure of this condensation process results in congenital subglottic stenosis.

The arytenoid cartilages develop from the arytenoid swellings, most likely derivatives of the sixth arch but possibly arising from the fourth arch. They are initially fused to the cricoid cartilage, but they eventually separate from it and form the cricoarytenoid joints. The origins of the corniculate and cuneiform cartilages remain unclear. The intrinsic laryngeal muscles develop from the mesoderm of the fourth through sixth arches.[28, 29]

The tracheal tube elongates, and the future carina or point of bifurcation descends caudally eight somite segments. The right bronchus descends more directly than the left bronchus, a relationship that is maintained in the adult. The smooth muscle fibers and the cartilaginous tracheal rings differentiate from the surrounding mesenchyme at the end of the seventh week. The minor salivary glands develop as ingrowths from the epithelium after four months of gestation.[30]

Branchial Arches

As mentioned earlier, specific osseous, cartilaginous, and vascular structures arise from each branchial arch. However, the muscles of the different arches do not necessarily attach to the osseous or cartilaginous components of their own arches. In some cases, the muscles may migrate to the surrounding regions; however, the origins of these muscles can always be established through their nerve supply, which comes from their arch of origin.

The first or mandibular pair of branchial arches are the precursors of the jaws. On either side of the face, the first arch borders the lateral margin of the stomodeum. The maxilla is derived from the small maxillary prominence that extends ventrally from the much larger mandibular prominence (Fig. 33-15). The cartilage skeleton of the first arch is Meckel's cartilage, which can be identified between 41 and 45 days of gestation. Most of this cartilage disappears in the formed mandible. The smaller dorsal portion of this cartilage is related to the developing ear and eventually becomes ossified to form the upper portions of the malleus and incus. The intermediate portion of this cartilage regresses, and its perichondrium forms the anterior ligament of the malleus and the sphenomandibular ligament. The ventral portion of this cartilage largely disappears, and the mandible is formed around it by secondary intramembranous ossification (Fig. 33-14). The trigeminal or fifth cranial nerve (V) is the nerve of the first arch, and it innervates the muscles of the first arch, which include the muscles of mastication (the medial and lateral pterygoids, the masseter, and the temporalis), the mylohyoid, the anterior belly of the digastric, the tensor tympani, and the tensor veli palatini muscles. In addition to this motor supply, the trigeminal nerve provides sensory supply to the region of the first branchial arch, that is, the mandible, its covering mucosa and gingiva, the mandibular teeth, the mucosa of the anterior two thirds of the tongue, the floor of the mouth, and the skin of the lower one third of the face. The first arch artery contributes to portions of the maxillary artery and the common carotid artery.

Reichert's cartilage, the cartilage of the second branchial or hyoid arch, appears between 45 and 48 days of gestation. The dorsal margin of the second arch is also closely related to the middle ear and ossifies to form the manubrium of the malleus, the long process of the incus, the crura of the stapes, and the styloid process of the temporal bone. The footplate of the stapes is not a branchial arch derivative, as it is derived from the otic capsule.[1] The portion of the cartilage between the styloid process and the hyoid bone regresses, and its perichondrium forms the stylohyoid ligament. (It is interesting to note that many adult mammals exhibit a chain of bony elements spanning the styloid process and the hyoid bone [Fig. 33-14].[31])

The ventral end of Reichert's cartilage ossifies to form the lesser cornuae (horns) and the upper portion of the body of the hyoid bone. The muscles of the second arch include the posterior belly of the digastric, the stylohyoid, the stapedius, and muscles of facial expression, all of which are supplied by the nerve of the second branchial arch, the facial nerve (VII). Other than a small sensory branch of cranial nerve VII that may supply a portion of the external auditory canal, there is no sensory distribution from cranial nerve VII to the ectodermal derivatives.[1] The main sensory component of the facial nerve, the chorda tympani, invades the first arch as a pretrematic nerve (i.e., a nerve that joins the nerve of the arch above by traveling over the ''trema'' or inter-arch cleft). The chorda tympani is thus carried in a branch of the trigeminal nerve to supply (taste) to the mucosa of the anterior two thirds of the tongue. The artery of the second arch is the stapedial artery, which disappears during the fetal period. Its prior location is marked by the stapes' central foramen, the gap between the stapes crura. Portions of the stapedial artery persist as part of the internal carotid artery proximally and the external carotid artery distally.

The cartilage of the third branchial arch ossifies to form the greater cornu and lower portion of the body of the hyoid bone (Fig. 33-14). The musculature of this arch is limited to the stylopharyngeus muscle, which is innervated by the nerve of the third arch, the glossopharyngeal nerve (IX). Because the mucosa of the posterior one third of the tongue is also derived from the third branchial arch, its sensory innervation is supplied largely by the glossopharyngeal nerve. Neural crest tissue in the third arch forms the carotid bodies that appear as mesenchymal condensations about the third aortic arch artery. Thus, the glossopharyngeal nerve (IX) supplies innervation to the carotid body.[14] The artery of this arch contributes to the common carotid artery and part of the internal carotid artery.

The cartilages of the fourth and fifth-sixth branchial arches fuse to form the larynx, although the precise arch of origin for some of the laryngeal structures clearly remains uncertain. Overall, it is believed that the line of division between the fourth and sixth arches is the vocal folds (true vocal cords). It is generally thought that all laryngeal

FIGURE 33-15 Drawings of the embryogenesis of the normal face at approximately 4, 5, 5½, 6, 7, and 8 weeks.

cartilages (with the possible exception of the epiglottis) are derived from the fourth through sixth arches (Fig. 33-14). It would appear logical that the cartilages are laid out in a craniocaudal arrangement corresponding to their arches of origin, but this remains to be shown (see the prior discussion on laryngeal embryology). The cricothyroid and constrictor muscles of the pharynx are derived from the fourth branchial arch. They are innervated by the nerve of this arch, the superior laryngeal branch of the vagus nerve (X), which also gives sensory innervation to the mucosa of the larynx above the vocal folds. The muscles of the fifth-sixth branchial arches are the intrinsic muscles of the larynx, innervated by the nerve of the sixth arch. This nerve is generally believed to be the cranial portion (i.e., *cranial root*) of the spinal accessory nerve (CN XI) whose fibers join the vagus (CN X) and are distributed within its recurrent laryngeal branch. The striated muscles of the upper half of the cervical esophagus are also derived from the sixth arch. The caudal portion of the esophagus is composed of smooth muscle and is derived from the splanchnic mesoderm of the primitive foregut.[1] In addition, the para-aortic bodies of chromaffin cells that secrete noradrenalin arise from the ectomesenchyme of the fourth and sixth arches.[14]

The left artery of the fourth arch forms the aortic arch. The right arch artery contributes to the right subclavian artery and the brachiocephalic arteries. The sixth arch arteries develop in part into the pulmonary arteries. The remainder of the artery disappears on the right side, while on the left side it forms the fetal ductus arteriosus that in the adult becomes the ligamentum arteriosum.

Copyright © 2003, Mosby, Inc. All rights reserved.

Of all the branchial clefts, only the first cleft contributes directly to an adult structure. It persists as the epithelium of the external auditory canal. The other branchial clefts, together with the cervical sinus of His, normally are obliterated as the neck develops.

In summary, the mesenchyme of the first branchial arch gives rise to the muscles of mastication (and some nonmasticatory muscles such as the tensor tympani and tensor veli palatini) and some of the swallowing muscles. The second arch mesenchyme gives rise to the muscles of facial expression (and some other muscles, such as the posterior belly of the digastric and stapedius). The mesenchyme of the third, fourth, and fifth-sixth arches merges into the palatofaucial, pharyngeal, and laryngeal muscles. The orofacial muscles are the first to develop in keeping with the craniocaudal sequence of fetal development.[12]

The specific adult derivatives of the branchial arches, their clefts and pouches, are summarized in Table 33-1.[32]

Table 33-1
DERIVATIVES OF THE BRANCHIAL ARCH ECTODERM, MESODERM, ENDODERM, ARTERIES, AND THE SPECIFIC ARCH NERVES

Arch	Ectodermal	Endodermal	Mesodermal	Arch Arteries	Nerve
First	External auditory canal and external layer of the tympanic membrane, contributes to anterior tongue mucosa	Eustachian tube, mucosa of middle ear, mastoid, and inner layer of tympanic membrane (from dorsal tubotympanic recess)	Malleus head and neck, incus body and short process, mandible and teeth, anterior ligament of malleus, sphenomandibular ligament, facial bones, middle layer of tympanic membrane, muscles of mastication, tensor tympani, tensor veli palatini, anterior belly of digastric, mylohyoid	External carotid and maxillary artery	Trigeminal (V); sensory V_1, V_2, V_3; motor V_3
Second	Skin of anterior triangle, contributes to anterior tongue mucosa	Tonsillar fossa and part of palatine tonsil	Manubrium of malleus, long process of incus, stapes crura, upper body and lesser cornua of hyoid, styloid process, stylohyoid ligament, muscles of facial expression, posterior belly of digastric, platysma, stapedius muscle, stylohyoid muscle, posterior belly of digastric muscle	Stapedial artery, ?part of facial artery	Facial (VII) motor to facial muscles, sensory to anterior two thirds of tongue
Third	Contributes to posterior tongue mucosa	Inferior parathyroid glands, thymus	Lower body and greater cornua of hyoid stylopharyngeus	Proximal one third of internal carotid artery, common carotid artery; cephalic portion fuses with dorsal aorta to form proximal internal carotid artery	Glossopharyngeal (IX) motor to pharyngeal plexus, sensory to posterior one third of tongue
Fourth	Skin of lower neck	Superior parathyroid glands, ultimobranchial body	Epiglottis, thyroid, and cuneiform cartilages, pharyngeal constrictors, some laryngeal muscles, ?palatoglossus	Arch of aorta (left), proximal right subclavian	Superior laryngeal nerve (X)
Fifth			Corniculate, arytenoid, and cricoid cartilages, some laryngeal muscles, striated muscles of cervical esophagus	Proximal part of both pulmonary arteries and ductus arteriosus	Recurrent laryngeal nerve (X)
Epipericardial Ridge			Sternocleidomastoid, trapezius muscles, infrahyoid muscles and muscles of the floor of the mouth, ?tracheal cartilages		Spinal accessory (XI), hypoglossal (XII)

FIGURE 33-16 Development of the great vessels. **A**, Diagram of the paired dorsal and ventral aortas, which are connected by six pairs of aortic arches. Each of the six paired aortic arches is the arterial component of a branchial arch. **B**, Diagram at a later stage of development shows that the first, second, and fifth arches have disappeared (*broken lines*). Errors in the obliterative process result in vascular rings. (From Langman J. Medical Embryology. 4th ed. Baltimore: Williams & Wilkins, 1981;186.)

EMBRYOLOGY OF THE AORTIC ARCHES

A review of the vascular anatomy of the branchial apparatus aids in understanding the basis for classification of second, third, and fourth branchial anomalies. Each branchial arch contains an aortic arch that connects the paired dorsal and ventral aortas (Figs. 33-2C and 33-16). Although six pairs of aortic arches develop, they are not all present at the same time. The first two arches involute by the time the sixth pair is formed.[33] Parts of the maxillary artery and portions of the external carotid artery appear to be remnants of the transient first aortic arch.

The dorsal segment of the second arch artery transiently persists in fetal life as the *stapedial artery*, around which the stapes crura ossify. Rarely, this artery may persist in the adult. This is discussed in Chapter 26.

The third arch artery on either side persists, forming the common carotid artery and the proximal portion of the internal carotid artery. The origin of the external carotid artery is controversial.[33–35] It arises from either the persistence of the ventral aorta or the surrounding mesenchyme. In either case, it connects with the ventral aspect of the third aortic arch. The dorsal aspect of the third arch artery also fuses with the primitive cephalic portion of the dorsal aorta to form the remainder of the internal carotid artery.

The right fourth arch artery becomes the proximal portion of the right subclavian artery, while the left fourth arch artery forms part of the postnatal aortic arch. The fifth arch arteries appear to involute (which, if any, arteries are derived from it remains unclear), and the sixth pair form the pulmonary arteries and ductus arteriosus.

All of the branchial arch nerves lie cranial to the respective arch artery, except the nerve of the sixth arch, the recurrent laryngeal nerve, which lies caudal to its arch artery on the left side. Since the sixth artery persists as the ductus arteriosus into fetal life and sometimes beyond, the recurrent laryngeal nerve on the left side curves around this structure or its adult counterpart, the ligamentum arteriosum. On the right side, the dorsal portion of the sixth arch artery disappears, so that there is no ductus arteriosus on the right. This results in the right recurrent laryngeal nerve coursing under the next most cranial persisting arch vessel, the fourth, which is the subclavian artery.

In some patients, a retroesophageal right subclavian artery develops because of the persistence of the right dorsal aorta distal to the origin of the seventh dorsal intersegmental artery (the right subclavian artery). The sixth arch artery disappears distal to the point of origin of the pulmonary artery, and the right recurrent laryngeal nerve is shifted cranially, to course around the next most cranial persisting arch artery, the right internal carotid artery. Thus the right recurrent laryngeal nerve descends almost vertically near the internal carotid artery to then enter the larynx. This situation is called a nonrecurrence of the right recurrent laryngeal nerve. In these patients, the right subclavian artery arises from the dorsal aorta beyond the left subclavian artery, and then the right subclavian artery passes behind the esophagus.

EMBRYOLOGY OF THE VEINS

There are three systems of paired veins that can be identified in the 20 somite (about 3 mm long) embryo: the umbilical veins from the chorion, the vitelline veins from the yolk sac, and the cardinal veins from the embryo itself.[30] There are actually two sets of cardinal veins, the precardinals that drain blood from the region of the head and the postcardinals that drain blood from regions caudal to the heart. Both pairs of cardinal veins unite at the heart in the short common cardinal veins (ducts of Cuvier).

Each precardinal (or anterior cardinal) vein actually consists of two veins. One is the primary head vein, which courses ventrolateral to the meninges and calvaria, except at the most caudal end of the head, and eventually develops into the cerebral veins and the dural sinuses. The other is the precardinal vein (the *true* precardinal vein) itself, which is laterally situated in the segmented portion of the head and neck and empties into the common cardinal vein. These true precardinal veins start near the base of the head and run caudally into the heart (Fig. 33-17). During the eighth fetal week, an oblique cross-channel develops (the intercardinal vein), which shunts blood from the left precardinal vein to the right one. As a result of this diversion of blood, the caudal portion of the left precardinal vein loses its communication with the common cardinal vein on the left side and survives in the adult as the highest intercostal vein and most of the inconstant oblique vein of the left atrium.[30]

The right common cardinal vein and the right precardinal vein, up to the level of the intercardinal vein, become the superior vena cava. The intercardinal vein itself becomes the left brachiocephalic (innominate) vein. The portion of the right precardinal vein between the intercardinal vein and the subclavian vein becomes the right brachiocephalic vein. Even more cephalad, the precardinal veins continue as the internal jugular veins. The external jugular veins and the subclavian veins are both extraneous vessels that develop independently and attach secondarily.[15, 30]

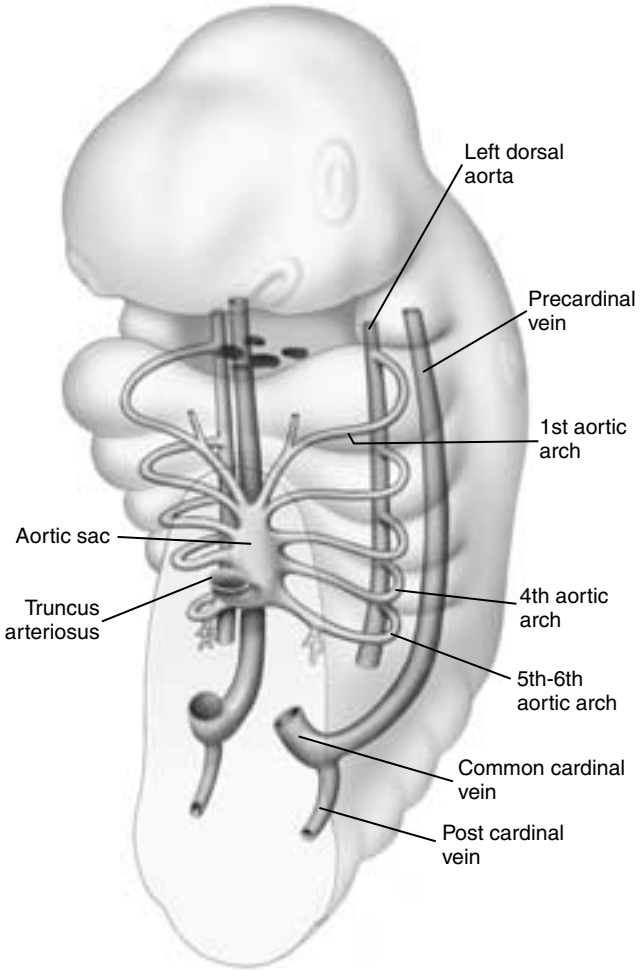

FIGURE 33-17 Oblique view of a 27-day-old embryo shows the developing arterial system and its relationship to the developing venous system.

VIEW IMAGE

EMBRYOLOGY OF THE LYMPHATIC SYSTEM

The development of the lymphatic system remains controversial. A number of different theories regarding their embryology have been proposed.[36]

Florence Sabin, in the early twentieth century, first proposed the theory that the lymphatics are formed from sprouts that arise from large central veins in certain locations. These sprouts then almost immediately demonstrate their own lymphatic character and form the primordial lymph sacs. Subsequently, the sacs enlarge, coalesce, and form new sprouts that grow in the periphery of the embryo (centrifugal spread).[37–39]

Huntington and McClure and then Kampmeier proposed that the lymphatic system develops independently of the mesenchyme. They believed that lymphatics are formed from the confluence of mesenchymal spaces in the periphery of the embryo. These lymphatic spaces spread centripetally by annexing other similar spaces, and anastomoses are eventually established with the venous system centrally.[40–43]

Van de Jagt and Kutsuna believed that the lymphatics originate from the confluence of small venules with spaces in the adjacent mesenchyme. These confluent spaces subsequently develop a lymphatic character.[44, 45]

S.C.J. van der Putte observed that the lymphatic system in humans arises from seven double and two single isolated primordia. He agreed with Sabin that the lymphatics are most likely of venous origin and that their subsequent development is due to centrifugal growth and sprouting.[46]

Today the most popular theory is closer to that proposed by Huntington, McClure, and Kampmeier in that it is believed that the lymphatic system originally develops in mesenchyme, independently of the venous system, and only later does any communication occur between the two systems. The lymphatics appear to develop as discrete mesenchymal lacunae with flattened mesenchymal cells, or endotheliocytes, bordering each space, and it is these cells that evolve into the endothelial cells of the lymphatics.[47–49]

The first spaces develop along the main primitive venous trunks near the anterior cardinal veins, at the site where eventually the primitive left and right internal jugular veins will meet the subclavian veins (Fig. 33-18). From these spaces sprouts develop, branch, and anastomose to form the jugular sacs at about six weeks of gestation. From these sacs,

FIGURE 33-18 Eleven mm human embryo (about 7½ weeks' gestational age). Large prevertebral blood vessels and first lymphatic primordia are shown. The jugular and axillary lymph sacs are quite small. They communicate with the anterior cardinal veins as blind-ending vessels.

lymphatic capillary beds spread to the neck, head, arms, and thorax. The more direct channels of these capillary beds enlarge to form the lymphatic vessels, and the larger vessels acquire smooth muscle coats, nerve connections, and eventually contractility (Fig. 33-19).

The jugular sacs are the only primitive sacs to acquire permanent connections with the venous system. The jugular sacs unite with each other and meet upgrowths from the cysterna chyli to produce the longitudinally coursing thoracic duct, which links the several lymphatic sacs in the body into a common system.[47–50] The jugular sac at the cranial termination of the thoracic duct bends and extends caudally to form a connection with the left subclavian vein.

The most popularly held view is that in the mesenchyme surrounding the lymphatic plexuses, groups of mesenchymal cells differentiate independently into hemopoietic centers that eventually produce cells that subsequently organize into lymph node structures. The primary lymph nodes begin to develop during the third month of gestation in the capillary lymphatic plexuses that were formed out of the large lymph sacs as the sacs start to break down. That is, the primary lymph nodes arise from the transformation of the lymphatic sacs into plexuses, eventually giving rise to the lymph node chains. Secondary lymph nodes develop later, even after birth, in peripherally located capillary lymphatic plexes.[47–49] The structural and functional unit of a lymphatic vessel is the lymphangion, and it is the circular layer of smooth muscle of the lymphangion's wall that seems to play a basic role in the pumping function of the lymphangions.[51]

More specifically, this concept suggests that the lymph nodes develop from groups of mesenchymal cells that become surrounded by a network of lymphatic vessels. The mesenchymal cells develop into the lymphocytes, reticular cells, and fibroblasts of the lymph node, while the lymph node sinuses arise from the surrounding lymphatic network. Parallel with this multiplication of lymphocytes, the surrounding mesenchyme forms a connective tissue capsule and the hilum of the node. Some researchers believe that it is from the capsule that trabeculae carrying blood vessels grow into the lymphoid tissue. Others believe that it is from the hilar region that the trabeculae and vessels spread into the node. In the larger trabeculae, collagenous fibers are laid down and continue as reticular fibrils into smaller trabeculae. The mesenchymal cells of the larger trabeculae become fibroblasts, while those accompanying the reticular fibrils become reticular cells. The marginal sinuses of the node can be identified in the fifth fetal month, while a true nodal cortex with germinal centers is identified mostly after birth.[47–49]

It is also now known that the cell surface ligand (lymphotoxin LT) is involved in immune organ morphogenesis. That is, exposure to LT beta-R-IG during gestation can disrupt lymph development and splenic architecture.[52] It has also been shown in mice that during fetal and early neonatal life, when only mucosal addressin MadCAM-1 is expressed on high endothelial venules, an unusual subset of CD4+ CD3− cells, exclusively expressing alpha 4 beta 7 as homing receptors, enters the lymph nodes. Starting 24 hours after birth, a developmental switch occurs that causes the peripheral node addressins to be upregulated on the high endothelial venules in peripheral and mesenteric lymph nodes. This switch in addressin expression facilitates tissue-selective lymphocyte migration and mediates a sequential entry of different cell populations into the lymph nodes.[53] This genetically related research represents the beginning of our understanding of the mechanisms involved in the embryology of the lymphatic system.

Tonsils

As mentioned earlier, the endoderm of the ventral portion of the second pharyngeal pouch, in the region between the tongue and the palate, forms the tonsillar fossa and invades the mesenchyme as a group of solid buds. The central portions of these buds degenerate to form tonsillar crypts, and invading lymphoid cells from the surrounding mesenchyme eventually become grouped as lymphoid follicles. In fact, during the third to fifth fetal months, lymphoid tissue invades not only the palatine region, but also the mucosa in the region of the future pharyngeal (adenoids) tonsils and the mucosa of the root of the tongue in the region of the future lingual tonsils. Together, these lymphoid tissues encircle the oropharynx forming Waldeyer's ring.[14]

EMBRYOLOGY OF THE SALIVARY GLANDS

The salivary glands share an overall common embryogenesis in that they all develop from the ingrowth of local proliferations of surface epithelium into the underlying mesenchyme, and they all have a similar anatomic structure. The secretory or parenchymal tissues all arise from these proliferations of oral epithelium, which are of ectodermal origin for the major salivary glands and of either ectodermal or endodermal origin (depending upon the anatomic location) for the minor salivary glands. The stroma of the glands develop from mesodermal origins, although an additional component migrating from the neural crest has been postulated (Fig. 33-20).[14]

The parotid anlagen are the first to develop, and they appear between the fourth and sixth weeks of intrauterine

FIGURE 33-20 Diagram of coronal section of human embryo at about 7 weeks. Anlagen of major salivary glands can be seen extending into adjacent mesenchyme. (Modified from Mason DK, Chisholm DM. Salivary Glands in Health and Disease. Philadelphia: WB Saunders, 1975.)

life. The submandibular gland anlagen appear later in the sixth week, and the sublingual gland anlagen arise in the seventh to eight weeks, while the minor salivary glands do not start to develop until late in the twelfth week of intrauterine life.[14, 54–56]

The epithelial buds of each gland enlarge, elongate, and branch, the last process being induced by the mesenchyme surrounding the epithelium. Initially these buds are solid structures; however, they eventually canalize, creating lumina. The canalization process results from a differential in mitotic rate between the more rapidly dividing outer cell layers of the epithelial cords and the inner cells layers that divide more slowly. This canalization process is completed prior to the development of lumina in the terminal buds, which are the distal ends of the ductal epithelial buds and which eventually develop into the acini.[57]

The epithelial cells lining the ducts, tubules, and acini then proceed to differentiate both morphologically and functionally. Surrounding the acini are the contractile myoepithelial cells that reach their peak density by the twenty-fourth fetal week in the submandibular glands and the thirty-fifth fetal week in the parotid glands.[57]

Interaction of the salivary gland parenchymal and stromal elements with the autonomic nervous system is necessary for normal salivary development and function, as sympathetic nerve stimulation leads to acinar differentiation, while parasympathetic nerve stimulation is important for overall glandular growth.

In the parotid glands, the ducts are canalized by the tenth fetal week, the terminal buds are canalized by the sixteenth fetal week, and secretions commence in the eighteenth fetal week. In the submandibular glands, the acini start to differentiate by the twelfth fetal week. Serous secretory activity starts at the sixteenth fetal week, increases until the twenty-eighth fetal week, and then diminishes. These serous secretions contribute to the amniotic fluids, and contain amylase and possibly nerve and epidermal growth factors. The mucous acini develop postnatally. The mucosal minor salivary glands are not morphologically mature until the twenty-fifth fetal week.[57]

Although the parotid anlagen are the first to emerge, they become ''encapsulated'' or ensheathed in a loose condensation of fibroconnective tissue only after the submandibular and sublingual glands have become encapsulated. This delayed encapsulation is critical to the parotid gland's adult anatomy because although all of the glands are developing within a loose condensation of mesenchymal tissue, the emergence of the lymphatic system occurs after encapsulation of the submandibular and sublingual glands but before that of the parotid glands. Thus, at the completion of embryogenesis, the parotid glands have lymph nodes and lymphatic channels within the gland's capsule, while the submandibular and sublingual glands do not. In addition, salivary epithelial cells can be included within the intraparotid and periparotid lymph nodes during their process of encapsulation. This unusual situation of salivary epithelial inclusions within lymph nodes is unique to the parotid and periparotid nodes.[56] The intraparotid and periparotid lymph nodes are elements of the mucosal associated lymphoid tissue (MALT) system that is found throughout the gastrointestinal tract, and which may be important in supplying all of the major salivary glands with IgA-producing plasma cells that are important components of mucosa-based immunity. This special embryogenesis of the parotid glands and their lymph nodes is believed to play a role in the development of Warthin's tumors, as discussed in Chapter 39.

The parotid gland is also unique in that as its epithelial buds are growing and branching, they extend between the divisions of the facial nerve that have already started to develop in the region. As a result, when these structures have completed their embryologic development, the facial nerve and its branches extend through the substance of the parotid gland.[14, 54, 55, 58, 59] Clearly, any surgical approach to the parotid must be mindful of this anatomy lest the nerve be seriously damaged.

The organ of Chievitz, found near the oral cavity, arises in the embryo as an oral epithelial invasion of the corners of the mouth, developing earlier than the parotid analgen. It is a small 7 to 17 mm long strand that resembles a nerve, and it lies in the cheek region between the buccopharyngeal fascia and the site where the parotid (Stenson's) duct penetrates the buccinator muscle. The organ of Chievitz is situated close to the buccal branch of cranial nerve V, which innervates it. Eventually, it loses its connection with the buccal sulcus and becomes embedded in a dense connective tissue sheath. The function of the organ of Chievitz is not known, but it may be a sensory receptor.[57]

Table 33-2 shows the embryologic development of the various systems described in relation to gestational age.

NORMAL POSTNATAL ANATOMY OF THE NECK

Traditionally in physical diagnosis, the superficial neck is analyzed as being divided into several palpable triangles (Fig. 33-21). These triangles not only define anatomic location, but often allow an initial differential diagnosis to be generated. However, because these triangles are not defined by the layers of the deep cervical fascia, they do not function as barriers to the spread of disease. The fasciae and

Table 33-2
THE TEMPORAL RELATIONSHIP OF FETAL AGE AND THE EMBRYOLOGY OF VARIOUS SYSTEMS

Fetal Age (Weeks)	Embryology
2.5	The embryonic disc is flat, the primitive streak is prominent, and the neural groove is indicated. The gut is not yet distinct from the yolk sac. Blood islands appear in the chorion and yolk sac. The notochordal plate and groove are present.
3.5	The neural groove deepens and closes. The neural crest is a continuous band. The optic and otic placodes are present, and the acoustic ganglia appear. Branchial arches 1 and 2 are identified, the stomodeum is a definite pit, and the oral membrane ruptures. The pharynx is broad and flat, and the pouches are forming. The thyroid anlagen are identified. The respiratory primordium appears as a groove on the floor of the pharynx. The foregut and hindgut are present.
4	The branchial arches are complete, and all 40 somites are present. The maxillary and mandibular processes are prominant. Rathke's pouch is identified. Five pharyngeal pouches are present, with pouches 1–4 having closing plates. The primary tympanic cavity is present, and the thyroid is a stalked sac. The laryngeal opening is a simple slit, and the trachea and paired lung buds are prominent. The esophagus is short. The optic cup and lens pit are forming. The auditory pit closes, and the otocyst detaches. The olfactory placodes arise and differentiate into nerve cells. Nerves and ganglia are forming.
5	The nasal pits are present, and the jaws are outlined. Rathke's pouch is a stalked sac. The pharyngeal pouches attain dorsal and ventral diverticula. The thyroid is bilobed, and the thyroglossal duct atrophies. The arytenoid swellings and the epiglottis are identified. The bronchial buds presage future lung lobes. There are premuscular masses in the head and neck, and the epidermis has a second layer. The lens vesicle is free, and the vitrous anlage appears. The otocyst elongates and develops the endolymphatic duct. The olfactory pits deepen. The nerves and ganglia are better represented.
6	The upper jaw components are present but separate; the lower jaw halves fuse. The head becomes dominant in size, and cervical flexure is marked. The external ear appears. The lingual primordia fuse, and the foramen caecum is established. The parotid and submaxilliary buds appear, as do the labio-dental laminae. The thymic sacs, ultimobranchial sacs, and solid parathyroids are prominent and ready to detach. The thyroid becomes solid and converts internally to plates. Definitive pulmonary lobes are identified. The laryngeal cavity is temporarily obliterated. Myotomes fuse into a continuous column, and muscle segmentation is lost. Nerve plexes are present, and sympathetic ganglia are forming segmental masses. The optic cup has nervous and pigmented layers. The lens vesicle thickens, and the eyes are set at 160°. The nasolacrimal duct is formed. Modeling of the external, middle, and inner ears continues, and the vomer-nasal region is identified.
7	The branchial arches are lost. The cervical sinus of His is obliterated. The lingual primordia merge into a single tongue. Separate labial and dental laminae are distinguishable. The jaws are formed and start to ossify. The palate folds are present and separated by the tongue. The thymi elongate further and lose lumina. The parathyroids become trabeculated and associated with the thyroid. The ultimobranchial bodies fuse with the thyroid, and the thyroid becomes crescentic in shape. The larynx and epiglottis are well outlined, and the laryngeal orifice is T-shaped. The laryngeal and tracheal cartilages are identified. The posterior nasal conchae appear and the primary conchae ruptures, creating two internal nasal orifices. The cardinal veins are transforming. Chondrification is more generalized, and muscles are rapidly differentiating. The infundibulum and Rathke's pouch are in contact. The choroidal fissure closes in the eye, enclosing the central artery. Nerve fibers invade the optic stalk, and the lens cavity is lost by elongating lens fibers. The eyelids form, and the olfactory sacs open into the mouth.
8	The nose is flat, the eyes are far apart, and the head is elevating. The tongue muscle become well differentiated, and the taste buds are identified. Rathke's pouch detaches from the mouth. The sublingual gland appears. The eustachian tube, tympanic cavity, external ear, and inner ear are distinguishable. The sites of the palatine tonsil and fossa appear. The thymic halves unite, and the gland becomes solid. The thyroid follicles start to form. The nostrils are closed by epithelial plugs. The major blood vessels assume their final shape. The primitive lymph sacs develop. The first indications of ossification occur. Definitive muscles are present, and the fetus has movement. The olfactory lobes are visible, the dura, pia, and arachnoid are distinct, and the chromaffin bodies appear. The eyes are rapidly converging.
10	The head is erect. The fungiform and vallate papillae are differentiating. The lips are separate from the jaw, and the enamel organs and dental papillae form. The palatal folds fuse. The thymic epithelium is transforming into reticulum and thymic corpuscles. The ultimobranchial bodies disappear. The nasal passages are partitioned by fusion of the septum and palate. The nasal cartilages appear. The laryngeal cavity reopens, and the vocal cords appear. The earliest hair follicles develop on the face. The iris and ciliary body organize, the eyelids fuse and the lacrimal gland develops. The spiral organ of the ear begins to differentiate. Early lymph nodes appear.
12	The bridge of the nose is identified. The filiform and foliate papillae become more prominent. The tooth primordia form prominent cysts. The cheeks can be identified. The tonsillar crypts invaginate. The thymus forms medullary and lymphoid tissue. The thyroid gland attains a typical structure. The nasal conchae are prominent, and the nasal glands develop. Blood formation begins in the marrow. The notochord is rapidly degenerating. Ossification is more extensive, and some bones are clearly identified. The smooth muscle layers of the gut are identified. The eye attains its characteristic organization, and the retina becomes layered. Fusion of the nasal septum and palate is completed.
16	There is now a human facial appearance, and head hair appears. The muscles become spontaneously active, and the body outgrows the head size. The hard and soft palates are differentiating. The hypophysis is acquiring a definitive structure. Lymphocytes start to accumulate within the palatine tonsil, and the adenoids appear. The paranasal sinuses start to develop, and the tracheal glands appear. Most bones are distinct, and the joint cavities develop. Body hair appears, and the sweat glands and sebaceous glands start to differentiate. The eye, ear, and nose grossly approach their adult forms.
20–40	Lanugo hair appears (5 months), becomes prominent (7 months), and is shed (10 months). The subcutaneous fat collects, and skin wrinkles start to smooth (8–10 months). Enamel and dentin are deposited (5 months), and the permanent tooth primordia are identified (6–8 months). The lingual tonsil forms, and adult tonsilar structure is seen (5 months). The nasal bones begin to ossify (5 months), and the nostrils reopen (6 months). The frontal and sphenoid sinuses are still only rudimentary (10 months). Myelinization of the cord begins (5 months), and the cerebral fissures and convolutions rapidly appear (7 months). The vascular tunia of the lens attains its highest development (5 months). The retinal layers are completed, and light perception develops (7 months). The eyelids reopen (7–8 months). Taste sensation is present (8 months). The mastoid cells are still unformed (10 months).

Copyright © 2003, Mosby, Inc. All rights reserved.

fascial spaces are detailed in Chapter 34. For discussion of the anatomy of the neck during the fetal, perinatal, and infant periods, see references 60 to 63.

One of the dominant anatomic landmarks in the neck is the sternocleidomastoid muscle, which courses obliquely down the lateral neck, from the mastoid process to the clavicle and sternum. By definition, this muscle is used to divide the neck into anterior and posterior triangles.[1] Structures that are palpated ventral to the anterior edge of the sternocleidomastoid muscle are within the anterior triangle, while those structures that lie posterior to this muscle but anterior to the trapezius muscle are considered to be within the posterior triangle. The clinically inaccessible region deep to the sternocleidomastoid muscle is defined as being part of the anterior triangle of the neck.

Traditionally on either side of the neck, the boundaries of the anterior triangle are the anterior border of the sternocleidomastoid muscle, the undersurface of the body of the mandible, and the anterior midline of the neck. Each anterior triangle can be further subdivided into four smaller triangles. Thus, the anterior belly of the digastric muscle separates the anterior midline submental triangle from the submandibular triangle. The posterior belly of the digastric muscle separates the submandibular and carotid triangles, while the superior belly of the omohyoid muscle separates the carotid and muscular triangles. The borders of the

Note the muscular sling, primarily provided by the mylohyoid muscles, forming the floor of the mouth. The submandibular and submental triangles lie below this sling, and contents of the oral cavity lie above it.

VIEW IMAGE

posterior triangle are the dorsal edge of the sternocleidomastoid muscle, the anterior border of the trapezius muscle, and the middle third of the clavicle. The posterior triangle can be subdivided by the inferior belly of the omohyoid muscle into the occipital and subclavian (omoclavicular) triangles.[1, 64–67]

The hyoid bone can also be used to subdivide the anterior triangle into suprahyoid and infrahyoid compartments. In this classification, the suprahyoid compartment contains the solitary midline submental triangle and the paired (lateral) submandibular triangles. Functionally the suprahyoid compartment is related to the oral cavity, floor of the mouth, oropharynx, and hypopharynx. The infrahyoid compartment on either side contains the carotid and muscular triangles.

The submental triangle is a midline unpaired triangle bordered laterally by the anterior bellies of the digastric muscles, inferiorly by the hyoid bone, and superiorly by the lower border of the symphysis of the mandible. The mylohyoid muscles and their fibrous median raphe form the deep boundary (or floor) of the triangle, separating it from the oral cavity. The contents of the submental triangle include small submental lymph nodes (level IA) and branches of the facial artery and vein (Figs. 33-21 and 33-22).

Each of the submandibular triangles, or digastric triangles, is bordered superiorly by the lower border of the body of the mandible and inferiorly by the anterior and posterior bellies of the digastric muscle. The deep surface (or floor) of each submandibular triangle is formed by portions of the mylohyoid muscle anteriorly and the hyoglossus muscle posteriorly. The submandibular triangles communicate with the sublingual space at the posterior margins of the mylohyoid muscles. Each submandibular triangle is almost completely occupied by the superficial portion of the submandibular gland. Three to five submandibular lymph nodes (level IB, see Chapter 36) lie superficial to the gland, as do portions of the posterior (retromandibular) and anterior facial veins (Figs. 33-21 and 33-23). The anatomy of this region is discussed in more detail in Chapter 27.

Each carotid triangle is the region of the lateral neck in which the carotid sheath structures are relatively superficial in location. These triangles are bordered by the posterior belly of the digastric muscle, the superior belly of the omohyoid muscle, and the midportion of the sternocleidomastoid muscle. The contents include the carotid sheath structures: the common carotid and internal carotid arteries, a portion of the external carotid artery, portions of cranial nerves IX, X, XI, and XII, and the internal jugular vein. Also present are the cervical sympathetic trunk and the ansa cervicalis, a part of the cervical plexus (see the section on Spinal Nerves). In addition, there are a number of lymph nodes that are primarily related to the internal jugular vein and the carotid sheath (level III) (Figs. 33-21, 33-24, and 33-25).

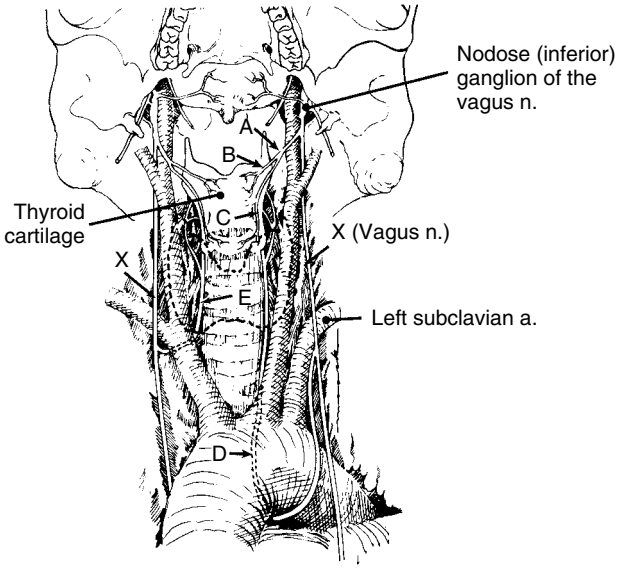
FIGURE 33-26 Muscular triangles—line diagram (AP view). Superficial strap muscles are identified on the left, and the deeper ones are labeled on the right.



VIEW IMAGE

FIGURE 33-27 Anterior triangle of neck (strap muscles have been removed)—line diagram (AP view). Note the different levels of origin of the two recurrent laryngeal nerves; the left recurrent laryngeal nerve arises below the level of the aortic arch, under which it loops in the region of the aortopulmonary window. **A**, Superior laryngeal nerve. **B**, Internal branch of superior laryngeal nerve. **C**, External branch of superior laryngeal nerve. **D**, Left recurrent laryngeal nerve. **E**, Right recurrent laryngeal nerve.

Each muscular triangle is bordered posteriorly and superiorly by the superior belly of the omohyoid muscle, posteriorly and inferiorly by the sternocleidomastoid muscle, and anteriorly by the midline of the neck. Together, these paired triangles contain the infrahyoid ''strap'' muscles, larynx, hypopharynx, cervical portion of the trachea, esophagus, thyroid, and parathyroid glands, the vascular supply to these structures, and the recurrent laryngeal nerves coursing in the tracheoesophageal grooves. There are also the visceral (level VI) and some of the lower internal jugular (level IV) lymph nodes (Figs. 33-21, 33-26 to 33-28).

The infrahyoid ''strap'' muscles include the superior belly of the omohyoid muscle and the sternohyoid, sternothyroid, and thyrohyoid muscles. As a result of their muscular attachments, the sternothyroid and thyrohyoid muscles lie in a deeper plane than do the sternohyoid muscle and the superior belly of the omohyoid muscle (Fig. 33-29).

The thyroid gland (so named because it resembles a shield, *thyreos* in Greek) lies below and on both sides of the thyroid cartilage, covered by three of the four infrahyoid strap muscles. (The thyrohyoid muscle does not cover the thyroid gland.) The thyroid gland consists of two lateral lobes, one on either side of the upper trachea and lower

FIGURE 33-28 Muscular triangle—gross dissection (oblique view). The sternocleidomastoid muscle has been removed. The pointer indicates the sternohyoid muscle, one of the two superficial strap muscles. The other superficial strap muscle, the superior belly of the omohyoid muscle (*1*), has been slightly displaced posterolaterally to reveal underlying structures. The sternothyroid (*2*) and thyrohyoid (*3*) muscles can be identified on a deeper plane. *4*, Submandibular gland; *5*, internal jugular vein; *6*, common carotid artery; *7*, superior thyroid branch of the external carotid artery.

VIEW IMAGE

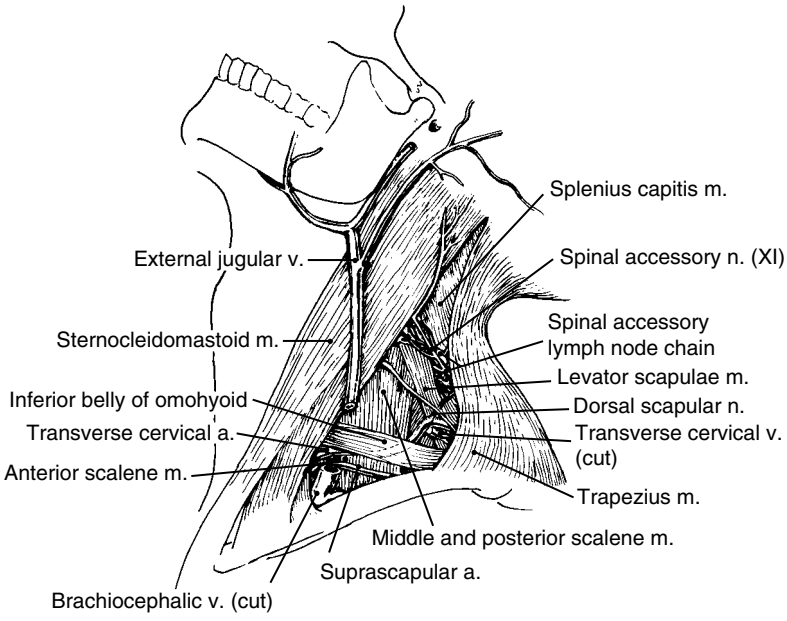
FIGURE 33-29 Infrahyoid region of neck (thyroid gland level)—line diagram (axial view). Superior belly of omohyoid muscle often can be seen as separate structure on deep surface of sternocleidomastoid muscle. Recurrent laryngeal nerves lie in tracheoesophageal grooves. Posterior aspect of thyroid gland is in intimate contact with common carotid artery. Note locations of vagus and phrenic nerves.

larynx, and an interconnecting isthmus that overlies the second to fourth tracheal rings, just below the cricoid cartilage. The gland varies greatly in size and is often larger in women and children than in men. In 40% of the population, a variably sized pyramidal lobe arises from the upper margin of the thyroid gland and projects superiorly, usually, but not always, in a midline location. It may be represented by a small stump of tissue or by a large, discrete lobe.[68] A remnant of the thyroglossal duct, the levator glandulae thyroideae, represented by a fibrous strand or a fibromuscular band, may attach the thyroid gland to the body of the hyoid bone. The parathyroid glands are usually embedded in the posterior surface of the thyroid gland, one pair in each lobe. The posterior aspect of each lobe of the thyroid gland is just medial to the common carotid artery. The anatomy of the thyroid gland is discussed in greater detail in Chapter 40.

The contents of the posterior triangle are the cutaneous branches of the cervical plexus (the lesser occipital, greater auricular, anterior cutaneous, and supraclavicular nerves), the spinal accessory nerve, the suprascapular and tranverse cervical arteries (branches of the thyrocervical trunk), the suprascapular, transverse cervical, and external jugular veins, and lymph nodes associated with the spinal accessory nerve (level V nodes). As mentioned, the inferior belly of the omohyoid muscle subdivides the posterior triangle into a larger occipital triangle and a smaller subclavian (omoclavicular) triangle (Figs. 33-21, 33-30, and 33-31).

Each occipital triangle is bordered anteriorly by the sternocleidomastoid muscle, posteriorly by the ventral edge of the trapezius muscle, and caudally by the inferior belly of the omohyoid muscle. Each triangle is primarily fat-filled and traversed by the spinal accessory and dorsal scapular nerves. Portions of the spinal accessory lymph node chain (level V) are contained in the midportion of this triangle, while portions of the transverse cervical artery and vein are contained in its inferior portion. From above downward (posteriorly to anteriorly), the floor of the posterior triangle is composed of the splenius capitus, levator scapulae, and posterior, middle, and anterior scalene muscles. The spinal accessory nerve enters the deep surface of the sternocleidomastoid muscle at Erb's point, which is just cranial to where the great auricular nerve surfaces from the deep neck (Fig. 33-32). Alternatively, the spinal accessory nerve can be located surgically where it disappears on the deep surface of the trapezius muscle, at a point roughly two finger-breadths



VIEW IMAGE

FIGURE 33-31 Posterior triangle of the neck—gross dissection (oblique view). The extensive amounts of fat have been removed during dissection. A portion of the trapezius muscle (*1*), forming the posterior border of the triangle, is visible as are the sternocleidomastoid muscle (*2*) and clavicle (*3*), forming the other two borders. The forceps is holding the spinal accessory nerve (cranial nerve XI) (*4*) as it traverses the posterior triangle. The suprascapular artery (*5*) is seen crossing the middle and posterior scalene muscles (*6*).

superior to the clavicle at the anterior border of the trapezius muscle. At the skull base, the spinal accessory nerve courses in front of the internal jugular vein at the level of the transverse process of the first cervical vertebra.[69]

The borders of each small subclavian triangle are anteriorly, the lower portion of the sternocleidomastoid muscle; superiorly, the inferior belly of the omohyoid muscle; and inferiorly, the middle third of the clavicle. Within each triangle is located the distal (third) portion of the subclavian artery, the trunks of the brachial plexus, and portions of the transverse cervical and suprascapular arteries and veins. Some of the supraclavicular lymph nodes are also located within this triangle (Figs. 33-21, 33-33, and 33-34).

The anterior scalene muscle is an important landmark for the anatomy of the lower neck, and it arises from the transverse processes of C3 to C6. The muscle then courses inferiorly, deep to the sternocleidomastoid muscle, to insert onto the first rib. The anterior scalene muscle separates the subclavian vein, which lies superficial (ventral) to the muscle, from the roots of the brachial plexus and the subclavian artery, which lie deep (dorsal) to it.[64, 66–68]

The anterior scalene muscle also can be used to subdivide the subclavian artery into three portions, all of which are within the subclavian triangle. The first portion lies medial to the anterior scalene muscle, the second portion lies deep to it, and the third portion extends from the lateral border of the muscle to the outer margin of the first rib. Beyond the first rib, the subclavian artery becomes the axillary artery.

THE PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system (PNS) is composed of three components that communicate and interact to supply afferent and efferent fibers to the somatic and visceral portions of the head and neck. The three components of the PNS are the cranial nerves, the spinal nerves, and the autonomic nervous system. While a review of these systems in their entirety is beyond the scope of this book, a discussion of the anatomic location of the major components of the PNS will allow a better understanding of where to look for these structures within the neck. In addition, noting the communications between them may possibly explain how disease in one nerve may spread to another nerve or component of the system. Discussions of some of these cranial nerves also appear elsewhere in this book.

Cranial Nerves

Cranial nerves I, II, III, IV, VI, and VIII are confined to the intracranial compartment and orbit and, in general, do not have manifestations in the neck. These nerves are also discussed elsewhere in the book.

Cranial nerve V, the trigeminal nerve, has three divisions: ophthalmic (V_1), maxillary (V_2), and mandibular (V_3). The ophthalmic nerve courses within the cavernous sinus before it enters the orbit via the superior orbital fissure and eventually branches into the frontal, nasociliary, and lacrimal nerves. The maxillary nerve runs from the cavernous sinus through the foramen rotundum, crosses the pterygopalatine fossa directed laterally and downward, and enters the the orbit via the inferior orbital fissure. It continues in the floor of the orbit as the infraorbital nerve and exits on the face of the maxilla through the infraorbital foramen (Fig. 33-35). The zygomatic nerve arises in the pterygopalatine fossa, enters the orbit via the inferior orbital fissure, and has two branches: the zygomaticotemporal and zygomaticofacial. The former leaves the orbit through the zygomaticotemporal foramen or passes through the sphenozygomatic suture to reach the temporal fossa, where the *zygomaticotemporal nerve communicates with the facial nerve (VII) and the auriculotemporal branch of the mandibular nerve (V_3)*. While in the orbit, *V_2 sends a branch through the pterygopalatine ganglion that reaches the lacrimal gland. The zygomaticofacial nerve* leaves the anterior orbit via the zygomaticoorbital and zygomaticofacial formina to emerge on the face, where it *joins VII and the infraorbital branch of V_1*.

Within the pterygopalatine fossa, *V_2 gives off the pterygopalatine branches, which are important functional communications between the pterygopalatine ganglion and the maxillary nerve. The greater palatine nerve, a branch of the pterygopalatine nerves, communicates with the terminal branches of the nasopalatine nerve, while the terminal facial branches of V_2 communicate with filaments of VII.*

The mandibular nerve, V_3, is the largest division of the fifth cranial nerve and has two roots, a larger lateral sensory root and a smaller medial motor root. The two roots leave the middle cranial fossa via the foramen ovale and unite to form a main trunk just below the skull base. After only 2 to 3 mm, the trunk divides into a smaller anterior division and a larger posterior division (main trunk). The otic ganglion lies just medial to the main nerve trunk (Fig. 33-35). The *recurrent branch or nervus spinosus* of the main trunk reenters the skull base via the foramen spinosum to supply the dura. It *communicates with the meningeal branch of V_2*. Muscular branches then go to the medial pterygoid and the tensor veli

VIEW IMAGE

palatini muscles, entering these muscles near their cranial origins. Near its zygomatic arch origin, the anterior division of V_3 sends branches to the masseter muscle and then to the temporalis muscle. *The buccal nerve penetrates the lower temporalis muscle and ramifies over the surface of the buccinator muscle, communicating with buccal branches of VII.* The auriculotemporal nerve arises close to the foramen spinosum as two roots that encircle the middle meningeal artery and then join and run behind the neck of the mandible to pass upward with the superficial temporal artery (Fig. 33-35). The *auriculotemporal nerve communicates with the otic ganglion and with the facial nerve in the substance of the parotid gland. The lingual nerve of V_3 lies deep to the lateral pterygoid muscle, where it is joined by the chorda tympani nerve of VII.* The lingual nerve then runs between the medial pterygoid muscle and the mandible, crosses over the superior pharyngeal constrictor and styloglossus muscle, and reaches the side of the tongue. It then passes between the hyoglossus and the submandibular gland, crosses the lateral side of the submandibular (Wharton's) duct, and runs along the undersurface of the tongue to its tip, lying just deep to the mucosa (Fig. 33-35). *The lingual nerve has communications with the submandibular ganglion and the hypoglossal nerve (XII)* along the anterior margin of the hyoglossus muscle. The inferior alveolar nerve enters the ramus of the mandible through the mandibular foramen and runs within the mandibular canal. It has branches to the mylohyoid muscle and dental branches before it emerges from the mental foramen of the mandible as the mental nerve. *The terminal branches communicate freely with the mandibular branch of the facial nerve.*

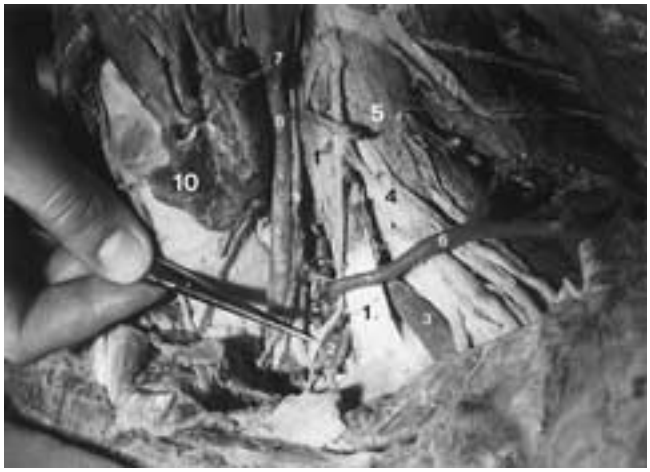

FIGURE 33-34 Left subclavian triangle—gross dissection (oblique view). Superficial musculature and veins have been removed. The forceps indicates the phrenic nerve as it crosses anterior to the first portion of the subclavian artery. Note the anterior scalene muscle (*1*) and its relationship to the subclavian artery, (*2*) first portion and (*3*) third portion (the second portion lies deep to the muscle tendon). The roots of the branchial plexus (*4*) course between the anterior scalene (*1*) and middle-posterior scalene (*5*) muscles. *6*, Transverse scapular artery (the suprascapular artery was absent in this specimen); *7*, internal jugular vein (cut); *8*, common carotid artery; *9*, vagus nerve; *10*, thyroid gland.

VIEW IMAGE

The facial nerve has two roots, a larger motor root and a smaller sensory and parasympathetic root called the nervus intermedius (see Chapter 19). Within the internal auditory canal, the *facial nerve communicates with the vestibulocochlear nerve (VIII). Via the geniculate ganglion it communicates with the pterygopalatine ganglion and sympathetic fibers.* Within the facial canal, just before it exits the stylomastoid foramen, *VII communicates with the auricular branch of the vagus nerve (X).* Below the skull base, *VII communicates with the glossopharyngeal nerve (IX), X, the great auricular nerve of the cervical plexus (C2,C3), and the auricular temporal nerve of V_3.* Within the parotid gland, the facial nerve then typically divides into five branches (Fig. 33-32). (The facial nerve is further discussed in Chapters 13 and 39).

The glossopharyngeal nerve exits the skull base through the jugular foramen, situated between the internal carotid artery and the internal jugular vein and posterior to the styloid process. Within the jugular fossa there is a smaller superior ganglion and a *larger inferior ganglion that communicate with X and the superior sympathetic ganglion.* Immediately below the skull base, *IX communicates with VII.* It then follows the posterior border of the stylopharyngeus muscle, which it supplies, for 2 to 3 cm and then curves

VIEW IMAGE

FIGURE 33-35 Drawing of the oblique frontal view of the skull and cervical spine showing the relationships of the cranial nerves, autonomic ganglia, and some of the connections with the cervical roots.

across the outer surface of the hyoglossus muscle. It then penetrates deeply, to be distributed to the palatine tonsil, the mucosa of the fauces and base of the tongue, and the minor salivary glands in the region (Fig. 33-35).

The vagus nerve is the longest of the cranial nerves, has the most extensive distribution of any of the cranial nerves, and leaves the skull base via the jugular foramen. Within the jugular foramen there is the 4 to 5 mm in diameter superior vagal (jugular) ganglion. About 1 cm below it and under the skull base is the 2.5 cm inferior (nodose) ganglion of X. The *jugular ganglion communicates with the spinal accessory nerve (XI), the inferior ganglion of IX, VII via the auricular branch, and the superior sympathetic cervical ganglion. The nodose ganglion communicates with XII, the superior sympathetic cervical ganglion, and the cervical plexus via the loop between the anterior rami of C1 and C2*. Within the neck, X lies within the carotid sheath, posterior to the internal carotid artery and anterior to the internal jugular

Copyright © 2003, Mosby, Inc. All rights reserved.

vein (Fig. 33-35). On the right side, the vagus nerve passes above and anterior to the subclavian artery, lying posterior to the brachiocephalic (innominate) vein (Fig. 33-27). As it passes under the subclavian artery, the right vagus contributes to the posterior pulmonary plexus, and below this it enters a plexus on the dorsal side of the esophagus. It then communicates with the left vagus and forms a single trunk, the posterior vagus nerve, which passes through the esophageal hiatus in the diaphragm. As the vagus nerve passes superficial to the first part of the subclavian artery, the right recurrent loops under this vessel and then ascends within the tracheoesophageal groove as the right recurrent nerve to enter the larynx near the posterior aspect of the cricothyroid joint.

The left vagus extends down around the left side of the aortic arch, passing above and anterior to it before going under it, lying between the aorta and the left pulmonary artery just distal to the ligamentum arteriosum (Fig. 33-27). Near the root of the lung, it contributes to the posterior pulmonary plexus and communicates with the right vagus to form the anterior vagus nerve, which then passes through the diaphragm. The left recurrent nerve arises near the posterior pulmonary plexus and ascends in the tracheoesophageal groove to enter the larynx near the posterior cricothyroid joint. Because of the nerves's low origin on the left, imaging of patients with paralysis of the left recurrent laryngeal nerve must be extended below the level of the aorticopulmonary window.

The vagus nerve has a meningeal branch to the dura and an auricular branch *(Arnold's nerve), which communicates with the inferior ganglion of IX* and then passes via the mastoid canaliculus into the temporal bone near the facial canal just above the stylomastoid foramen. *It communicates with VII* and then passes through the tympanomastoid fissure to be distributed on the skin of the posterior external auditory canal and the back of the pinna, joining *the posterior auricular nerve of VII*. There are *pharyngeal branches that arise just under the nodose ganglion and contain fibers from XI. The pharyngeal branches then communicate with IX, the sympathetics, and the external branch of X to form the pharyngeal plexus*, which is on the upper margin of the middle pharyngeal constrictor muscle. The *vagus also has branches to the carotid body, along with fibers from IX and the superior cervical sympathetic ganglion*. The superior laryngeal nerve arises near the lower border of the nodose ganglion and passes downward, near the internal carotid artery, to the thyrohyoid membrane of the larynx. The *superior laryngeal nerve communicates with the superior cervical sympathetic ganglion*.

The spinal accessory nerve has a cranial and a spinal portion. The *cranial portion (cranial root)* passes through the jugular foramen separately from the spinal portion (spinal root) and *joins X* proximal to the nodose ganglion. The spinal portion also passes through the jugular foramen, lying immediately adjacent to the cranial portion, and then passes below the skull base either anterior (two thirds) or posterior (one third) to the internal jugular vein. Then XI passes posterior to the stylohyoid muscle and the posterior belly of the digastric muscle to the upper portion of the sternocleidomastoid muscle, which it pierces. It then courses obliquely downward and backward across the posterior triangle of the neck to the anterior border of the trapezius muscle. Via the cervical plexus*, XI communicates with C1, C2, C3, and C4* (Figs. 33-35 and 33-36).

The hypoglossal nerve rootlets join to form two bundles that pass through the hypoglossal canal and then unite below the skull base. Nerve XII runs downward within the carotid sheath and becomes superficial to the internal carotid artery and internal vein near the angle of the mandible. Nerve XII then becomes anterior to the external carotid and lingual arteries below the tendon of the digastric muscle. It passes above the hyoid bone and goes deep to the stylohyoid and digastric muscles between the mylohyoid and hyoglossus muscles. It then continues forward near the genioglossus muscle to the tip of the tongue. *Nerve XII communicates with the nodose ganglion of X, the pharyngeal plexus, the superior cervical sympathetic ganglion, the lingual nerve of V, and the cervical plexus C1 and C2 loop* (Figs. 33-35 and 33-36).

Spinal Nerves

The spinal nerves have both ventral and dorsal rami. The dorsal rami supply the intrinsic muscles of the back (i.e., those muscles evolutionarily derived from the axial skeleton) and the skin of the midline areas of the occipital region of the skull and back. The suboccipital or C1 dorsal ramus emerges above the posterior arch of C1 and supplies the rectus capitis posterior (major and minor), oblique capitis (superior and inferior), and semispinalis capitis muscles. *The dorsal C1 ramus communicates with a filament of C2*. The dorsal division of C2 emerges between the posterior arch of C1 and the lamina of C2. It supplies the oblique capitis inferior muscle and then divides into the greater occipital nerve and the lateral branch. The *greater occipital nerve communicates with dorsal branches of C3 and supplies the scalp and vertex of the head, communicating with the lesser occipital nerve*. It also supplies the semispinalis captis. The *lateral branch* supplies the splenius capitis and semisplenius capitis and often *communicates with the lateral branch of C3*. The dorsal rami of C3 supply the skin of the lower back of the neck. The dorsal rami of C4 to C8 supply the semispinalis capitis and cervicis, the multifidus, interspinales, iliocostalis cervicis, and longissimus capitis and cervicis muscles and the skin of the back.

The cervical plexus is formed by the ventral primary rami of the upper four cervical nerves. The rami of C2 to C4 each divide into upper and lower branches, and these branches unite to form three loops. The *cervical plexus has communications with cranial nerves X, XI, and XII and the superior sympathetic ganglion* (Figs. 33-36 and 33-37). The ventral ramus of C1 leaves the spinal canal above the posterior arch of C1 and runs forward around the lateral aspect of the superior articular process while being medial to the vertebral artery. Most often it remains medial and anterior to the lateral rectus capitis muscle. The ventral rami of C2 to C4 extend out between the anterior and posterior intertransversarii muscles, lying on the grooved upper surfaces of the transverse processes of the vertebrae. The cervical plexus lies opposite the first four cervical vertebrae, anterior and lateral to the levator scapulae and middle scalene muscles and deep to the sternocleidomastoid muscle.

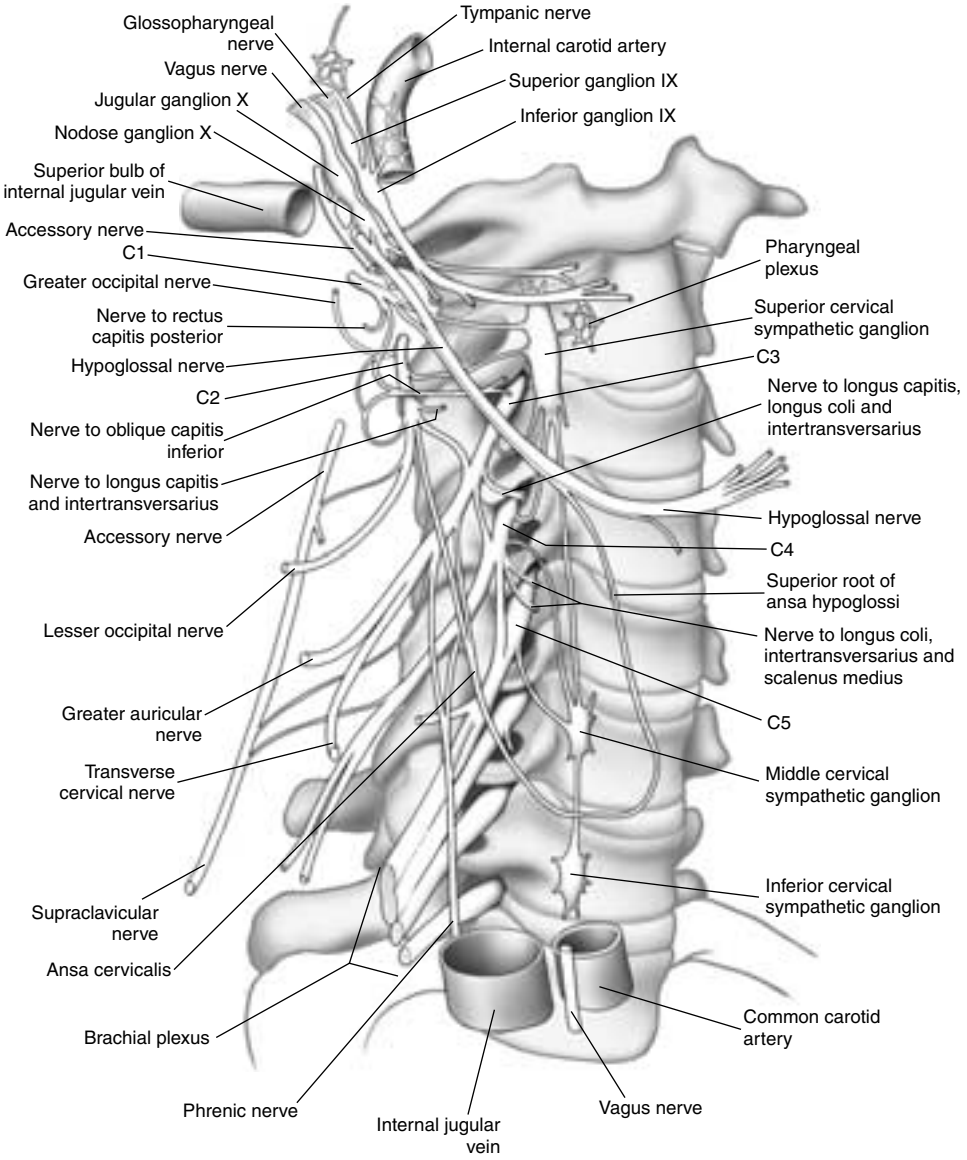

FIGURE 33-36 Drawing of the oblique frontal view of the cervical spine showing the relationship of the cervical nerves, the glossopharyngeal and vagus nerves, and the cervical sympathetic ganglia.

VIEW IMAGE

Following its exit from the skull base, the *hypoglossal nerve is joined by fibers from the loop between C1 and C2*, and these fibers course with the hypoglossal nerve until it crosses the internal carotid artery. At this point, most of the cervical nerve fibers separate from the main trunk and descend as the superior ramus of the ansa hypoglossi or the descending hypoglossal ramus. This ramus courses inferiorly on the internal carotid artery to unite with the inferior ramus of the ansa cervicalis (ansa hypoglossi) or the descending cervical ramus, formed by fibers from the C2 and C3 nerves. The ansa supplies motor innervation to the sternohyoid, omohyoid, and sternothyroid muscles. The thyrohyoid and geniohyoid muscles are supplied by the few C1 fibers that course with the hypoglossal nerve beyond the origin of the superior ramus.[1, 64–67] *The hypoglossal nerve sends a branch to communicate with the nodose ganglion of the vagus nerve, as do fibers from the loop between C1 and C2. Communication between the cervical plexus and the spinal accessory nerve occurs at several places; branches from the loop between C2 and C3 join XI to supply the sternocleidomastoid muscle; fibers from C3 join XI to supply the trapezius muscle; and proprioceptive fibers from C4 also join XI and go to the deep surface of the trapezius muscle* (Figs. 33-36 and 33-37).

Other deep or muscular branches of the cervical plexus include those from the loop between C1 and C2 to the anterior rectus capitis and lateral rectus capitis muscles; from C1 to C3 branches go to the longus capitis muscle and from C2 to C4 to the longus colli muscle; fibers from the C1/C2 loop run with XII and then leave it as the descending hypoglossi. Fibers from the descending hypoglossi supply the superior belly of the omohyoid muscle and the thyrohyoid and geniohyoid muscles prior to joining fibers from C2/C3 (the descending cervical nerve) to form the ansa cervicalis. The descendens hypoglossi supplies the inferior belly of the omohyoid muscle, and fibers from the ansa

Copyright © 2003, Mosby, Inc. All rights reserved.

(cervicalis) go to the sternohyoid and sternothyroid muscles (Fig. 33-37).

There are also superficial or cutaneous branches of the cervical plexus. *The lesser occipital nerve* usually arises from the C2/C3 loop and ascends along the sternocleidomastoid muscle to the retroauricular area, where it supplies the skin, *communicating with the greater occipital and great auricular nerves and the posterior auricular branch of VII. The great auricular nerve* arises from C2 and C3 and goes along the posterior border of the sternocleidomastoid muscle deep to the platysma muscle, where an anterior branch supplies the skin over the parotid gland and fibers *communicate with the substance of the gland*. The *posterior branch of the great auricular nerve* supplies the skin over the mastoid process and portions of the auricle. This branch *communicates with the lesser occipital nerve, the auricular branch of X, and the posterior auricular branch of VII. The cervical cutaneous nerve* arises from C2 and C3 and runs horizontally across the sternocleidomastoid muscle, deep to the external jugular vein and platysma, to form ascending and descending branches. The ascending branches go to the skin of the submaxillary region and the upper anterior lateral neck. A few fibers *communicate with the cervical branch of VII*. The descending branch supplies the lateral anterior neck down to the sternum. The *supraclavicular nerves* arise from C3 and C4 and extend posterior to the sternocleidomastoid muscle to form the following branches: the anterior supraclavicular nerves that supply the skin over the medial infraclavicular region to the midline; the middle supraclavicular nerves that supply the skin over the pectoralis major muscle and the deltoid muscle, *communicating with the cutaneous branches of the upper intercostal nerves*; and the posterior supraclavicular nerves that supply the skin over the upper and posterior shoulder (Figs. 33-32 and 33-35). The brachial plexus is formed by the ventral primary rami of the lower four cervical nerves and the first thoracic nerve, with occasional small contributions from the fourth cervical and second thoracic nerves (Fig. 33-36).[64, 66–68] These ventral rami course between the anterior and middle scalene muscles, superior to the second portion of the subclavian artery. The brachial plexus extends from the lateral border of the anterior scalene muscle to the lower border of the pectoralis minor muscle, at which point the cords divide into their terminal branches. The detailed anatomy and imaging of the brachial plexus are discussed in Chapter 42.

The phrenic nerve arises primarily from the fourth cervical nerve, with contributions from the third and fifth cervical nerves (Figs. 33-36 and 33-38). It courses inferiorly on the anterior scalene muscle, deep to the transverse cervical and suprascapular branches of the thyrocervical trunk and deep to the prevertebral fascia. It gains access to the medial surface of the pleura by crossing anterior to the first portion of the subclavian and internal thoracic (mammary) arteries.[64, 66–68]

Sympathetic System

The cervical portion of the sympathetic system consists of three ganglia (superior, middle, and inferior) connected by intervening cords (Figs. 33-36, 33-38). This system lies ventral to the transverse processes of the vertebrae, near the carotid artery, either embedded within the carotid sheath or between the sheath and the fascia over the longus capitis and longus colli muscles. Its preganglionic or white rami come from the upper five thoracic spinal nerves, primarily from T2 and T3, and travel up to the three cervical ganglia. The superior ganglion is the largest, being about 30 mm long by 8 mm wide. It is embedded in the connective tissues between the carotid sheath and the longus capitis muscle at the level

FIGURE 33-38 Diagram showing the relationship of the cervical sympathetic ganglia, the glossopharyngeal, vagus, and spinal accessory nerves, the cervical nerves, and the ansa cervicalis.

of the second cervical vertebra. The superior cervical ganglion gives off a collection of postganglionic fibers known as the *internal carotid nerve*, which extends into the head. *The superior ganglion communicates with the inferior ganglion of IX, the jugular and nodose ganglia of X, XII, branches (sympathetic roots or gray rami) to and ventral roots of C1, C2, and usually C3, and C4, a pharyngeal branch to the pharyngeal plexus, and branches to the external carotid artery, the intercarotid plexus, and the superior cardiac nerves*. These cardiac nerves have different courses on either side of the neck. On the right side, the nerves pass either anterior or posterior to the subclavian artery and then along the brachiocephalic artery to the deep cardiac plexus. On the left side, the cardiac nerve is anterior to the common carotid artery and then extends across the left side of the aortic arch to reach the superficial cardiac plexus.

The middle cervical ganglion is the smallest cervical ganglion and may be either double or missing. It is usually near the transverse process of the sixth cervical vertebra, on the longus colli muscle at the level of the bend of the inferior thyroid artery. It may also be at the level of the seventh cervical vertebra near the vertebral artery. *Sympathetic roots from the middle ganglion go to the C5 and C6 ventral roots*. There are also *middle cardiac nerves* that run down with the common carotid artery and *communicate with the superior cardiac nerve and the recurrent laryngeal nerve of X on either side*. Lastly, there is the *thyroid nerve*, which forms a plexus on the inferior thyroid artery and supplies the thyroid gland. It also *joins the plexus on the common carotid artery and may communicate with branches of the superior laryngeal nerve of X*.

The inferior cervical ganglion is situated near the transverse process of the seventh cervical vertebra and the neck of the first rib. It may be completely separate from the first thoracic ganglion or, more commonly, it may be fused with it and is then called the *stellate ganglion*. The *middle cervical ganglion has sympathetic roots to the ventral rami of C6, C7, and C8*. There are also the inferior cardiac nerve and the vertebral nerve, the latter accompanying the vertebral artery.

The *stellate ganglion* (when present) is usually formed by

Copyright © 2003, Mosby, Inc. All rights reserved.

a fusion of the inferior cervical and first thoracic ganglia, but may include the middle cervical and second thoracic ganglia. *Gray rami go to the spinal nerves C6, C7, C8, T1, and T2, and to the vertebral artery*.[64, 66–68]

Autonomic (Parasympathetic) Ganglia of the Face and Neck

Four parasympathetic ganglia are found in the head and upper neck: the ciliary, pterygopalatine, submandibular, and otic (Fig. 33-35). These ganglia are distinctive in that in contrast to the usual body plan of having secondary sympathetic cell bodies in discrete ganglia, these are the major instances in which secondary parasympathetic neurons occur in discrete ganglia rather than at or in the walls of the structures they innervate, as is usually found throughout the body. All four ganglia have a similar plan of composition. Traditionally, each ganglion is described as having four ''roots'': a motor root (preganglionic parasympathetic—the only site of any synapse), a sensory root, a sympathetic root, and a distribution root.

The Ciliary Ganglion

The ciliary ganglion is about 1 to 2 mm in diameter and lies on the lateral side of the optic nerve (II) just in front of the ophthalmic artery about 1 cm from the posterior globe. The motor root comes from the Edinger-Westphal nucleus of the third nerve and reaches the ganglion via the inferior division of this nerve within the orbit. The sympathetic root comes from the cavernous sinus plexus, whose postganglionic fibers come from the superior sympathetic cervical ganglion. The sensory fibers come from the nasociliary nerve, a branch of V_1. Via the short ciliary nerves, all three roots reach the eye. The parasympathetic fibers are distributed to the sphincter pupillae and ciliary muscles. The sympathetic fibers are vasoconstrictive fibers that go to the intraocular blood vessels. Some sympathetic fibers also go via the long ciliary nerves to the dilator pupillae muscle. The sensory fibers go to the entire globe, including the cornea.

The Pterygopalatine Ganglion

The pterygopalatine ganglion (sphenopalatine ganglion) is in the deep portion of the pterygopalatine fossa, just below the maxillary nerve as it crosses the fossa to the pterygopalatine canal. It is triangular in shape and about 5 mm in length. It is closely attached to the pterygopalatine branches of the maxillary nerve (V_2). The motor root comes from the superior salivary nucleus. The fibers leave the brainstem in the nervus intermedius that accompanies VII until the geniculate ganglion, where the motor fibers leave VII as the greater petrosal (greater superficial petrosal) nerve. The sympathetic root comes from the internal carotid plexus via the superior sympathetic cervical ganglion as the deep petrosal nerve. The sensory root comes from two short branches of the trigeminal ganglion that join the greater petrosal nerve. The joining of the greater petrosal and deep petrosal nerves forms the nerve of the pterygoid canal (the Vidian nerve). The parasympathetic fibers go to the lacrimal gland and the mucous glands of the nose, paranasal sinuses, nasopharynx, and palate. The sympathetic fibers are vasoconstrictive to the mucosa of the same region, and the sensory fibers provide sensation to the same mucosa.

The Submandibular Ganglion

The submandibular ganglion is 2 to 5 mm in diameter and is situated above the deep portion of the submandibular gland, on the hyoglossus muscle, near the posterior border of the mylohyoid muscle. The ganglion is suspended from the lower border of the lingual nerve by two 5 mm filaments. The motor root comes from the superior salivary nucleus, and the fibers leave the brainstem in the nervus intermedius that accompanies VII until the corda tympani nerve. The fibers then travel with the corda tympani nerve to join the lingual nerve of V_3. The sympathetic root comes from the superior sympathetic cervical plexus via the plexus around the facial artery. The sensory root comes from the trigeminal ganglion through the lingual nerve. The parasympathetic, sympathetic, and sensory fibers go to the sublingual and submandibular glands and the mucous glands in the floor of the mouth.

The Otic Ganglion

The otic ganglion is a flattened, oval, stellate ganglion 2 to 4 mm in diameter. It is closely approximated to the medial surface of V_3, just below the foramen ovale. It is lateral to the cartilaginous portion of the pharyngotympanic auditory, (eustachian) tube, anterior to the middle meningeal artery, and posterior to the origin of the tensor veli palatini muscle. The motor roots come from the inferior salivary nucleus and leave the brainstem with IX. They pass via the tympanic (Jacobson's) nerve to the tympanic plexus. Here they unite with fibers from the nervus intermedius part of the facial nerve, and the united fibers leave the tympanic plexus as the lesser petrosal (lesser superficial petrosal) nerve. The sympathetic root comes from the superior cervical sympathetic ganglion via the plexus on the middle meningeal artery. The sensory root enters the ganglion from the auriculotemporal nerve (V_3) from cells originating in the trigeminal ganglion. The branches are distributed to the parotid gland via the auriculotemporal nerve. They also go to the glands of the buccal mucosa and lower lip.

A detailed discussion of the lymphatics of the neck is presented in Chapter 36. The origins, insertions, motor innervations, and actions of the muscles discussed in this chapter, as well as other neck muscles discussed elsewhere in the book, are listed in Table 33-3. The normal anatomy of the neck, with emphasis on the muscles and major vessels, is shown in the atlas at the end of this chapter.

DIFFERENTIAL DIAGNOSIS

The formulation of a list of differential diagnoses of a neck lesion is based on several factors including the location of the mass, the patient's age, and physical findings such as tenderness, firmness, and fixation. A thorough discussion of the imaging for each area occurs in the respective chapters relating to these regions. This section presents an overview of differential diagnoses based on the location of the mass. The most likely causes of a mass are mentioned, as are the

Table 33-3
MUSCLES OF THE NECK, ORAL CAVITY, AND PHARYNX

Muscle	Origin	Insertion	Innervation	Action
Platysma	Fascia and skin over the upper part of the pectoralis and deltoid muscles	Lower border of the mandible and muscles of the lip	Cervical branch of the facial nerve (VII)	Produces a slight wrinkling of the skin surface of the neck, in an oblique direction, when the entire muscle is brought into action. Anterior portion depresses the lower jaw and draws the lower lip and angles of the mouth down on either side
Sternocleidomastoid	Sternum and medial third of the clavicle	Mastoid process of the temporal bone and the superior nuchal line	Spinal accessory nerve (XI) and C2	Acting alone, it bends the head to its own side and rotates so that the face is turned to the opposite side. The two muscles, acting together, flex the neck. If the neck is kept extended by the posterior vertebral muscles, the muscles act together to raise the sternum and assist in inspiration
Anteror Belly of the Digastric Muscle	Lower border of the mandible near the symphysis	Into an intermediate tendon, where it is united with the posterior belly	Mylohyoid nerve-branch of the inferior alveolar branch of the mandibular division of the trigeminal nerve (V_3)	
Posterior Belly of the Digastric Muscle	Digastric notch of the temporal bone	Into an intermediate tendon, where it is united with the anterior belly	Facial nerve (VII)	Chief action of both bellies, acting together, is to raise the hyoid bone during swallowing. Acting with the infrahyoid muscles, they fix the hyoid bone, forming a stable platform on which the tongue can move
Stylohyoid	Styloid process of the temporal bone	Distally it splits to surround the intermediate tendon of the digastric muscle before inserting on the hyoid bone	Facial nerve (VII)	Helps pull the hyoid up and backward during swallowing
Mylohyoid	Entire length of the mylohyoid line of the mandible	Into a midline fibrous raphe, extending from the mandibular symphysis to the hyoid bone	Mylohyoid nerve-branch of the inferior alveolar nerve branch of the mandibular division of the trigeminal nerve (V_3)	Raises the hyoid bone and tongue during swallowing and forms the muscular floor of the mouth
Hyoglossus	Body and greater cornu of the hyoid bone	Posterior half of the side of the tongue	Hypoglossal nerve (XII)	Depresses the side of the tongue and enlarges the cavity of the mouth
Geniohyoid	Inferior genial tubercle on the inner surface of the mandible	Anterior surface of the body of hyoid bone	Branch C1 through the hypoglossal nerve (XII)	Elevates the hyoid bone and tongue
Genioglossus	Upper genial tubercle on the inner surface of the mandible	Lowest fibers to the hyoid bone. Middle fibers to undersurface of the tongue, upper fibers to tip of the tongue	Muscular branches of the hypoglossal nerve (XII)	Posterior fibers protrude the tongue. Anterior fibers retract tongue, aided by styloglossus muscle. Tongue depressed by genioglossus and hyoglossus
Transverse and Verticalis Tongue Muscles	Transverse from median fibrous septum. Vertical from mucous membrane on dorsum and tip of tongue	Dorsum and sides of the tongue and from dorsum to undersurface of the tongue	Trigeminal (V_3) sensory anterior two thirds of the tongue. Corda tympani (VII) taste anterior two thirds of the tongue. Glossopharyngeal (XI) sensory and taste posterior one third of the tongue. Hypoglossal (XII) extrinsic and intrinsic muscles	Modifies shape of tongue. Transverse muscle narrows and elongates tongue. Verticalis muscle flattens and broadens tongue
Superior and Inferior Longitudinal Muscles of Tongue	Superior muscle fibers in back of tongue. Inferior muscle undersurface of tongue between genioglossus and hyoglossus	Tip of tongue	Trigeminal (V_3) sensory anterior two thirds of tongue. Corda tympani (VII) taste anterior two thirds of tongue. Glossopharyngeal (IX) sensory and taste posterior one third of tongue. Hypoglossal (XII) extrinsic and intrinsic muscles	Modifies shape of tongue. Superior: shortens tongue and turns tip and sides up. Inferior: turns tip and sides down

Table continues on following page

Table 33-3
MUSCLES OF THE NECK, ORAL CAVITY, AND PHARYNX *Continued*

Muscle	Origin	Insertion	Innervation	Action
Styloglossus	Anterior border of styloid process	Sides of tongue. Fibers mix with those of palatoglossus and hyoglossus	Hypoglossal nerve (XII)	Retracts tongue with aid of genioglossus. Elevates tongue with aid of palatoglossus
Palatoglossus	Anterior surface of soft palate	Dorsum and side of tongue, blending with styloglossus and transverse linguae	Pharyngeal plexus (sympathetic, IX, X), cranial portion XI	Narrows fauces and elevates back of tongue
Palatopharyngeus	Soft palate and mucous membranes	Posterior border of thyroid cartilage and aponeurosis of pharynx	Pharyngeal plexus (sympathetic, IX, X), cranial portion XI	Narrows oropharyangeal isthmus, elevates pharynx, shuts off nasopharynx
Superior Pharyngeal Constrictor	Lower third of posterior border of medial pterygoid plate, pterygomandibular raphe, and alveolar process of mandible	Median raphe of posterior pharynx and to pharyngeal tubercle	Cranial IX, X through pharyngeal plexus	Contracts pharynx in swallowing
Middle Pharyngeal Constrictor	Both cornua of hyoid bone, stylohyoid	Posterior pharyngeal raphe	Pharyngeal plexus (IX, X, sympathetic)	Contracts pharynx in swallowing
Inferior Pharyngeal Constrictor	Oblique line of thyroid cartilage, side of cricoid cartilage, posterior border of cricothyroid muscle	Posterior pharyngeal raphe	Pharyngeal plexus (IX, X, sympathetic), external and recurrent laryngeal branches of vagus X, and cranial XI	Contracts pharynx in swallowing
Stylopharyngeus	Medial root of styloid process. Passes between internal and external carotid arteries	Superior and posterior borders of thyroid cartilage and fibers of pharyngeal constrictors	Glossopharyngeal (IX)	Raises and dilates pharynx
Salpingopharyngeus	Pharyngeal end of eustachian tube near its orifice	Blends with palatopharyngeus	Pharyngeal plexus (IX, X, sympathetic), and cranial XI	Raises nasopharynx, helps open eustachian tube during swallowing with tensor veli palatini and levator veli palatini
Levator Veli Palatini	Lower surface of petrous temporal bone and medial side of eustachian tube	Fibers extend down to palate and blend with those of opposite side	Pharyngeal plexus (IX, X, sympathetic), and cranial XI	Raises soft palate in swallowing and helps open eustachian tube during swallowing with tensor veli palatini and salpingopharyngeus
Tensor Veli Palatini	Scaphoid fossa and spine of sphenoid and lateral side of eustachian tube	Tendon winds around hamulus into aponeurosis of soft palate and posterior palatal bone	Trigeminal (V_2)	Tenses soft palate and helps open eustachian tube during swallowing with levator veli palatini and salpingopharyngeus
Musculus Uvulae	Posterior nasal spine and palatal aponeurosis	Mucous membrane of uvula	Pharyngeal plexus (IX, X, sympathetic), and cranial XI	Raises uvula
Sternohyoid	Posterior manubrium and medial third of clavicles	Lower border of hyoid	Ansa hypoglossi	Depresses larynx and hyoid bone. Steadies hyoid bone
Sternothyroid	Posterior manubrium and first costal cartilage	Oblique line of thyroid cartilage lamina	Ansa hypoglossi	Depresses larynx and thyroid cartilage
Thyrohyoid	Oblique line of thyroid lamina	Lower border of body of hyoid bone	Thyrohyoid branch of C1 through descendens hypoglossi	Depresses larynx and hyoid bone and elevates thyroid cartilage
Superior Belly of Omohyoid	Body and greater cornu of hyoid bone	United with inferior belly by tendon deep to sternocleidomastoid muscle	Descendens hypoglossi (branches of C2 and C3)	Steadies hyoid bone and depresses and retracts hyoid and larynx
Inferior Belly of Omohyoid	Upper border of scapula	United with superior belly by tendon deep to sternocleidomastoid muscle	Descending cervical nerve of cervical plexus	Steadies hyoid bone and depresses and retracts hyoid and larynx
Longus Colli	Bodies of C3 to C7 and D1 to D3 vertebrae	Bodies of C2 to C4, atlas, and anterior tubercles of C2 to C6	Branches of anterior rami of C2 to C8	Flexes and assists in rotating cervical vertebrae and head. Acting singly, it flexes vertebral column laterally
Longus Capitis	Anterior tubercles of transverse processes of C3 to C6	Inferior basilar surface of occipital bone	Muscular branches of C1 to C4	Flexes and assists in rotating cervical vertebrae and head

Anterior Rectus Capitis	Lateral mass of atlas	Base of occipital bone in front of foramen magnum	Muscular branches of C1 and C2	Flexes and rotates head
Lateral Rectus Capitis	Upper transverse process of atlas	Inferior surface of jugular process of occipital bone	Branches of anterior rami of C1 and C2	Flexes head laterally
Anterior Scalene	Anterior tubercles of transverse processes of C3 to C6	Scalene tubercle and ridge of first rib	Anterior branches of C5 to C8	Acting from above, it elevates first rib. Acting from below, it flexes and rotates vertebral column
Middle Scalene	Posterior tubercles of transverse processes of C2 to C7	Upper surface of first rib behind subclavian groove	Posterior branches of anterior rami of C3 and C4, lateral muscular branches of C3 and C4	Flexes and assists in rotating cervical vertebrae and head. It flexes cervical column laterally. Acting from above, it elevates first rib on inspiration
Posterior Scalene	Posterior tubercles of transverse processes of C4 to C6	Outer surface of second rib behind attachment of serratus anterior	Posterior branches of anterior rami of C4 and C7 and lateral muscular branches of C3 and C4	Flexes and assists in rotating cervical verebrae and head. Acting alone, it flexes cervical column laterally. Acting from above, it elevates second rib on inspiration
Splenius Capitis	Lower half of ligamentum nuchae and spinous processes of C7, and D1 to D4	Mastoid process of temporal bone and lateral portion of superior nuchal line under sternocleidomastoid muscle	Lateral branches of posterior rami of C4 to C7	Bends the head and neck back and turns the face toward its own side
Trapezius	Medial portion of superior nuchal line, external occipital protuberance, nuchal ligament from spines of C7 and all dorsal vertebrae	Lateral third of clavicle, spine of scapula, acromion	Spinal accessory (XI) and C3 and C4	Adducts scapula, draws back acromion, rotates scapula, tilts chin
Levator Scapulae	Transverse processes of C1 to C4	Vertebral border of scapula between medial angle and root of spine	C3, C4, and possibly C5	
Temporalis	Floor of temporal fossa and temporal fascia	Anterior border of coronoid process and anterior border of mandibular ramus	Trigeminal (V)	Elevates jaw, retracts mandible, clenches teeth
Masseter	Lower border and deep surface of zygomatic arch	Lateral surface of coronoid process of mandible and outer surface of ramus and angle of the mandible	Trigeminal (V)	Elevates jaw and clenches teeth
Lateral (External) Pterygoid	Upper head from infratemporal surface of greater wing of sphenoid. Lower head from lateral surface of lateral pterygoid plate	Anterior neck of mandibular condyle and capsule of temporomandibular joint	Trigeminal (V)	Protrudes mandible, pulls articular disc forward, and assists in rotary motion while chewing
Medial (Internal) Pterygoid	Medial surface of lateral pterygoid plate, pyramidal process of palatine bone, and tuberosity of maxilla	Lower posterior medial surface of ramus and angle of mandible	Trigeminal (V)	Protracts and elevates mandible and assists in rotary motion while chewing
Buccinator	Alveolar process of mandible opposite molar teeth and anterior border of the pterygomandibular raphe	Fibers converge toward angle of mouth, where they blend with fibers of orbicularis oris muscle	Facial (VII)	Compresses cheeks, expels air from mouth, and aids in chewing

likely sites of primary tumors that commonly have nodal metastases to these regions. Abscesses may occur virtually anywhere in the neck, and their clinical presentation strongly suggests their diagnosis. Thus, although they can occur in every area, abscesses are not included in the various differential diagnoses.

In the submental triangle (level IA), a mass could be a dermoid, an epidermoid, a thyroglossal duct cyst, or lymphadenopathy. If it is lymphadenopathy, the probable source could be in the central lower lip, chin, anterior floor of the mouth, or tip of the tongue. The adenopathy may also be reactive or secondary to a lymphoma or another systemic disease such as sarcoidosis, mononucleosis, etc. (Table 33-4).

In the submandibular triangle (level IB), a mass could be due to enlargement of the submandibular gland (due to diffuse disease or a focal mass), a ranula, a solitary lymphangioma, or lymphadenopathy. If it is lymphadenopathy, the likely source could be in the submandibular or sublingual glands, the sides of the anterior two thirds of the tongue, the floor of the mouth or lower gums, the paranasal sinuses, the buccal cheek and lips, the anterior cheek, the sides of the nose, the upper lip and lateral lower lip, or the eyelids and conjunctiva. The adenopathy may also be reactive or secondary to a lymphoma or another systemic disease such as sarcoidosis, mononucleosis, etc. (Table 33-5).

In the carotid triangle, a mass could be a carotid body tumor, ectasia or an aneurysm of the carotid artery, phelbectasia of the internal jugular vein, a schwannoma or neurofibroma, a second or third branchial cleft cyst, a lateral thyroglossal duct cyst, a laryngocele, a lymphangioma, or lymphadenopathy. If it is lymphadenopathy, the likely source could be in the supraglottic larynx, the floor of the mouth, the sides or base of the tongue, the pharynx or palatine tonsil, the gums or palate, the posterior nasal cavity, the deep infratemporal or temporal fossa, the lower pinna of the ear, the occipital scalp, the parotid gland, the thyroid or parathyroid glands, or the upper cervical esophagus. Reactive nodes or lymphoma, metastasis from a distant site, or a systemic disease may also cause such lymphadenopathy (Table 33-6).

In the muscular triangle, a mass could represent diffuse enlargement of the thyroid gland or a localized thyroid mass, a parathyroid mass, a subglottic or cartilaginous laryngeal mass, a laryngocele, a third or fourth branchial cyst, a thyroglossal duct cyst, a cervical thymic cyst, an esophageal mass such as a Zenker's diverticulum, or lymphadenopathy. If it is lymphadenopathy, the likely source could be reactive nodes or a primary tumor in the thyroid or parathyroid

DIFFERENTIAL DIAGNOSES BASED ON THE SUBMENTAL TRIANGLE OF THE NECK

- Submental triangle (level I)
  - Dermoid
  - Epidermoid
  - Thyroglossal duct cyst
  - Lymphadenopathy: likely source in:
    - Central lower lip
    - Chin
    - Anterior floor of mouth
    - Tip of the tongue
    - Reactive (hyperplastic)
    - Lymphoma
    - Systemic disease (sarcoidosis, etc.)

Table 33-5
DIFFERENTIAL DIAGNOSES BASED ON THE SUBMANDIBULAR TRIANGLE OF THE NECK

- Submandibular triangle (level II)
  - Submandibular gland
    - Diffuse disease (inflammatory)
    - Focal mass
    - Ranula
    - Solitary lymphangioma
    - Lymphadenopathy: likely source in:
      - Submandibular gland
      - Sublingual gland
      - Sides of the anterior two thirds of the tongue
      - Floor of the mouth or lower gums
      - Paranasal sinuses
      - Buccal cheek and lips
      - Anterior cheek
      - Sides of the nose
      - Upper lip and lateral lower lip
      - Eyelids and conjunctiva
      - Reactive (hyperplastic)
      - Lymphoma
      - Systemic disease (sarcoidosis, etc.)

Table 33-6
DIFFERENTIAL DIAGNOSES BASED ON THE CAROTID TRIANGLE OF THE NECK

- Carotid triangle
  - Carotid body tumor
  - Carotid ectasia
  - Carotid aneurysm
  - Phlebectasia of the internal jugular vein
  - Schwannoma
  - Neurofibroma
  - Second branchial cleft cyst
  - Third branchial cleft cyst
  - Lateral thyroglossal duct cyst
  - Laryngocele
  - Lymphangioma
  - Lymphadenopathy: likely source in:
    - Supraglottic larynx
    - Floor of mouth
    - Sides off tongue
    - Base of tongue
    - Pharynx
    - Palatine tonsil
    - Gums
    - Palate
    - Posterior nasal cavity
    - Deep infratemporal fossa
    - Deep temporal fossa
    - Lower pinna of the ear
    - Occipital scalp
    - Parotid gland
    - Thyroid gland
    - Parathyroid glands
    - Upper cervical esophagus
    - Reactive (hyperplastic)
    - Lymphoma
    - Metastasis (lung, breast, colon, kidney)
    - Systemic disease (sarcoidosis)

DIFFERENTIAL DIAGNOSES BASED ON THE MUSCULAR TRIANGLE OF THE NECK

Muscular triangle
Thyroid gland
Diffuse enlargement (goiter, etc.)
Localized thyroid mass
Parathyroid mass
Larynx
Subglottic mass
Cartilaginous laryngeal mass
Laryngocele
Third branchial cleft cyst
Fourth branchial cleft cyst
Thyroglossal duct cyst
Cervical thymic cyst
Esophageal mass
Zenker's diverticulum
Lymphadenopathy: likely source in:
Reactive (hyperplastic) diseases
Thyroid tumor
Parathyroid tumor
Cervical esophagus
Postcricoid pharynx
Pharynx
Palatine tonsil
Lymphoma

glands, the cervical esophagus, the postcricoid pharynx, the pharynx, or the palatine tonsil. Lymphoma can also cause lymphadenopathy in this region (Table 33-7).

In the posterior triangle, the most likely cause of a mass could be a lymphangioma or hemangioma, a lipoma or rarely a liposarcoma, a neural tumor of either the spinal accessory nerve or part of the brachial plexus, an aneurysm of the subclavian artery, or lymphadenopathy. If it is lymphadenopathy, the most likely source would be lymphoma or a mass in the pharynx, the palatine tonsil, the base of the tongue, the parotid gland, or a metastasis from a distant primary below the clavicles. The adenopathy may also be reactive in etiology (Table 33-8).

Table 33-8

SUMMARY AND CONCLUSION

INTRODUCTION

The importance of the fasciae of the neck is their ability to define spaces that may limit to some degree the spread of most infections and some tumors. However, these fasciae vary in thickness and composition, and they have been described in numerous forms by a variety of authors. In fact, the literature is filled with such varying descriptions of the anatomy of the cervical fasciae and spaces that there is confusion due to unclear statements and contradictory reports. As a sign of this frustration, Malgaigne in 1838 was prompted to note that ''the cervical fasciae appear in a new form under the pen of each author who attempts to describe them.''[1–3]

Part of the problem is that there is no consistent definition of what constitutes fascia. Fascia has been variously described in the literature as a collection of fat and fibrous tissue that seems to equate with a ''fat layer''; a thin but firm, well-defined layer of fibrous tissue such as an aponeurosis; and a localized thickening or condensation of fibroadipose tissue within a larger, more diffuse area of such tissue. This problem prompted Hollinshead to write: ''If the reader will recall that there is no generally accepted definition as to how dense connective tissue must be before it can be regarded as forming a fascia, and that fascial spaces are simply areas of relatively loose connective tissues, the reasons for many of the discrepancies in various descriptions will be obvious.''[4]

Another part of the problem relates to the varied descriptions of the anatomic boundaries of the fasciae. However, when one considers that the fasciae may split to surround muscles, vessels, and nerves and then merge with other fascial layers, it becomes apparent that any description is somewhat arbitrary.[2, 4] In addition, many of the smaller muscles have their own surrounding fascia, or epimysium, which is not necessarily considered to arise from any of the classic fascial layers.

The interest in the fasciae and spaces of the neck stems from early anatomic investigations performed by surgeons who were seeking ways to predict the spread of infection.[5] They believed correctly that knowledge of such routes of spread would allow them to approach and drain abscesses more effectively. However, interest in this subject waned with the introduction of the antibiotic era and the advent of medical control of many of these infections. Hollinshead wrote in 1954, ''It should be noted that with the widespread use of antibiotics, the anatomy of these spaces is necessarily becoming less important.''[4] But with the emergence of the

Copyright © 2003, Mosby, Inc. All rights reserved.

HIV pandemic within the past decades, the incidence of infections not well controlled by medical therapy has risen and the need to understand the fascial and spatial anatomy of the neck has again gained importance. Lastly, with the utilization of CT and MR imaging, it has been noted that the growth of some tumors appears to be restricted by certain fasciae, and knowledge of the anatomy of these fasciae allows one to predict such growth patterns.

This chapter reviews the major anatomic descriptions of the fasciae and spaces of the neck, mentions the various synonyms used for the fascia and spaces, points out areas of confusion and divergent description, and presents what the authors believe is the present understanding of this topic.[1–15] Once the often complex anatomy of these fasciae is mastered, one can achieve a better understanding of the spread of both infections and some tumors in the neck.

THE FASCIAE

Traditionally, the fasciae of the neck are classified into two major divisions: superficial and deep. The superficial cervical fascia (SCF) is a fairly thick, well-defined, primarily fatty layer of relatively loose connective tissue that lies deep to the skin and superficial to the deep cervical fascia. The SCF covers the head, face, and neck and in its deeper portions contains the thin platysma muscles, the muscles of facial expression, and portions of the anterior and external jugular veins.

The deep cervical fascia (DCF) is more complex than the SCF and is made up of thinner but denser, better-defined discrete layers that are more deserving of the classic term *fascial sheet*. The DCF exists in the neck below the skull base and encloses the muscles of the neck, as well as the mandible and the muscles of mastication and deglutition.

The DCF is classically subdivided into three layers: (1) the superficial or investing layer of the deep cervical fascia (SLDCF), (2) the middle layer, which includes the pretracheal and visceral layers (MLDCF), and (3) the deep layer (DLDCF).[2, 4] This terminology itself may lead to some confusion, as there is both an SCF and an SLDCF. Although these two layers border one another, they are distinctly separate entities.

In the literature, there is reasonable agreement, except for some minor variations, regarding the descriptions of the SCF, the SLDCF, and the DLDCF. Thus, most of the variations in the fascial descriptions concern the MLDCF, which is found between the more uniformly described SLDCF and DLDCF layers.

The Superficial Fascia

Deep to the skin and superficial to the SLDCF, the subcutaneous tissues of the head and neck are referred to as the SCF. This superficial fascia is not a fascial sheet in the classic sense, but rather a fatty, loose connective tissue in which are embedded the voluntary muscles of facial expression and the platysma muscles. The subcutaneous nerves, venules, and lymphatics are also within the SCF, and in some descriptions portions of the anterior and external jugular veins are included in the SCF (Drawings 1–5) (Fig. 34-1).[2, 4]

In the neck, the fat of the SCF is fairly loose. However, in the facial area the fat is much denser, except in the region of the eyelids, where it is fairly loose on both the superficial and deep aspects of the orbicularis oculi. In the scalp, the subcutaneous fat is dense and contains the epicranius (frontalis) muscle in its deep portion. Beneath the epicranial aponeurosis, between it and the periosteum of the calvarium, there is loose areolar tissue that permits motion of this muscle and, like the tissue about the eyelids, can hold large accumulations of fluid.[2, 4]

The skin, the SCF, and the platysma muscle function as a complex morphologic unit, interconnected by a system of fine connective tissue fibers and less well defined muscular elements called the superficial musculo-aponeurotic system (SMAS). Although the muscles of facial expression are often considered to be a separate functional unit, the SMAS interlinks these facial muscles with the dermis and amplifies the effect on the skin caused by the contractions of the facial muscles. The SMAS extends from the temporalis and frontalis muscles superiorly to the platysma muscle inferiorly. Thus, the SMAS has come to be considered an important functional unit in plastic surgery of the face and upper neck. Many surgeons consider the SMAS to be the most important component of a rhytidectomy and the factor that most contributes to a longer-lasting result.[13]

The Deep Cervical Fascia

Deep to the SCF, the DCF surrounds and encloses the musculature of the neck. The DCF is traditionally subdivided into three layers: the SLDCF, the MLDCF, and the DLDCF.

As mentioned, the various descriptions in the literature of the SLDCF and the DLDCF are fairly uniform. However, the layers between the SLDCF and the DLDCF are more arbitrarily described—at times being assigned to the MLDCF, at other times referred to as derivations of the SLDCF or the DLDCF, and at still other times considered to be separate fasciae that are not ascribed to any of these layers. This discussion of the DCF will start by describing the less controversial SLDCF and DLDCF. Then the ''middle regions'' and layers will be discussed, exploring the labyrinth of fascial webs and partitions found in the perplexing zone that separates the SLDCF and DLDCF.

The Superficial Layer of the Deep Cervical Fascia

The SLDCF is a well-defined sheet of fibrous tissue that completely encircles the neck, incorporating the sternocleidomastoid and trapezius muscles and attaching posteriorly to the vertebral spines and ligamentum nuchae. This layer extends cranially into the face and caudally into the pectoral and axillary regions. The SLDCF may be thought of as arising from the cervical vertebral spines and the ligamentum nuchae. It extends to the left and right sides of the neck, splits to enclose each trapezius muscle, and then

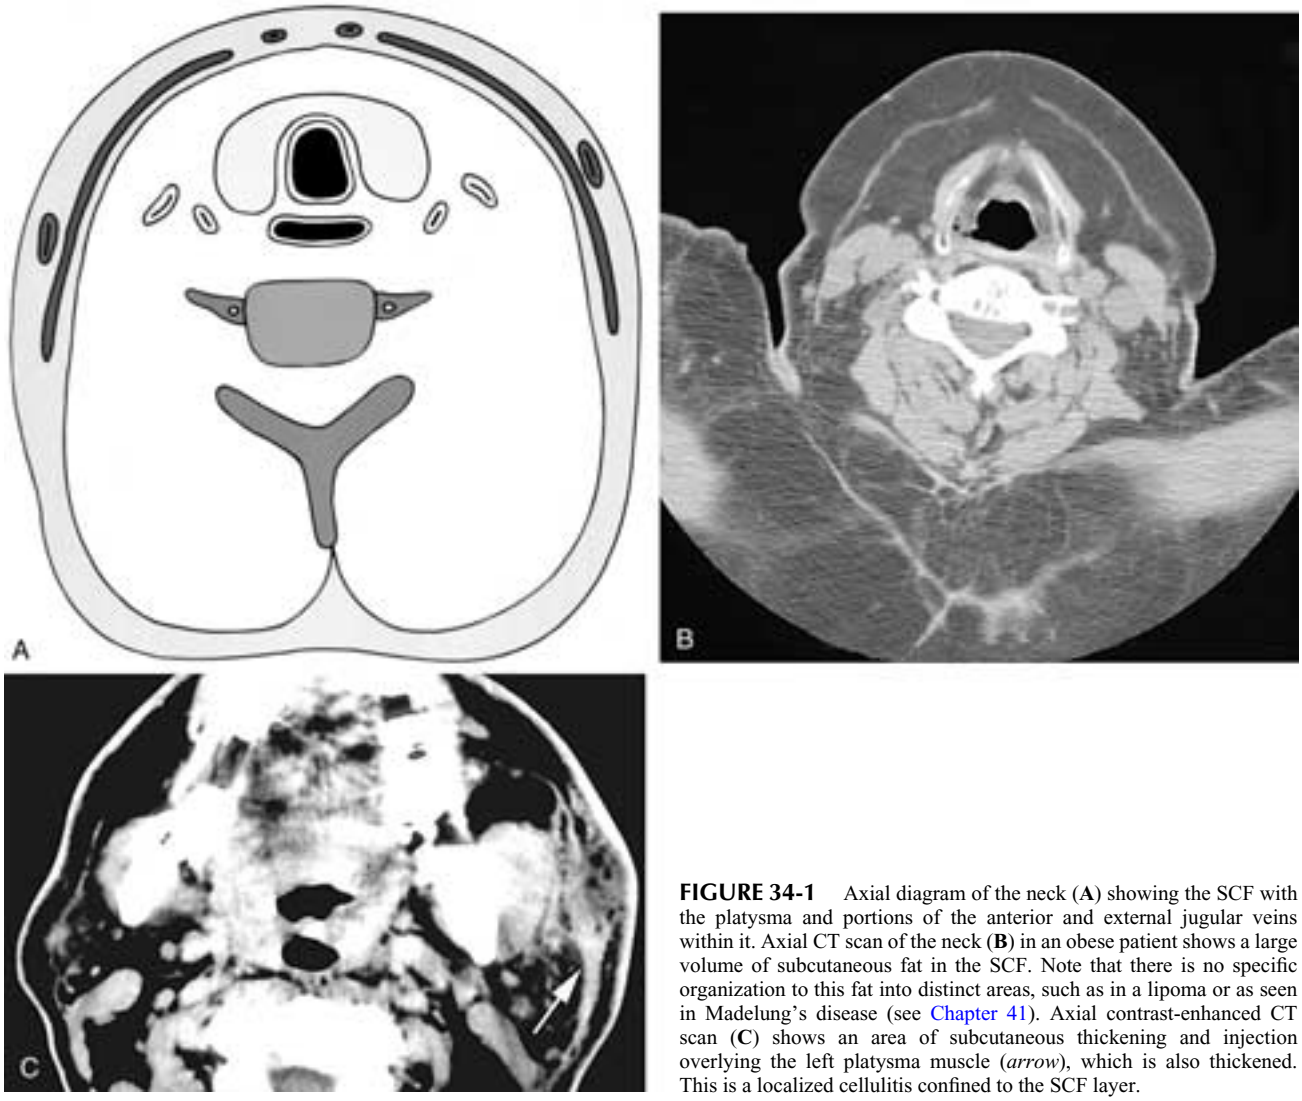

FIGURE 34-1 Axial diagram of the neck (**A**) showing the SCF with the platysma and portions of the anterior and external jugular veins within it. Axial CT scan of the neck (**B**) in an obese patient shows a large volume of subcutaneous fat in the SCF. Note that there is no specific organization to this fat into distinct areas, such as in a lipoma or as seen in Madelung's disease (see Chapter 41). Axial contrast-enhanced CT scan (**C**) shows an area of subcutaneous thickening and injection overlying the left platysma muscle (*arrow*), which is also thickened. This is a localized cellulitis confined to the SCF layer.

VIEW IMAGE

crosses the posterior triangle of the neck. The SLDCF then splits again to enclose each sternocleidomastoid muscle and finally crosses the anterior midline of the neck in front of the strap muscles as a single fascia connecting the anterior borders of the sternocleidomastoid muscles (Drawings 2–9) (Fig. 34-2).

Caudally in the midline, the SLDCF splits into two layers, one attaching to the anterior aspect and one to the posterior aspect of the manubrium. This creates the variably sized suprasternal space of Burns (or Gruber), which primarily contains fat and a communicating vein between the left and right anterior jugular veins (Drawings 8, 9). This space either can extend nearly halfway up the neck or can be localized to just above the manubrium. The clinical importance of this space lies in the fact that if it is entered during a tracheostomy, inadvertent transection of the communicating vein may result in considerable blood loss.[2, 14] Although of minor importance, even the small suprasternal space of Burns is somewhat controversial, as some authors describe the posterior layer of this space as being formed from the MLDCF.[2] Lateral to the sternum, the SLDCF attaches to the superior margin of each clavicle along the entire extent of this bone. Even more laterally, the fascia attaches to the acromion and spine of each scapula. Most portions of the anterior and external jugular veins are considered to be embedded in the superficial surface of the SLDCF, rather than lying between it and the deeper fascial layers. As mentioned, small portions of these veins also extend into the SCF.

The literature also contains ambiguity regarding the origin of the fascia around the strap muscles (sternothyroid, sternohyoid, and thyrohyoid muscles). Although some authors believe this fascia to be part of the SLDCF, most authors refer to it as being part of the MLDCF.[2, 4] However, the MLDCF has in turn been described as either encircling the strap muscles or as comprising only the most posterior layer of fascia, deep to the strap muscles.[4] There is also some controversy over the origin of the fascial sling between the superior and inferior bellies of the omohyoid muscle. This sling is attached below to the clavicle and first rib and maintains the angulated course of this muscle. Some authors believe the sling is formed by the SLDCF, while most other authors believe it is formed by the sternohyoid-omohyoid layer of the MLDCF.[2, 4] What is clearly apparent is that

Copyright © 2003, Mosby, Inc. All rights reserved.

these are only differences in nomenclature, and there is no controversy over the presence and location of these fascial planes and slings.

Above the hyoid bone, the SLDCF extends to the lower border of the mandible, and as this fascia passes over the muscles below the floor of the mouth, it fuses with the fascial covering of each digastric muscle. Grodinsky and Holyoke consider the fasciae about the anterior belly of each digastric muscle, the mylohyoid, the geniohyoid, the hyoglossus, and the genioglossus muscles to be separate fasciae related to each of these muscles and not actually part of the SLDCF.[2] However, more posteriorly these same authors considered the fascial sheaths of the posterior belly of the digastric muscles and the stylohyoid muscles to be direct derivatives of the SLDCF.

On either side of the neck in the submandibular triangle, a portion of the SLDCF splits to form a thin, often flimsy capsule about each submaxillary gland (Drawing 10). Then, as the SLDCF reaches the mandible, the fascia divides into superficial and deep leaflets. These leaflets extend superiorly, enclosing the muscles of mastication and forming the masticator spaces.[7, 12, 15, 16]

The superficial leaflet, or fascial sheet, overlies the masseter muscle and attaches to the zygomatic arch. The fascia here splits once again to enclose the zygomatic arch and creates a small space on the cranial surface of the arch that is filled with fat. The superficial fascial leaflet then continues cranially to overlie the temporalis muscle, attaching along the temporal ridge cranially and dorsally and along the lateral orbital margin ventrally (Drawings 10–13).

Anteriorly, the fascia covering the masseter muscle curves medially to attach to the mandible and to the fascia of

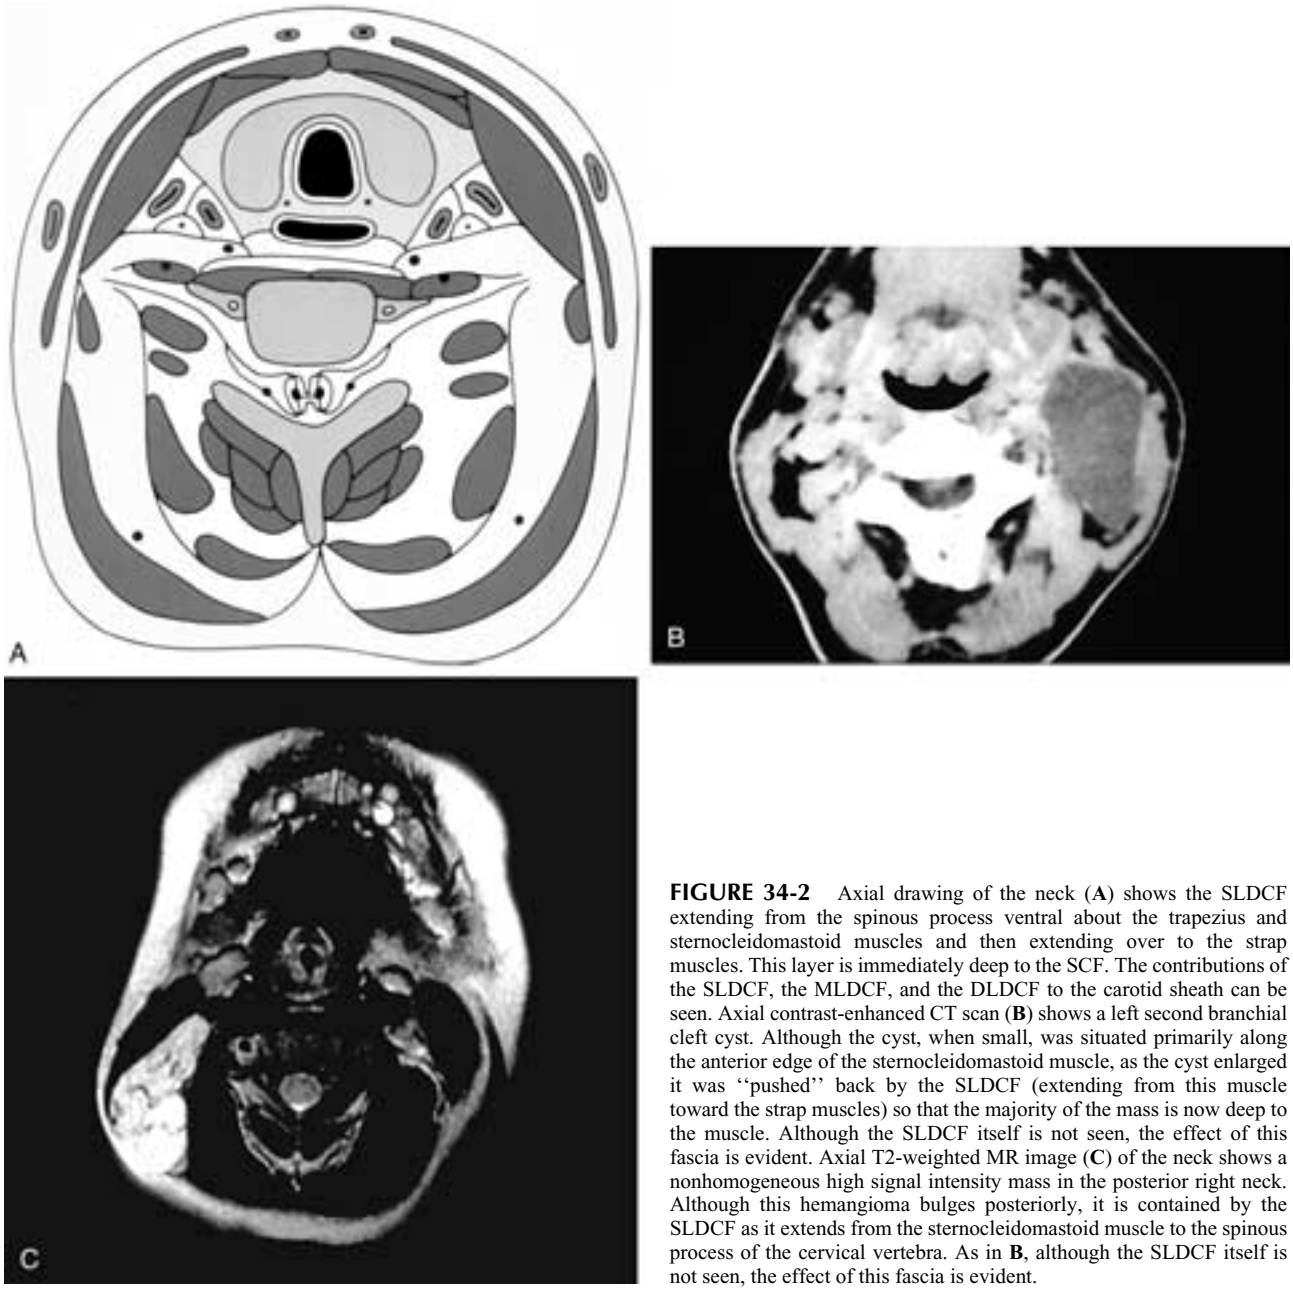

FIGURE 34-2 Axial drawing of the neck (**A**) shows the SLDCF extending from the spinous process ventral about the trapezius and sternocleidomastoid muscles and then extending over to the strap muscles. This layer is immediately deep to the SCF. The contributions of the SLDCF, the MLDCF, and the DLDCF to the carotid sheath can be seen. Axial contrast-enhanced CT scan (**B**) shows a left second branchial cleft cyst. Although the cyst, when small, was situated primarily along the anterior edge of the sternocleidomastoid muscle, as the cyst enlarged it was ''pushed'' back by the SLDCF (extending from this muscle toward the strap muscles) so that the majority of the mass is now deep to the muscle. Although the SLDCF itself is not seen, the effect of this fascia is evident. Axial T2-weighted MR image (**C**) of the neck shows a nonhomogeneous high signal intensity mass in the posterior right neck. Although this hemangioma bulges posteriorly, it is contained by the SLDCF as it extends from the sternocleidomastoid muscle to the spinous process of the cervical vertebra. As in **B**, although the SLDCF itself is not seen, the effect of this fascia is evident.

FIGURE 34-3 Coronal T1-weighted MR image (**A**) of a patient with a rhabdomyosarcoma in the left masticator space. Although this is an aggressive tumor, the deep (*white arrow*) and superficial (*black arrow*) leaflets of the SLDCF contain the tumor. In this instance, the integrity of the fascia belies the aggressive nature of the tumor. Axial T1-weighted MR image (**B**) shows an infiltrating mass in the right masticator space (*arrowhead*). Both the superficial and deep layers of the masticator space fascia have been violated, attesting to the invasive nature of this breast carcinoma metastasis.

the temporalis tendon and muscle as it attaches to the coronoid process of the mandible.[17] Fascia also extends from the temporalis muscle to the buccinator fascia near the pterygomandibular raphe. However, in some reports, a separate fascial leaflet is described as passing from the anterior margin of the masseter muscle directly to the buccinator fascia.[17, 18] In one or another of these ways, the fascia covering the masseter muscle attaches to the buccinator fascia and to the maxilla, and in so doing it encloses a small fat pad referred to as the masticator fat pad. This fat pad is intimately associated with the masticator space, often being included as part of the space, and the fat has small projections into the pterygopalatine fossa as well as along the lateral pterygoid muscle. Thus, these various fasciae, either with or without the masticator fat pad, attach to the maxilla and to the buccinator fascia and, in so doing, close the masticator space anteriorly (Drawings 2 and 12) (Fig. 34-3).

Just as the superficial leaflet of the SLDCF forms the outer boundary of the masticator space, the deep leaflet of the SLDCF extends cranially to form the medial or inner boundary of this space. The fascial covering of the medial pterygoid muscle is fairly thin, but does attach to the lower border of the mandible and thus can be considered a derivation of the SLDCF. A stronger fascia, the interpterygoid fascia (also probably derived from the SLSCF), attaches to the inner surface of the mandible, medial to the insertion of the medial pterygoid muscle. From here the interpterygoid fascia sweeps cranially to the superior edge of the medial pterygoid muscle, where the fascia covering the medial surface of the muscle fuses with the interpterygoid fascia. The resultant combined fascia continues up to the skull base and attaches along a line that extends from the root of the medial pterygoid plate to the sphenoid spine, just medial to the foramen ovale. The fascia then curves posterolaterally to reach the posterior glenoid fossa. The sphenomandibular ligament, which extends from the sphenoid spine to the ramus of the mandible, is a localized thickening of the interpterygoid fascia.

The superficial and deep leaflets of the SLDCF also fuse along the dorsal border of the mandibular ramus. The space thus enclosed by these leaflets contains the muscles of mastication (the temporalis, masseter, and pterygoid muscles). It was first described by Juvara in 1870 and was first called the masticator space by Coller and Yglesias in 1935 (Drawings 2 and 10–13) (Fig. 34-3).[2, 4, 7, 12]

On either side of the neck, between the angle of the dorsal edge of the mandibular ramus and the ventral border of the sternocleidomastoid muscle, the SLDCF splits again to form the capsule of the parotid gland. The deep layer, in particular, is quite thin and flimsy and in the opinion of many investigators is actually deficient. The external carotid artery, with adherent prolongations from the carotid sheath, and the posterior facial vein (retromandibular vein) each perforate the parotid gland capsule and pass through the substance of this gland (Drawings 2 and 12).[2] The SLDCF then attaches to the mastoid process of the skull and extends dorsally to attach to the external occipital protuberance.

The Deep Layer of the Deep Cervical Fascia

The DLDCF, like the superficial layer, can be considered to originate from the cervical vertebral spinous processes and the ligamentum nuchae. The fascia then extends to either side, covering and investing the muscles that form the floor of the posterior triangle of the neck. These muscles are, from dorsally to ventrally, the splenius capitis, the levator scapulae, and the posterior, middle, and anterior scalene muscles. The portion of the fascia that relates to the scalene muscles is often called the scalene fascia. On either side of the neck as the DLDCF extends between the middle and anterior scalene muscles, the fascia is reflected outward, forming a sleeve around

Copyright © 2003, Mosby, Inc. All rights reserved.

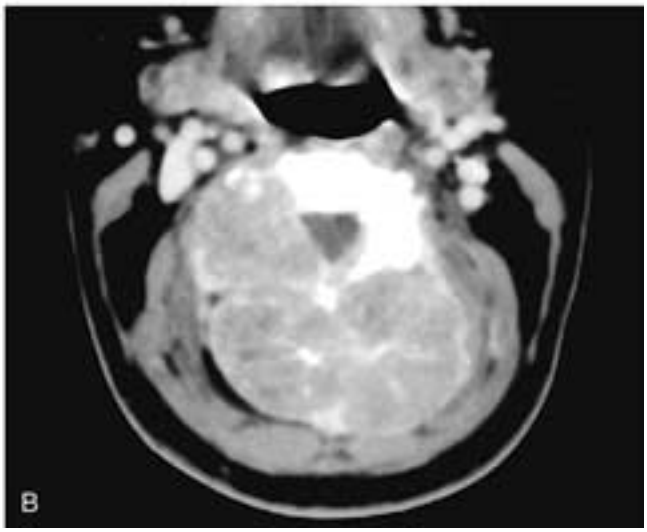
the brachial plexus and subclavian artery, which are all situated between these muscles. More laterally, this sleeve becomes the axillary sheath (Drawings 2–5, 7–9, and 14–16) (Fig. 34-4).

More specifically, the posterior scalene muscle arises from the posterior tubercles of the transverse processes of C4–C6 and the middle scalene muscle arises from the posterior tubercles of the transverse processes of the C2–C7 cervical vertebrae. By comparison, the anterior scalene muscle arises from the anterior tubercles of the transverse processes of C3–C6, and the respective anterior cervical nerve roots exit through the sulci or canals between the anterior and posterior tubercles. More caudally in the neck, the subclavian artery also passes between the anterior and middle scalene muscles. Thus, as the DLDCF extends ventrally over the middle and posterior scalene muscles, this fascia attaches to the origins of these muscles on the posterior tubercles of the transverse processes of the cervical vertebrae. The DLDCF then is reflected outward over the anterior cervical nerve roots and the subclavian artery (Fig. 34-5). Ventrally, the DLDCF then attaches again to the anterior tubercles about the origins of the anterior scalene muscle. The fascia then extends around the anterior scalene muscles, where it splits into two layers, both of which cross the anterior surface of the cervical vertebral bodies essentially extending between the anterior tubercles of the transverse processes on either side.

The dorsal layer, or the prevertebral fascia, lies closest to the vertebral bodies and covers the anterior surface of the longus capitis and colli muscles. This fascia extends from the skull base to the coccyx, and the proximal portion of each phrenic nerve lies deep to the prevertebral fascia on the anterior face of each anterior scalene muscle. The ventral layer, or alar fascia, lies anterior to the prevertebral fascia from which it is separated by loose connective tissue.[2] The alar fascia extends from the skull base caudally to a level between the sixth cervical and the fourth thoracic vertebrae, usually at the level of the seventh cervical vertebra, at which point it merges with the more anterior visceral fascia (see the discussion of the MLDCF) (Drawings 2–5, 8, 9, and 15) (Fig. 34-6).[4]

Charpy originally described a small, sagittally oriented fascial sheet that, on either side of the neck, extended from the fusion line of the DLDCF on the anterior tubercles of the cervical vertebrae ventrally toward the fascia over the posterolateral pharyngeal wall. He called this fascia the cloison sagittale, or sagittal partition, and it in effect separated the midline retropharyngeal and danger spaces from the more lateral parapharyngeal spaces.[1, 10]

However, 7 years later, Dean referred to this sagittal partition as the alar fascia and thus created confusion in terminology.[19] It was not until 19 years later that Grodinsky and Holyoke described the alar fascia as a coronally oriented fascial sheet that was parallel to and ventral to the prevertebral fascia.[2] Today, this coronally oriented fascia is generally accepted as the alar fascia, while the fascia



VIEW IMAGE

FIGURE 34-4 Axial drawing of the neck (**A**) shows the DLDCF extending from the spinous process over the muscles of the floor of the posterior triangle of the neck. After splitting to form the sheath about the brachial plexus and subclavian artery, the fascia attaches to the cervical vertebra. Ventrally, one layer of the DLDCF extends across the face of the flexor muscles of the cervical spine (prevertebral fascia). A second layer of fascia (alar fascia) also crosses the vertebral body and extends just ventral to the prevertebral fascia. These two layers form the boundaries of the danger space. Slips of fascia extend from the alar fascia (DLDCF) to contribute to the carotid sheath. Axial contrast-enhanced CT scan (**B**) of the neck shows a destructive lesion involving the right side of the cervical vertebra and all the muscles of the floor of the posterior triangles of the neck. Despite the aggressive nature of this metastatic breast cancer, the DLDCF contains the tumor.

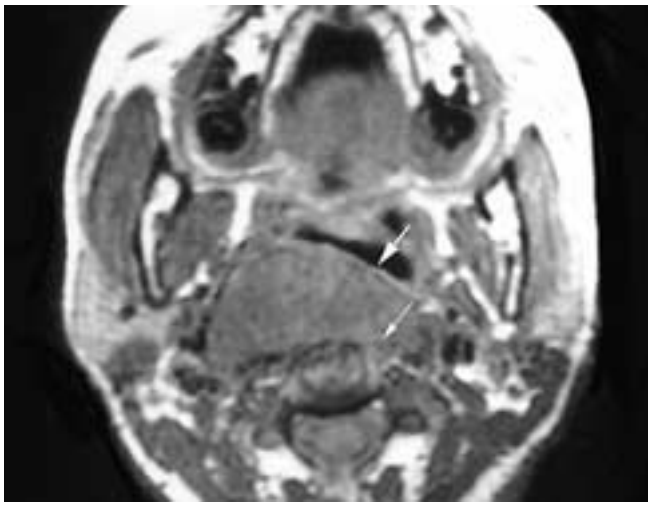
VIEW IMAGE

FIGURE 34-5 Axial T1-weighted, contrast-enhanced MR image (**A**) shows a schwannoma of the left brachial plexus. The thickened proximal nerve is seen extending toward the spinal cord, directly dorsal to the anterior scalene muscle (*arrow*). The DLDCF extends from the adjacent muscles of the floor of the posterior triangle of the neck out over the brachial plexus as a sheath, which more caudally also contains the subclavian artery. Axial T1-weighted MR image (**B**) shows a schwannoma of the right brachial plexus (*large arrow*) situated just dorsal to the anterior scalene muscle (*small thinner arrow*). This case illustrates how the anterior scalene muscle is a good marker for identifying the location of the brachial plexus in this region of the neck.

described by Dean is probably best referred to as the cloison sagittale, as described by Charpy.

Sibson's Fascia

On either side of the neck, the DLDCF extends laterally from the transverse process of the seventh cervical vertebra, covers the dome of the pleura, and then attaches to the medial surface of the first rib. This fascia, called Sibson's fascia, serves as a plane of separation between the lower neck and the thorax .[2, 4, 14]



VIEW IMAGE

FIGURE 34-6 Axial T1-weighted MR image shows a mass involving the flexor muscles of the cervical spine (*small thinner arrow*) and pushing the pharyngeal constrictors forward (*large arrow*). This schwannoma was in the prevertebral space, pushing the danger and retropharyngeal spaces forward. Because the actual fascia (prevertebral, alar, and visceral) cannot be routinely seen on imaging, the involvement of the prevertebral muscles indicates the space of origin of the mass.

The Middle Layer of the Deep Cervical Fascia in the Infrahyoid Neck

As mentioned, the MLDCF is the most arbitrarily described of the fascial layers. Although originally described only as the fascia in the neck that takes its origin from the fascial covering of the omohyoid muscle, the term *middle layer of the deep cervical fascia* was subsequently used to describe the fascia associated with the strap muscles and the ''visceral'' fascia surrounding the esophageal and pharyngeal walls.

Hollinshead stated that the MLDCF most commonly is the fascia between the sternocleidomastoid muscles that passes behind the strap muscles, thus lying in front of the thyroid gland and trachea.[4] This description and relationship gave rise to the term *pretracheal fascia*. However, Grodinsky and Holyoke considered the MLDCF to be more complex and composed of three layers.[2] The first layer was called the sternohyoid-omohyoid layer, and it formed the sling of the omohyoid muscle and the fascia of the sternohyoid and omohyoid muscles. The second layer was called the sternothyroid-thyrohyoid layer, and it formed the fascia about these muscles. This layer was the one most analogous to the pretracheal fascia. The third layer was the deepest or most central of the three layers and was called the visceral or buccopharyngeal fascia (BPF). This last layer was closely adherent to the muscular walls of the esophagus and pharynx (Drawings 3–5, 7, 8, 15, and 16).

Whether one considers all of the fascia about the strap muscles to be formed by the MLDCF or the SLDCF, or instead believes that the MLDCF forms only the fascial layer deep to the strap muscles, is purely an academic issue. Regardless of the fascial derivation, the fascia about these muscles extends caudally behind the sternum to the origin of these muscles and then fuses with the fibrous pericardium as it is prolonged out along the great vessels and their adventitia in the superior mediastinum. This inferior fusion occurs at about the level of the fourth thoracic vertebra.

Copyright © 2003, Mosby, Inc. All rights reserved.

Cranially, this fascia fuses with the thyroid cartilage and the hyoid bone. Laterally, the fascia fuses with and contributes to the carotid sheath on either side of the neck.

The term *visceral fascia* refers to the layer of the MLDCF that is adherent to the outer surface of the esophagus and pharynx. This fascia is best defined at the level of the upper pharynx, and in this location it is often referred to as the buccopharyngeal fascia, which not only adheres to the outer surface of the pharyngeal constrictors but extends ventrally via the pterygomandibular raphe over the buccinator muscles.

Confusion was introduced when Grodinsky and Holyoke also stated that below the level of the thyroid cartilage, the ''visceral fascia'' surrounded not only the esophagus, but also the trachea and thyroid gland. They described a space (their space 3) that contained a small amount of loose adipose tissue and existed between the outer surface of this visceral fascia and the fasciae covering the inner surface of the strap muscles ventrally (SLDCF and/or MLDCF), the carotid sheaths laterally (all layers of the DCF contribute to this sheath), and the alar fascia (DLDCF) dorsally (Drawings 3–5, 7 and 8). However, Grodinsky and Holyoke referred to the structures within their visceral fascia (including the esophagus, trachea, and thyroid gland) as being in a visceral space (see discussion in the section on The Fascial Spaces).

Other authors, including Hollinshead, found it difficult to consider the loose, often incomplete connective tissue about the esophagus, trachea, and thyroid gland as a layer of fascia.[4] They considered the fascia immediately about the cervical esophagus and pharynx either to be the only true visceral fascia or to be analogous to the subperitoneal connective tissue of the serous coat of the thoracic esophagus and the bowel.[4] The trachea was considered to have its own fascia, and the thyroid gland capsule was considered to develop from the thyroid anlagen. These authors, in general, considered the visceral fascia of the esophagus and pharynx to be the deep division of the MLDCF and the fascia about the trachea, thyroid gland, and surrounding loose connective tissue not to be part of the MLDCF. Today, this is the view that is most commonly held.

Again, these are problems of nomenclature. There is no dispute that in the lower neck there is a thyroid gland capsule, a filmy loose connective tissue around the thyroid gland, trachea and cervical esophagus that is incomplete or absent in many people but that has a fairly consistent thickening on each side between the posterior margin of the thyroid gland and the esophagus. There also is a better-defined fascia about the cervical esophagus (which extends cranially to surround the pharynx) and a surrounding, less well defined connective tissue zone.

The Middle Layer of the Deep Cervical Fascia in the Suprahyoid Neck

Although the controversies concerning the fasciae in the infrahyoid neck are of limited clinical concern, the fasciae of the suprahyoid neck figure prominently in discussions of the clinically important retropharyngeal and parapharyngeal spaces. Critical to any discussion of this fasciae is an understanding of the anatomy of the cranial portion of the pharynx, the attachments of the tensor and levator veli palatini muscles to the skull base, and the relationship of these muscles to the eustachian tube as the visceral fascia attaches to and surrounds these structures.

The superior pharyngeal constrictor muscle attaches dorsally to the skull base at the midline pharyngeal tubercle via an aponeurosis. From this point, on either side, the muscle arches caudally to attach to the lower portion of the medial pterygoid plate. This arching shape results in a gap on either side of the midline between the skull base and the upper surface of the superior constrictor muscle. This gap is almost entirely filled by the thick pharyngobasilar fascia, which can be considered as the cranial continuation of this muscle and which helps define and restrict the shape of the nasopharynx.[2, 4] On either side, just under the skull base and dorsal to the posterior edge of the medial pterygoid plate, the pharyngobasilar fascia is deficient, creating a space known as the sinus of Morgagni, through which passes the cartilaginous portion of the eustachian tube and the levator veli palatini muscle (Drawings 2 and 13–16).

The levator veli palatini muscle arises from the undersurface of the petrous apex and the medial lamina of the cartilaginous eustachian tube. This muscle then passes through the sinus of Morgagni in the pharyngobasilar fascia, descending submucosally along the inner surface of the pharyngeal constrictor to finally reach the soft palate. Once through the sinus of Morgagni, the levator veli palatini muscle has been described as being enclosed in a fascial space ''la loge peristaphyline interne'' (box or space of the levator palatini) that is formed by small medial and lateral leaves of the BPF at the skull base, the skull base itself, the eustachian tube, and the pharyngobasilar fascia. The muscle moves freely within this fascial space, is partly responsible for maintaining the patency of the eustachian tube, and is an integral part of the pharyngeal wall. It is best considered as a part of the pharynx and is innervated by the pharyngeal plexus (Fig. 34-7).

The tensor veli palatini muscle arises from a scaphoid fossa and spine of the sphenoid bone near the base of the medial pterygoid plate and from the lateral lamina of the cartilaginous eustachian tube. It then descends lateral to the pharyngeal constrictor, between the medial pterygoid plate and the medial pterygoid muscle, which arises in the pterygoid fossa. Its tendon then wraps around the hamulus of the medial pterygoid plate, and the muscle inserts into the palatine aponeurosis. The tensor veli palatini muscle, which remains outside of the pharynx, is best considered to be part of the muscles of mastication and is supplied by the fifth cranial nerve. This muscle also helps maintain the patency of the eustachian tube and, as noted, is really part of the deglutitional group of muscles.

The visceral fascia or BPF extends from the skull base and follows the outer surface of the pharyngobasilar fascia and the pharyngeal constrictors. This fascia is firmly adherent to the muscular wall of the pharynx and the esophagus, and no real space exists between this fascia and the viscera. However, this potential space has caused some confusion in the literature because it has also been referred to as the visceral space. Today the visceral space is generally considered to be the space between the BPF and the alar fasciae (see the discussion in the section on The Fascial

Spaces) (Fig. 34-8). This current usage is virtually the opposite of that of Grodinsky and Holyoke.

Descriptions of the most superior visceral fascial attachments vary, with most authors indicating that the BPF has an intimate association with the eustachian tube and the levator veli palatini muscle. The BPF splits to enclose the more cranial portion of the levator muscle, and a lateral leaflet is sometimes described in association with the lateral margin of the tensor veli palatini muscle. According to most authors, a well-defined, fairly thick fascial sheet arises directly from the posteroinferior edge of the tensor veli palatini muscle and extends caudally and posterolaterally from this muscle to the styloid process and the styloid muscles, fusing inferiorly with the fascia covering the styloglossus muscle.[9, 16, 20] This fascial sheet thus closes the gap between the tensor veli palatini, the skull base (from the sphenoid spine along the medial side of the foramen ovale to the root of the medial pterygoid plate), and the styloid process with its associated musculature. Anteriorly this fascia reaches the pterygomandibular raphe and there fuses with the interpterygoid fascia as well as the BPF.

In the English literature this important fascia has been described by Gaughran, who referred to it as the vascular fascia because it contains the ascending palatine artery and vein.[9] Other names given to this fascia include the nerve-vessel sheath of Weintraub, the lame vasculaire, and the lateral aponeurosis of the pharynx.[9, 21, 22]

As to the origin of this fascia, it is clearly located between the SLDCF and the DLDCF and it is immediately contiguous with the BPF, which is derived from the MLDCF. However, the subclassification of the DCF into three different layers is not usually applied to the region above the hyoid bone and is rarely utilized in the area under the skull base. Some authors believe it to be part of the MLDCF; other authors describe it as an independent fascial layer. In either case, its derivation is less important than knowledge of its existence and its location. In this discussion, we will refer to this fascia by the anatomically descriptive name *tensor-vascular-styloid fascia*. This fascia plays a key role in the descriptions of the parapharyngeal space, as discussed in Chapter 38 (Drawings 2, 13–16).

THE CAROTID SHEATH

Most authors have described the primary fascial contributions to the middle and lower carotid sheath as coming from the SLDCF (from the fascia covering the sternocleidomastoid muscle) and from the DLDCF (from the alar fascia). There also may be contributions to the sheath from the MLDCF about the strap muscles (this fascia is variously thought to come from either the SLDCF or the MLDCF). Overlapping of these fascial contributions occurs in some areas, giving added strength to that portion of the carotid sheath, while in other areas there may be focal dehiscences, especially along the medial wall (Drawings 2–5, 8, 15 and 16).

The upper portion of the carotid sheath remains a composite compartment formed by the various regional fasciae. Typically, the upper carotid sheath is described as being formed by the SLDCF (represented by contributions from the adjacent muscular investing fasciae) that forms the lateral wall, the DLDCF (represented by the alar and/or prevertebral fasciae) that forms the posterior wall, the cloison sagittale (either part of the DLDCF or the MLDCF) that forms the medial wall, and the stylopharyngeal aponeurosis or the tensor-vascular-styloid fascia (MLDCF) that forms the anterior wall (see the discussion below).

There is general agreement among anatomists and surgeons that in the neck, caudal to the carotid artery bifurcation, the carotid sheath is a complete, well-defined structure. However, more cranially, many authors describe the internal carotid artery as being in an incomplete sheath with variable areas of dehiscence (Fig. 34-9).

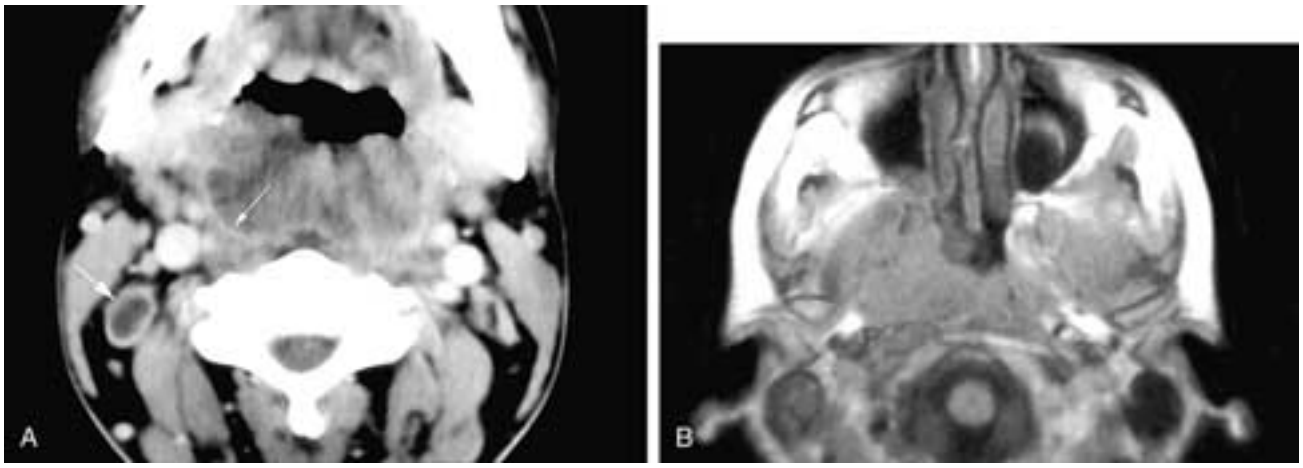

FIGURE 34-8 Axial contrast-enhanced CT scan (**A**) shows a large, bulky tumor in the pharynx. The visceral fascia around the pharyngeal constrictor muscles can be seen containing the tumor (*small arrow*). This imaging appearance is not uncommon with pharyngeal tumors and often belies the malignant nature of the tumor. However, a necrotic right level II node is present (*large arrow*), attesting to the aggressive nature of the cancer. Axial T1-weighted MR image (**B**) shows an infiltrative nasopharyngeal tumor that has violated the visceral fascia. The penetration of this fascia signifies the aggressive nature of the carcinoma.

VIEW IMAGE

FIGURE 34-9 Axial T1-weighted MR image shows a mass (*medium arrow*) separating the internal carotid artery (*small arrow*) and the internal jugular vein (*large arrow*). Although the fascia forming the carotid sheath cannot be seen on imaging, its presence is noted by the fact that it restrains the vessels from simply sliding away from the schwannoma and thus allows the mass to separate them.

THE FASCIAL SPACES

The fascial spaces or compartments are regions of loose connective tissue that fill the areas between the fascial layers. In some cases these compartments are readily identifiable, while in others they represent more potential spaces. The descriptions of these fascial spaces vary almost as much as those of the fasciae themselves, and there is little agreement among surgeons and anatomists as to whether the spaces communicate freely with each other, allowing unobstructed spread of infections, or whether most of these spaces are closed and separate so that infections from one space must ''point'' and penetrate in order to spread to adjacent spaces. The explanation of these differing opinions may be the normal anatomic variations of the fasciae that occur among people.

Another difficulty when discussing the spaces of the neck is that there are no officially accepted names for many of these spaces. A number of the spaces do have names that have been so commonly utilized for years that they have become acceptable terms. However, throughout the literature, a variety of less common names have been employed for some spaces. These differences in nomenclature will be mentioned throughout the discussion of the spaces.

In the previous sections, a detailed description of the fasciae that form these spaces has been given. In this section a summary of the boundaries of these spaces will be given, and Drawings 17 to 22 show the overall relationship of each of the major spaces to one another.

The Visceral Compartment and Its Spaces

Probably the most controversial and confusing terminology is for the space that contains the pharynx, cervical esophagus, trachea, thyroid gland, parathyroid glands, larynx, recurrent laryngeal nerves, and portions of the sympathetic trunk. This space is referred to by various authors as either the visceral compartment or the visceral space. This region extends from the skull base down to the upper thorax. In its more cranial portion it is defined by the visceral fasciae or BPF ventrally, the alar fascia dorsally, the cloison sagittale fasciae on either side, and the skull base superiorly. In its caudal portion it has two sections. There is an anterior or ventral portion enclosed by the strap muscles ventrally, the carotid sheaths laterally, and the alar fascia dorsally. There is also a caudal or posterior continuation of the more cranial portion of this region around the cervical esophagus.

Most authors today refer to this region as the visceral space. It is considered to have two subdivisions: an anterior pretracheal space and a more posterior retrovisceral space.[2, 4] These spaces communicate freely between the levels of the thyroid cartilage and the inferior thyroid artery. However, caudal to this level, these spaces are separated by a fascia associated with the inferior thyroid artery. As a result, the pretracheal space extends down into the superior mediastinum, while the retrovisceral space extends into the middle mediastinum. As mentioned, the reader should be aware of the confusing terminology, as in the literature the entire visceral space is referred to by some authors as the visceral compartment, with two lower regions: the pretracheal space and the retrovisceral space.

The Pretracheal Space

The pretracheal space (itself a somewhat confusing term, as this space contains the trachea) extends from the hyoid bone and the attachments of the strap muscles and their fascia to the hyoid bone and thyroid cartilage down to the superior mediastinum about the upper border of the aortic arch and great vessels. This space contains the trachea, thyroid gland, parathyroid glands, larynx, cervical esophagus, recurrent laryngeal nerves, and portions of the sympathetic trunk. The pretracheal space communicates freely with the retrovisceral space around the sides of the larynx, the lowermost pharynx, and the upper cervical esophagus between the levels of the thyroid cartilage and the inferior thyroid artery. Caudal to this level, the pretracheal space is separated from the retrovisceral space by dense connective tissue that extends from each lateral wall of the visceral compartment to the lateral margins of the esophagus. This tissue accompanies the inferior thyroid artery on either side as it courses cranially from the thyrocervical trunk, extends ventral to the vertebral artery and the longus colli muscle, and then runs to the caudal and dorsal aspect of the thyroid gland (Drawings 3–5, 8, 9, and 17–22).[2, 4]

The Retrovisceral Space

The posterior portion of the visceral compartment, referred to as the retrovisceral space, is behind the pharynx and upper esophagus. It extends from the skull base down to the mediastinum, where its caudal limit is between the levels of the sixth cervical vertebra and the fourth thoracic vertebra, where the alar fascia fuses with the visceral fascia. Often the space actually stops at the more cranial of these levels, corresponding to the level of the tracheal bifurcation (Drawings 2–5, 8, 9, and 17–22).[2, 4] As the retrovisceral

Copyright © 2003, Mosby, Inc. All rights reserved.

space lies behind the pharynx and upper esophagus, in the upper neck it is often referred to as the retropharyngeal space.

More specifically, in its upper regions, this space lies between the BPF anteriorly (as this fascia surrounds the pharyngeal musculature) and the alar fascia posteriorly. On either side, the cloison sagittale separates the retropharyngeal space from the more laterally positioned parapharyngeal space. In the middle and lower neck, the continuation of this space surrounds the esophagus, and it is commonly referred to as the retroesophageal space. Thus the ''retropharyngeal'' and ''retroesophageal'' spaces are the upper and lower aspects of one space (the retrovisceral space or portion of the larger visceral space), which communicates freely with the pretracheal space between the levels of the thyroid cartilage and the inferior thyroid artery. This fascial anatomy explains why a retropharyngeal abscess can extend down into the pretracheal space and affect the thyroid gland and anterior mediastinum, or why a large thyroid goiter can extend behind the esophagus and grow either upward as a retropharyngeal mass or downward as a retroesophageal mass (Figs. 34-10 to 34-14).

To confuse the issue even further, a few authors have restricted the use of the term *visceral space* to the potential space between the visceral fascia and the enclosed viscera. However, this opinion is not held by most authors.

The Danger Space

Grodinsky and Holyoke described the danger space (their space 4) as lying between the alar fascia (ventrally) and the prevertebral fascia (dorsally).[2] The space extends from the skull base down into the posterior mediastinum to a level just above the diaphragm where the fused alar and visceral fascia, in turn, fuse with the prevertebral fascia. Grodinsky and Holyoke considered this space an important potential pathway for the spread of cranial and cervical infections into the middle and lower mediastinum. Since the space is closed superiorly, inferiorly, and laterally, infections must enter the space by penetrating its walls (Drawings 2–5, 8, 9, and 17–22).[2]

The Prevertebral Space

This space is a potential space that exists between the prevertebral fascia and the vertebrae, extending from the skull base to the coccyx.[2, 4] The prevertebral muscles are within this space (Drawings 2–5, 8, 9, and 17–22). The vast majority of the pathology that affects this space arises from the adjacent vertebral bodies, discs, and neural elements.

The Carotid Sheath

There is lack of agreement in the literature as to whether the potential cavity within the carotid sheath can act as a space that allows the spread of infections from the upper neck down into the lower neck and mediastinum. Coller and Yglesias, like Pearse, believed it to be a true pathway for the spread of infection.[7, 23] However, Grodinsky and Holyoke found this space to be of limited value as a pathway for infectious spread.[2] Their experimental injections into the sheath remained confined to the sheath around the common carotid artery between the carotid bifurcation and the root of the neck, levels where the sheath is closely adherent to the vessels. They suggested that it is probably most accurate to consider the carotid sheath as a true space only below the level of the carotid bifurcation and above the root of the neck.

There is some controversy in the literature as to whether the portion of the carotid sheath about the internal carotid artery (i.e., above the hyoid bone) should be considered as part of the parapharyngeal space or as a separate ''carotid space.'' Historically, the anatomic and surgical literature is of the opinion that this portion of the carotid sheath should be considered as part of the parapharyngeal space.[2, 4, 6, 9, 10, 15] The reasoning is based on three observations: (1) Grodinsky and Holyoke found that above the carotid bifurcation, the carotid sheath did not act as a space that allowed the spread of infection; (2) the anatomic literature traditionally has accepted that the posterior layers of the carotid sheath are the posterior boundary of the parapharyngeal space (Drawings 2–5, 8, 9, 15, 16, and 17–22); and (3) most importantly, during the surgical approach to the parapharyngeal space, the tensor-vascular-styloid fascia acts as a boundary between the more superficial prestyloid compartment (containing the retromandibular portion of the parotid gland) and the deeper retrostyloid compartment (containing the carotid sheath).

Harnsberger offered the concept that the carotid sheath and its contained structures should be considered as the carotid space.[24] Although this may not necessarily reflect the anatomic evidence regarding the true presence of a carotid space, the benefit of this concept lies in its ability to help generate a differential diagnosis of lesions that can be localized on imaging to the carotid sheath[25] (Fig. 34-9). The major limitation of this approach is that most surgeons use the prestyloid/retrostyloid terminology and are not as familiar with the carotid space concept.

The Space of the Body of the Mandible

As the SLDCF reaches the caudal border of the mandible, the fascia splits into two leaflets, with the outer leaflet firmly attaching along the lower buccal border of the mandible. The deep fascial leaflet attaches to the lingual surface of the mandible along the line of origin of the mylohyoid muscle that is 1 to 1.5 cm above the caudal edge of the mandible. This deep portion of the fascia can be elevated away from the bone, creating a potential space between the fascia and the lingual cortex of the bone. This potential space contains no loose connective tissue, is limited anteriorly by the attachment of the anterior belly of the digastric muscle, and is delineated posteriorly by the attachment of the internal pterygoid muscle.[2, 4]

The Space of the Submandibular Gland

This space is not a real space in the sense that the submaxillary gland can be easily shelled out of it, leaving the SLDCF behind as a capsule.[2, 4] Instead, the septa of the

FIGURE 34-10 *Continued.* Axial contrast-enhanced CT scans at the level of the middle to upper oropharynx (**G**) and the thyroid bed (**H**) of another patient with a goiter. The larger left thyroid lobe (*arrow*) extends up via the retropharyngeal space. Axial contrast-enhanced CT scan (**I**) shows a thyroid goiter extending down into the pretracheal space portion of the visceral space behind the sternum. Axial CT scan (**J**) shows a thyroid goiter extending down into the retrovisceral portion of the visceral space behind the trachea.

gland are continuous with the capsule. However, the submandibular gland has its own volume and so can be thought of as occupying a space bounded by its own capsule or thin fascia (Drawing 13).

The Space of the Parotid Gland

The SLDCF also splits to enclose the parotid gland. Like the submaxillary gland space, the parotid gland cannot be shelled out, leaving behind a real compartment with strong fascial boundaries. In fact, the fascia about the parotid gland is attached by septae to the gland and is inseparable from the gland. The fascia along the medial or deep portions of the gland is also thin or deficient in most people. However, conceptually, this space encloses the parotid gland, the parotid lymph nodes, and portions of the external carotid artery and the posterior facial or retromandibular vein (Drawings 12, 21, and 22).[2, 4]

The Submandibular Space

Overall, this space is the volume described within the mandibular arch, limited above by the mucosa in the floor of the mouth and caudally by the SLDCF as it extends from the hyoid bone to the mandible. The space is divided into an upper and a lower portion by the mylohyoid muscle that

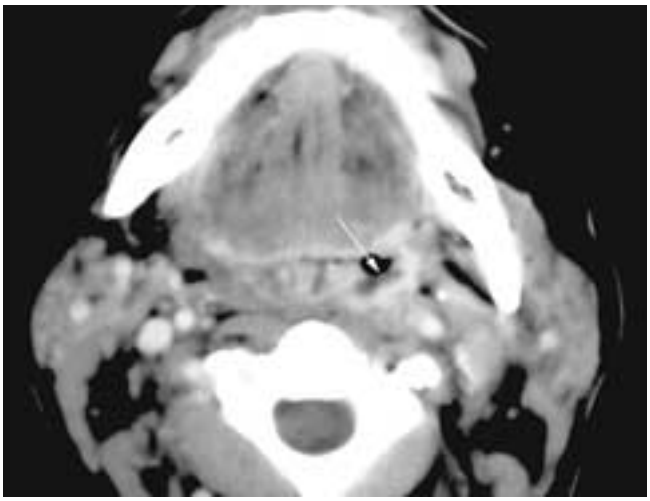
FIGURE 34-11 Axial contrast-enhanced CT scan (**A**) through the lower neck shows a nonhomogeneous thyroid mass replacing the right thyroid lobe. The mass has displaced the trachea to the left and has invaded the lower larynx (*short arrow*). The fat planes around the right thyroid lesion are infiltrated, obliterating the separation from the adjacent muscles and vessels. The right common carotid artery and internal jugular vein are obscured. All of these imaging findings are evidence of the aggressive nature of this anaplastic thyroid carcinoma as it violates the fascial planes. There also is a necrotic right metastatic level III node (*long arrow*). Axial contrast-enhanced CT scan (**B**) through the lower neck and anterior mediastinum shows an infiltrating thyroid mass that has violated the fascial boundaries, obscuring the adjacent structures. This imaging appearance attests to the aggressive nature of this anaplastic thyroid carcinoma.

attaches to the lingual surface of the mandible along the mylohyoid line. The submaxillary (submandibular) gland is folded around the back of this muscle so that the gland lies partially above and partially below its dorsal edge. In fact, the upper and lower portions of the submandibular space communicate freely with each other around this dorsal margin of the mylohyoid muscle. In general, there is also free communication between the left and right sides of this space (Drawings 10, 13, and 20–22) (Figs. 34-15 and 34-16). As the submandibular gland lies within the submandibular space, a distinction should be made between this larger space and the *space for the submandibular gland*, which essentially refers to the capsule of this gland (see above).

The upper or cranial portion of the submandibular space is often called the *sublingual space*. It is filled with loose connective tissue that surrounds both sublingual glands and their ducts, the lingual and hypoglossal nerves, the lingual arteries, and the smaller or deep portion of each submandibular gland along with its hilum and Wharton's duct. On either side, the lower or caudal portion of the submandibular space is usually referred to as the submaxillary space, and the larger superficial portion of the submandibular gland and its lymph nodes lie within its loose connective tissue. The facial artery and vein as well as the digastric muscle are also in each submandibular space. The submental triangle and the submandibular triangles of the neck are the superficial landmarks that correspond to the region of this space.[2, 4, 14]



VIEW IMAGE

FIGURE 34-12 Axial contrast-enhanced CT scan through the oropharynx shows an enhancing, thickened mucosa on the left side. There is a mucosal ulceration (*arrow*); however, the visceral fascia appears to prevent the tumor from spreading further into the deep spaces of the neck. This is not an uncommon imaging appearance of pharyngeal carcinomas and illustrates the potential resistance of this fascia to tumor spread.

The Masticator Space

The SLDCF splits about the lower edge of the mandible, and the outer or superficial layer encloses the masseter muscle, extends over the zygomatic arch, and attaches to the calvarium about the dorsal and cranial margins of the temporalis muscle and the lateral orbital wall. The inner or deep layer of fascia covers the medial pterygoid muscle before fusing with the interpterygoid fascia and continuing to the skull base.[15, 16] The split layers of the SLDCF fuse again along the ventral and dorsal borders of the ramus of the mandible and, in so doing, close this space about the muscles of mastication. The lateral pterygoid muscle lies freely within this space, while the fasciae about the masseter, temporalis, and internal pterygoid muscles con-

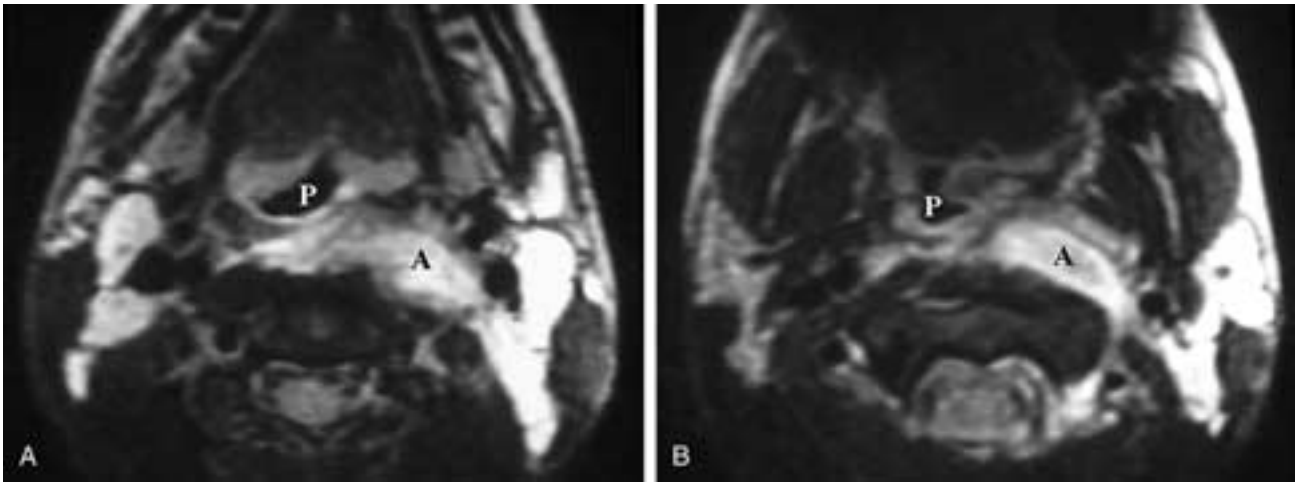
FIGURE 34-13 Axial contrast-enhanced CT scan (**A**) through the oropharynx shows air infiltrating throughout the neck in this patient who required an emergency tracheotomy. Air is seen in the retropharyngeal space (*R*) behind the pharyngeal airway (*P*) and the vallecullae (*v*). The posterior pharyngeal constrictor muscles are seen (*arrow*) between these air collections. Air is also dispersed throughout the soft tissues of the neck. Axial contrast-enhanced CT scan (**B**) through the oropharynx of another patient shows air in the retropharyngeal space in this patient who had a tracheotomy. Note that there is a midline attachment of the visceral fascia to the alar fascia (*arrow*), incompletely dividing the retropharyngeal space (*R*) into two compartments. This type of compartmentalization occurs in nearly half of the cases (compare to **A**, where there is no such division of the retropharyngeal space). The pharyngeal airway is indicated by *P*.

tribute to the boundaries of this space. The portion of the masticator space that extends cranially between the calvarium and the outer layer of the SLDCF is occasionally referred to as the temporal space, but it is probably better regarded as the cranial extension of the masticator space (Fig. 34-17). The internal maxillary artery and the third division of the trigeminal nerve run within the masticator space (Drawings 2, 10–13, 21, and 22) (Fig. 34-3); see Chapter 38.[2, 4, 7, 12, 15, 16]

The Parapharyngeal Space

What today is commonly referred to as the parapharyngeal space has also been referred to in the literature as the lateral pharyngeal, peripharyngeal, pharyngomaxillary, pterygopharyngeal, pterygomandibular, and pharyngomasticatory space, and it boundaries have been described with more variation than those of any other space of the neck (Drawing 2).[2, 4, 6, 8, 9, 15] The parapharyngeal space is a



VIEW IMAGE

FIGURE 34-14 Axial T2-weighted MR image (**A**) shows an area of high signal intensity in the retropharyngeal space (*A*). Although the lesion is larger on the left side, the process extends across the midline to involve the right side. Thus, the entire retropharyngeal space is affected by this abscess. The pharyngeal airway is indicated by *P*. Axial T2-weighted MR image (**B**) shows an area of high signal intensity in the left retropharyngeal space (*A*). The remaining portions of the retropharyngeal space are uninvolved. This was an abscessed node, but in a different patient the same imaging appearance could represent a retropharyngeal metastatic node. It is the localized nature of this nodal disease that differentiates this case from the retropharyngeal space abscess shown in **A**. The pharyngeal airway is indicated by *P*.

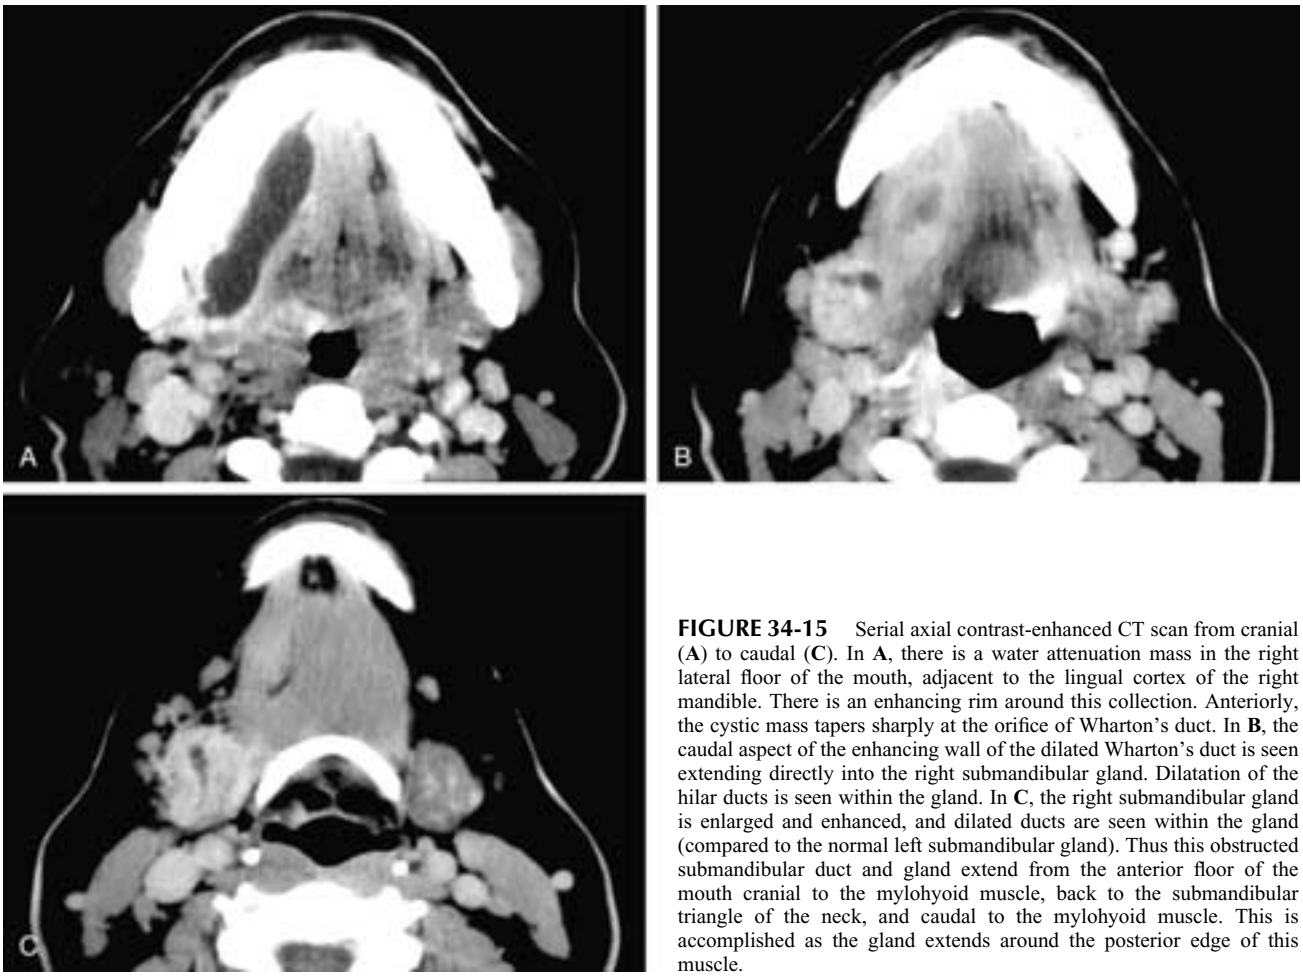

FIGURE 34-15 Serial axial contrast-enhanced CT scan from cranial (**A**) to caudal (**C**). In **A**, there is a water attenuation mass in the right lateral floor of the mouth, adjacent to the lingual cortex of the right mandible. There is an enhancing rim around this collection. Anteriorly, the cystic mass tapers sharply at the orifice of Wharton's duct. In **B**, the caudal aspect of the enhancing wall of the dilated Wharton's duct is seen extending directly into the right submandibular gland. Dilatation of the hilar ducts is seen within the gland. In **C**, the right submandibular gland is enlarged and enhanced, and dilated ducts are seen within the gland (compared to the normal left submandibular gland). Thus this obstructed submandibular duct and gland extend from the anterior floor of the mouth cranial to the mylohyoid muscle, back to the submandibular triangle of the neck, and caudal to the mylohyoid muscle. This is accomplished as the gland extends around the posterior edge of this muscle.

VIEW IMAGE

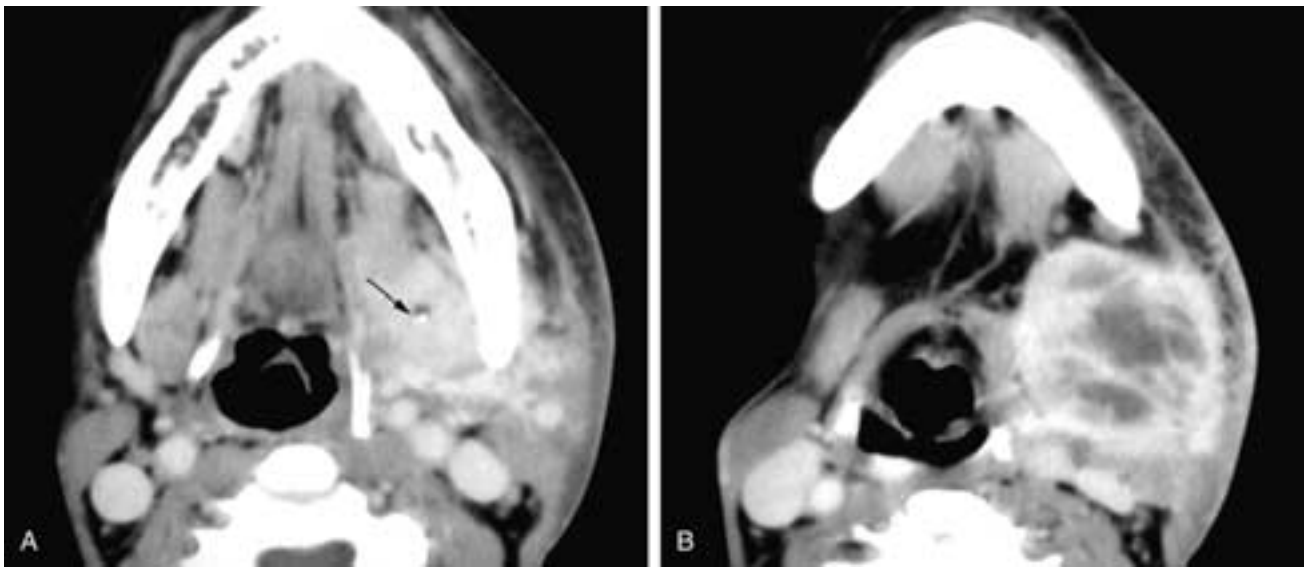

FIGURE 34-16 Axial contrast-enhanced CT scans through the floor of mouth (**A**) and the caudal suprahyoid neck (**B**). In **A**, there is an enhancing mass in the region of the left submandibular gland. A small calculus is present near the hilum of the gland (*arrow*), and the process extends beyond the gland into the adjacent floor of the mouth and the submandibular triangle. In **B**, an abscess is seen in the submandibular triangle, with adjacent thickening of the platysma muscle and thickening and injection of the overlying subcutaneous fat and skin. This abscess arose in the acutely obstructed submandibular gland and spread over the back of the mylohyoid muscle into the submandibular triangle of the neck. Such an abscess from an acutely obstructed gland is unusual. This patient turned out to be HIV positive, which accounted for the rapid spread of the infection.

hatchet-shaped space on either side of the neck. Its ventral (prestyloid) compartment lies just lateral to the pharynx and deep to the masticator space and the ramus of the mandible. It is filled with fat and connective tissue, and the deep portion of the parotid gland protrudes into it. The dorsal (retrostyloid) compartment of the parapharyngeal space corresponds to the carotid sheath and its enclosed structures. The parapharyngeal space extends from the skull base down to the level of the angle of the mandible.

More specifically, the medial wall of the parapharyngeal space is formed by the BPF or visceral fascia as it extends from the skull base caudally, first covering the pharyngobasilar fascia and then the outer aspect of the pharyngeal constrictor muscles (Drawing 3).

On either side of the neck, the pterygomandibular raphe is a linear fascial condensation that extends from the hamulus of the medial pterygoid plate to the lingual surface of the mandible near the posterior margin of the mylohyoid line. This raphe serves as the point of attachment of the superior pharyngeal constrictor muscle, and it is also the origin of the buccinator muscle. In addition, the BPF (covering the pharyngeal constrictor and extending ventrally to cover the buccinator muscle) and the interpterygoid fascia (from the masticator space) both fuse with the pterygomandibular raphe. As the parapharyngeal space is between these fasciae, the pterygomandibular raphe is considered to be the anterior or ventral boundary of the parapharyngeal space.

Caudally, the parapharyngeal space has been described as extending down to the hyoid bone. However, in actuality, the fascia about the submaxillary gland, the sheaths of the styloid muscles, the fascia over the posterior belly of the digastric muscle, the fascia on the lingual aspect of the mandible, and the visceral fascia all fuse near the level of the angle of the mandible, functionally obliterating the parapharyngeal space. Running at the caudal aspect of this region is the styloglossus muscle, which is most often considered to be the inferior boundary of the parapharyngeal space.[2, 4, 6, 8, 9, 15]

The lateral boundary is the fascia on the medial aspect of the masticator space and the fascia over the deep surface of the parotid gland, both of which are formed by the superficial layer of the deep cervical fascia.

The posterior boundary of the parapharyngeal space is the most controversial. As already mentioned, most anatomists and surgeons have placed the carotid sheath in the retrostyloid compartment of the parapharyngeal space, while some radiologists have referred to the sheath as representing a separate carotid space.[2, 4, 6, 8–10, 15, 24, 26] In general, when communicating sectional imaging findings to surgeons, as well as for consistency with the clinical literature, the carotid sheath is considered to be the retrostyloid compartment of the parapharyngeal space. However, it should be remembered that in the literature there is no disagreement about the anatomy itself, only about the terminology used to describe this anatomy (Drawing 4).

Within the boundaries of each parapharyngeal space just described, the parapharyngeal space is usually subdivided into three compartments defined in various descriptions by the tensor-vascular-styloid fascia, the stylopharyngeal aponeurosis (aileron), and the sagittal partition (cloison sagittale) (Drawing 5).

As previously discussed, there is a well-defined, fairly thick fascial sheet, the tensor-vascular-styloid fascia, that closes the gap between the tensor veli palatini muscle and the medial pterygoid plate, the skull base, and the styloid process and its associated musculature (Drawings 3 and 5).[9, 10, 16, 20]

Gaughran mentioned a continuation of this fascia laterally from the styloid process to the posterior border of the mandibular ramus.[9] He referred to this fascial extension as the stylomandibular fascia; a thickening in the lower edge of this fascia is the stylomandibular ligament. This ligament, along with the posterior border of the mandibular ramus and the skull base, forms the stylomandibular tunnel, through which the deep or retromandibular portion of the parotid gland protrudes into the parapharyngeal space. This stylomandibular fascia may also be thought of as a fusing of the SLDCF, as it covers both the medial aspect of the parotid gland and the styloid musculature.

There are two more fascial layers that relate to the tensor-vascular-styloid fascia and further subdivide or partition the parapharyngeal space. The first layer is a roughly coronally oriented fascia that has been variously described as extending medially from either the tensor-vascular-styloid fascia or the styloid musculature to the BPF. It attaches to the BPF near the location of the lateral pharyngeal recess or fossa of Rosenmuller.[15] This fascia has been described by Testut, Zuckerkandl, and others and is most often referred to in the literature as the stylopharyngeal aponeurosis. Some French anatomists refer to it as the *aileron* (Drawings 3 and 5).[6, 8, 9]

The second fascial layer is positioned approximately in the sagittal plane and extends from the BPF, at or near the attachment of the stylopharyngeal aponeurosis, to the alar fascia and prevertebral fascia near their attachments to the transverse processes of the cervical vertebrae. This fascia is referred to by Charpy as the *cloison sagittale* (sagittal partition) (Drawings 3 and 5).[1, 2, 6, 8, 9, 15] Probably reflecting anatomic variation, Cazalas described this cloison sagittale fascia as extending directly from the tensor-vascular-styloid fascia (rather than from the BPF) to the alar fascia.[6] He also described the *aileron* as extending from the tensor-vascular-styloid fascia to the BPF. Cazalas used the term *sphenopharyngeal ligament* to identify the thickening in the tensor-vascular-styloid fascia from which, in his opinion, the cloison sagittale and the aileron had their origins.

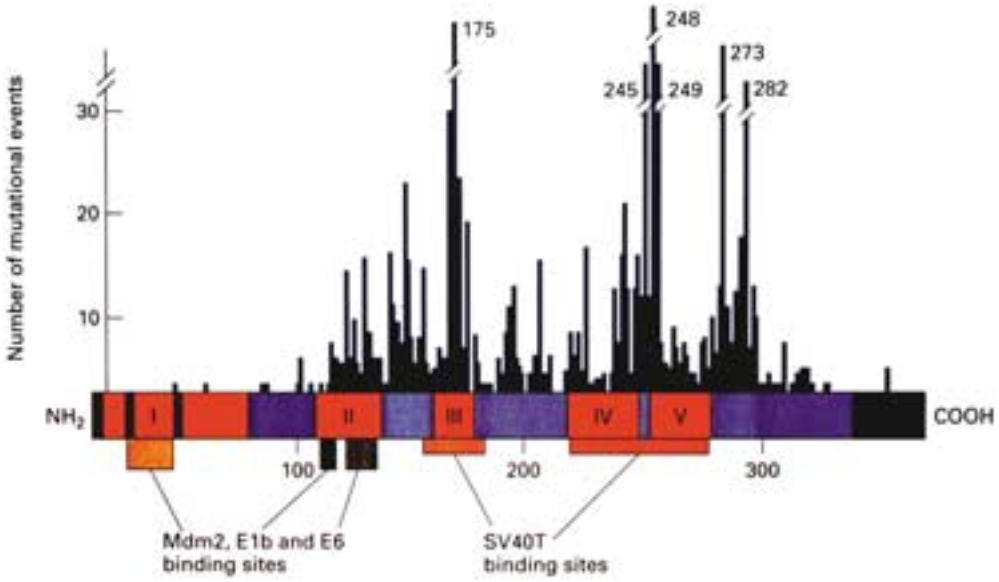
COLOR PLATE 1 The Ras-Map kinase pathway for intracellular growth factor signal transduction. The figure depicts signal transduction initiated by binding of a generalized growth factor to a dimerized receptor tyrosine kinase (RTK) at the cell plasma membrane. Ras is recruited to the inner surface of the membrane by the proteins shown in response to internal phosphorylation of tyrosine in the RTK. In its active GTP-bound form, Ras interacts with and activates the protein kinase Raf, initiating a cascade of protein phosphorylation events denoted by *P*. A GTPase-activating protein, GAP, interconverts active and inactive Ras forms. Mitogen-activated kinase (MAPK) can phosphorylate several transcription factors that enter the nucleus, as exemplified here by Fos and Jun, which together activate transcription of several genes, including the *PRAD1* gene, which encodes the protein cyclin D1. The protein kinase RSK is involved in translational aspects of protein synthesis. Mutation of genes encoding several proteins in this pathway can lead to self-sufficiency of growth signaling independence of the extracellular factor.



VIEW IMAGE

COLOR PLATE 2 Distribution of mutations in the *p53* tumor suppressor gene in various tumors. The p53 protein is schematized, and amino acids are enumerated on the x-axis.[19] On the y-axis, numbers of mutations at each amino acid position are presented as recorded in a variety of tumors. The majority of mutations occur in the central DNA-binding domains of p53. Note that regions in these domains are also targeted for binding by viral proteins that inactivate p53. E1b is an adenoviral protein, E6 is a papilloma viral protein, and the SV40 large T antigen is a simian virus 40 protein. The site specificity of the mutations is due in part to the environmental agents that caused them. For example, certain sites are preferentially mutated by aflatoxin B1 in hepatocellular carcinoma, and other sites are preferentially observed in lung adenocarcinoma, presumably mutated by benzo-a-pyrene or other agents in cigarette smoke. (From Denissenko MF, Pao A, Tang M, Pfeifer GE. Preferential formation of benzo [a]pyrene adducts at lung cancer mutational hotspots in P53. Science 1996;274:430. VIEW IMAGE

COLOR PLATE 3 Involvement of several tumor suppressor gene products in pathways leading to cessation of cell growth or to apoptosis in response to DNA damage. Processes leading to activated cell proliferation, that is, entry to S-phase of the cell cycle, are indicated in green. Processes inhibiting cell proliferation are indicated in red. In response to DNA damage, such as that caused by ionizing radiation, for example, the ATM protein kinase phosphorylates and activates p53. The p53 protein, in turn, through effects on gene transcription, activates pathways leading to either apoptosis or cessation of cell growth. Transcription of the *p21* gene is activated by p53. The p21 protein is an inhibitor of both CDK2, necessary for initiation of DNA replication, and CDK4, which catalyzes phosphorylation of Rb. Hyperphosphorylation of Rb is necessary to trigger events leading to the G1-S transition. Two different products of another tumor suppressor gene, *p16/ARF*, play important roles in inhibiting cell proliferation. ARF binds to MDM2 and prevents it from targeting p53 for proteolytic destruction. The p16 protein specifically inhibits CDK4 kinase activity, preventing phosphorylation of Rb. Several proteins are indicated in magenta. It is believed that at least one of the four genes encoding these proteins, *ARF/p16*, *cyclin D1*, *p53*, and *Rb*, is mutated in every neoplasia.

These three fascial planes subdivide the parapharyngeal space into three compartments. The first compartment (A) is lateral to the tensor-vascular-styloid fascia and deep to the medial boundary of the masticator space. This area contains a small amount of fat, and the deep or retromandibular portion of the parotid gland protrudes into its lateral margin. The second compartment (B) is a very thin, slit-like region between the BPF medially and the tensor-vascular-styloid fascia laterally. There is only a small amount of loose connective tissue in this second compartment, which is bounded posteriorly by the stylopharyngeal aponeurosis (aileron). The third compartment (C) of the parapharyngeal region is posterior to the stylopharyngeal aponeurosis and separated from the retropharyngeal space by the cloison sagittale. This third compartment contains the internal carotid artery, internal jugular vein, and, at various levels, cranial nerves IX to XII. Thus, this third compartment is primarily the carotid sheath and its contents. Almost all descriptions of the parapharyngeal space include some or all of these compartments, albeit under a variety of names and combinations.

Gaughran referred to the region between the BPF and the medial wall of the masticator space as the lateral pharyngeal cleft.[9] This cleft is analogous to the anterior part of the parapharyngeal space and includes the first two compartments (A+B) just described. Gaughran described the vascular fascia as extending from the tensor veli palatini and separating the lateral pharyngeal cleft into a very thin medial compartment and a larger, more lateral compartment called, respectively, the paratonsillar and paramasticator regions of the lateral pharyngeal cleft. This same fascial organization was described by Cazalas and Coulomb, who referred to the thin medial compartment as the meta-amygdalin space and the larger lateral compartment as the para-amygdalin space.[6, 8] Amygdalin refers to the tonsil, and in this nomenclature there is also a periamygdalin space between the tonsil and the constrictor muscles (referred to today as the peritonsillar space).

Hall used the terms *prestyloid* and *poststyloid parapharyngeal spaces*.[10] The poststyloid space was essentially the carotid sheath. The two spaces were separated by the stylopharyngeal aponeurosis, which indicates that the prestyloid compartment included the first two compartments described above (A+B). Hall did not describe any structure resembling the tensor-vascular-styloid fascia. Instead, he ascribed the entire region between the BPF overlying the constrictor muscles medially and the masticator space laterally to the prestyloid space. The paratonsillar and paramasticator spaces (meta- and para-amygdalin) were combined.

Hollinshead referred to the parapharyngeal space as the lateral pharyngeal space, stating that it was continuous with the retropharyngeal space.[4] He also stated that the area was subdivided by some authors into prestyloid and poststyloid compartments, referring to Hall, but not stating precisely which fascia, if any, divided the two compartments.

Som et al. referred to the prestyloid and retrostyloid compartments of the parapharyngeal space as being separated by the tensor-vascular-styloid fascia.[20] They mentioned a fascia extending from the tensor-vascular-styloid fascia to the prevertebral fascia, separating the retrostyloid compartment from the retropharyngeal space. This fascia is analogous to the cloison sagittale, as described by Charpy. Thus Som et al. combined the spaces on either side of the stylopharyngeal aponeurosis, the second and third compartment described above (B+C), into one compartment called the retrostyloid space. The prestyloid compartment referred to the first compartment (A) described above, which is lateral to the tensor-vascular-styloid fascia and into which protrudes the deep portion of the parotid gland (Fig. 34-18).

Support for the use of this prestyloid and retrostyloid compartment terminology comes from the surgeons, who note that in their operative approach to the parapharyngeal space, the plane of the tensor-vascular-styloid fascia acts as an important landmark, with the great vessels and cranial nerves lying deep to the plane. In this sense, this fascia and its boundaries act as a protective barrier to these vital structures. Today, this terminology for the parapharyngeal space is most often used by surgeons.[20]

In the radiology literature, the various compartments of the parapharyngeal space have been used to help generate a differential diagnosis for lesions arising in this region. As previously discussed, two conventions are used. The first uses the prestyloid and retrostyloid configuration emphasizing the tensor-vascular-styloid fascia.[16, 20] The second, discussed by Harnsberger, separates the region into the carotid space and the parapharyngeal space.[24, 26] In this second convention, the separation closely approximates the stylopharyngeal aponeurosis, as discussed by Hall.[10]

In the opinion of most authors, the parapharyngeal space is considered as a closed space that is surrounded by a number of other ‘‘spaces.’’[10] These include the pharynx, the submandibular space, the submaxillary gland space, the masticator space, the parotid gland space, the retropharyngeal space, the danger space, and the prevertebral space. However, when one considers the wide variety of descriptions of the fascial planes themselves, there is certainly a possibility that in some people, portions of these fasciae are weak or incomplete. This presumably explains why a few authors believe that the parapharyngeal space communicates freely with the submaxillary and retropharyngeal spaces.

One of the main reasons for interest in the parapharyngeal space is its critical location and anatomic relationships that allow it to act as a highway for the spread of infections and

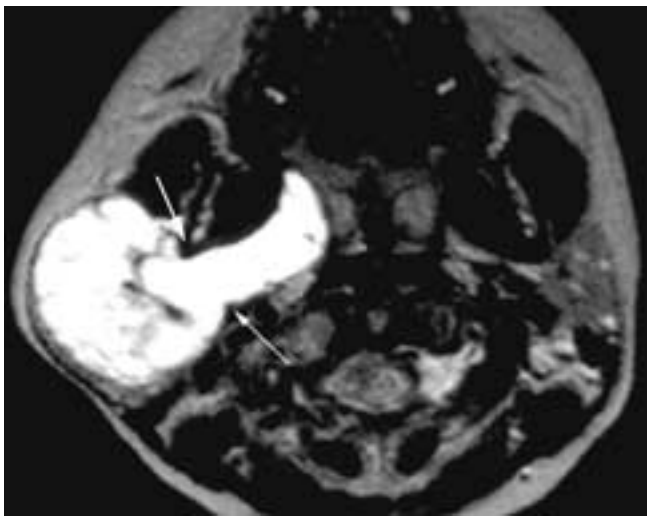

FIGURE 34-18 Axial T2-weighted MR image shows a high signal intensity lymphangioma filling the right parotid gland and extending through the stylomandibular tunnel into the prestyloid compartment of the parapharyngeal space. The thin arrow indicates the styloid process, and the thick arrow indicates the dorsal edge of the ramus of the mandible.

some tumors from any of the areas that surround it to any of the other bordering spaces (see Chapter 38).

The Peritonsillar Space

The palatine tonsil is surrounded by a capsule. Between this capsule and the laterally positioned superior pharyngeal constrictor muscle is a potential space that is limited anteriorly by the palatoglossus muscle and its fascia (the anterior tonsillar pillar) and posteriorly by the palatopharyngeus muscle and its fascia (the posterior tonsillar pillar). This space, called the peritonsillar or paratonsillar space, is filled with loose connective tissue. The space is inside (medial to) the constrictor muscles and the BPF and should not be confused with the paratonsillar division of the parapharyngeal space mentioned by Gaughran.[9]

A tonsillar infection can break through the tonsillar capsule into the peritonsillar space. Such an infection (quinsy) can produce bulging of the tissues about the tonsillar pillars, spreading cranially to the level of the hard palate and caudally to the pyriform sinus. However, these infections tend not to extend axially beyond the tonsillar pillars and their site of pointing.[4]

The "Paravertebral Space"

The DLDCF extends from the spinous processes of the cervical vertebrae and the ligamentum nuchae to the left and right transverse processes of the cervical vertebrae. In so doing, this fascia covers the muscles of the upper back and the muscles of the ''floor'' of the posterior triangle. This space deep to the DLDCF has no official name; however, the term *paravertebral space* has been suggested as being anatomically appropriate. The space is adjacent to but separate from the prevertebral space, the danger space, and the carotid sheath structures (Drawings 2–5 and 8). (Fig. 34-4).

However, using reasoning based on imaging studies and the observation that the DLDCF surrounds both spaces, Harnsberger has suggested that this space and the prevertebral space are actually one space, the perivertebral space, and he refers to the prevertebral and paraspinal portions of the perivertebral space to describe the spaces more commonly known to the surgical community as the prevertebral and paravertebral spaces.[27] It should be noted that the reluctance of most surgeons to utilize the Harnsberger classification stems from the observation that the DLDCF firmly attaches to the transverse processes of the cervical vertebrae, effectively separating the prevertebral and ''paravertebral'' spaces.

The "Posterior Triangle (Cervical) Space "

One final compartment or space deserves mention but lacks a common name. Grodinsky and Holyoke referred to this region as space 4A.[2] This compartment lies between the SLDCF and the DLDCF, dorsal to the carotid sheath and ventral to the cervical vertebral spinous processes and the ligamentum nuchae. Its deep boundary is the DLDCF over the so-called paravertebral space, and its superficial boundary is the SLDCF as it defines the posterior triangle of the neck.

This compartment contains mostly fat, hence the term *coussinet adipose*, or ''small cushion of fat,'' used in the French literature. The compartment also contains the spinal accessory nerve and its associated lymph node chain, and so has important surgical and radiologic significance. Potential descriptive terms include *spinal accessory nodal space*, *posterior cervical nodal space*, and *posterior triangle space* (Drawings 2–5 and 8) (Figs. 34-2, 34-19, and 34-20). Harnsberger has suggested the term *posterior cervical space*.[28]

SUMMARY AND CONCLUSION

The most often quoted descriptions of the fasciae, compartments, and spaces of the head and neck have been discussed, and we have given our opinion as to the anatomy and terminology that are most widely accepted. It should be noted that some controversy still remains in the literature regarding the actual anatomy and the descriptive terminology. Some of the variations in the descriptions may be explained by the observation that these fascial sheets may be incomplete or absent in some people; dissection techniques may also account for some reported differences. In the face of such variations in the descriptions of the anatomy itself, it is difficult to expect a uniform terminology. However, the use of a common nomenclature would be an advantage in comparing information and in reporting cases. Such a standard language should use terms acceptable and recognizable to all groups interested in the field including anatomists, surgeons, and radiologists. Drawings 17 to 22 summarize the various spaces in the neck. Table 34-1 summarizes the contents of the various spaces, and Table 34-2 provides an approach to differential diagnosis based on the spaces.

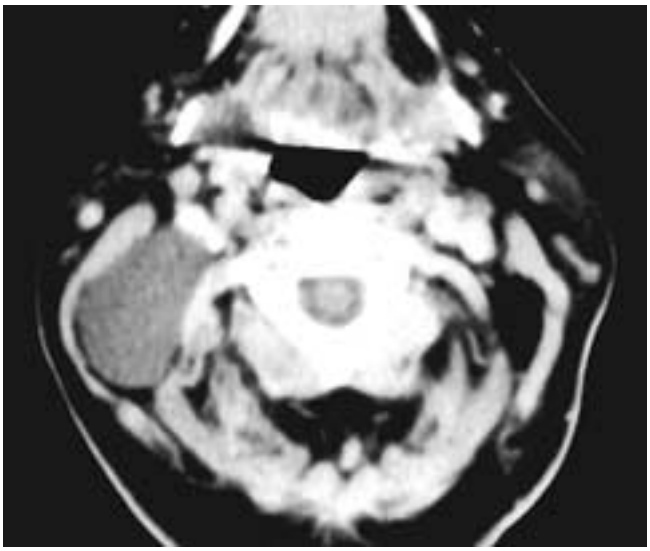

FIGURE 34-19 Axial contrast-enhanced CT scan shows a cystic mass in the right neck deep to the sternocleidomastoid muscle and superficial to the muscles that comprise the floor of the posterior triangle of the neck. The mass fills this space, which has been variously referred to as the spinal accessory nodal space, the posterior cervical nodal space, the posterior triangle space, and the posterior cervical space. This lesion was a solitary lymphangioma in an adult but could just as easily have been a node in a patient with lymphoma.

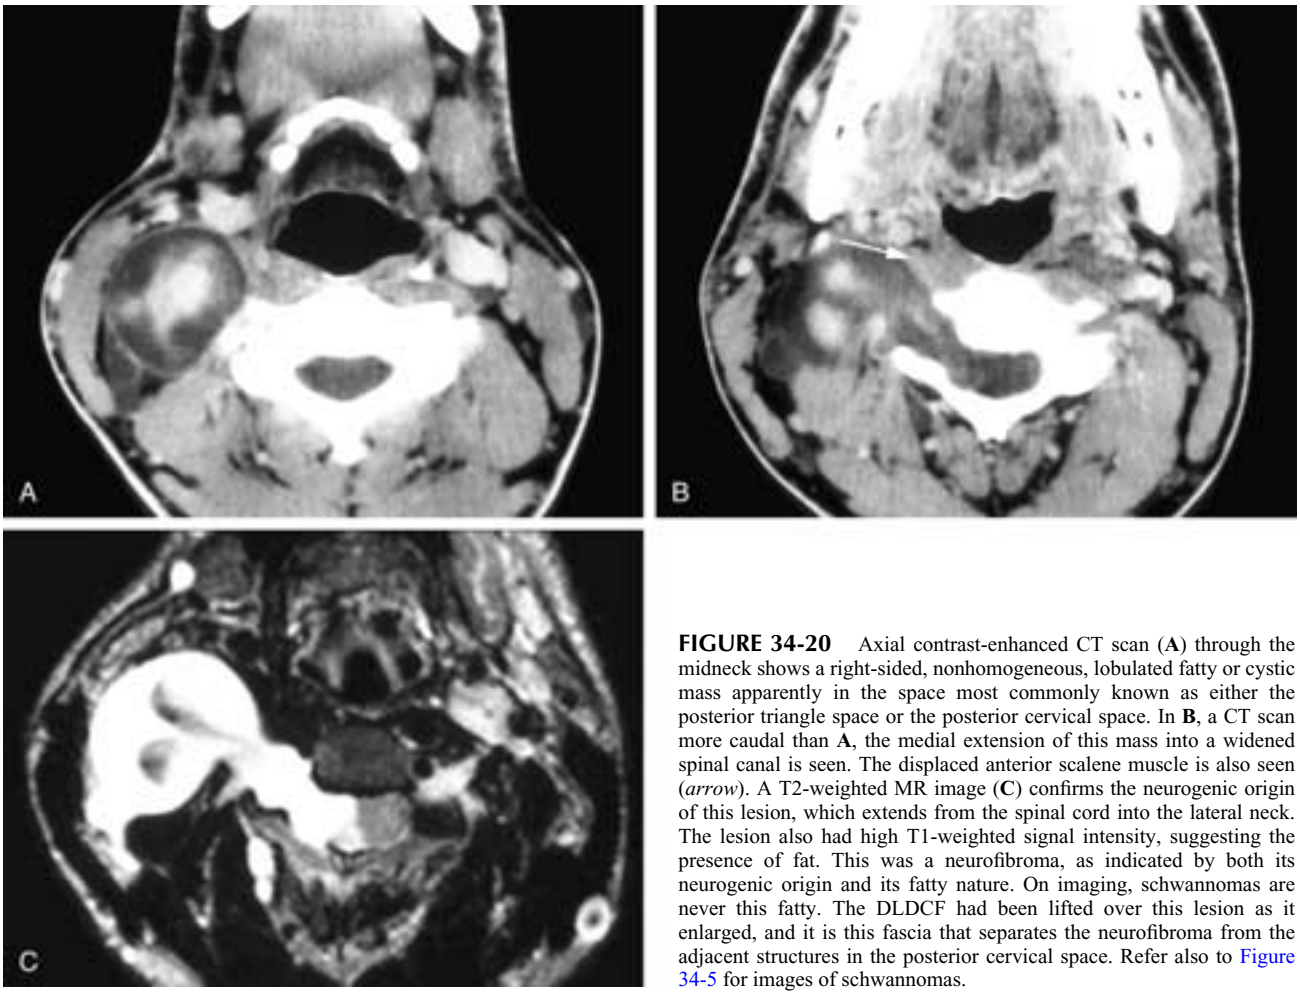

FIGURE 34-20 Axial contrast-enhanced CT scan (**A**) through the midneck shows a right-sided, nonhomogeneous, lobulated fatty or cystic mass apparently in the space most commonly known as either the posterior triangle space or the posterior cervical space. In **B**, a CT scan more caudal than **A**, the medial extension of this mass into a widened spinal canal is seen. The displaced anterior scalene muscle is also seen (*arrow*). A T2-weighted MR image (**C**) confirms the neurogenic origin of this lesion, which extends from the spinal cord into the lateral neck. The lesion also had high T1-weighted signal intensity, suggesting the presence of fat. This was a neurofibroma, as indicated by both its neurogenic origin and its fatty nature. On imaging, schwannomas are never this fatty. The DLDCF had been lifted over this lesion as it enlarged, and it is this fascia that separates the neurofibroma from the adjacent structures in the posterior cervical space. Refer also to Figure 34-5 for images of schwannomas.

Table 34-1
THE SPACES OF THE NECK AND THEIR CONTENTS

Space or Anatomic Region	Major Structures Either Within or Bordering Each Space
Superficial Fascia (subcutaneous tissues)	Subcutaneous fat, subcutaneous venules, lymphatics and nerves, platysma muscle, portions of anterior and external jugular veins
Visceral Compartment	
Retropharyngeal space	Pharynx, medial and lateral retropharyngeal lymph nodes, fat
Retrovisceral space (retroesophageal)	Esophagus, fat
Pretracheal space	Larynx, trachea, thyroid gland, parathyroid glands, recurrent laryngeal nerve, sympathetic trunk, level VI lymph nodes, thyroid arteries, fat
Danger Space	Fat, retropharyngeal and retroesophageal space in front, prevertebral space behind, parapharyngeal spaces on either side
Prevertebral Space	Anterior longitudinal ligament, cervical vertebrae and discs, longus coli and longus capitis muscles, phrenic nerve, fat
Carotid Sheath	Internal carotid artery, common carotid artery, internal jugular vein, cranial nerves IX, X, XI, XII, level II, III, and IV lymph nodes, fat
Space of the Body of the Mandible	Mandible, fat
Space of the Submandibular Gland	Submandibular gland, fat
Space of the Parotid Gland	Parotid gland, facial nerve, parotid lymph nodes, external carotid artery, retromandibular (posterior facial) vein, fat
Submandibular Space	
Sublingual space	Sublingual glands, deep portion (including hilum) of submandibular glands, Wharton's ducts, lingual artery, lingual vein, lingual nerve (sensory V3 and chorda tympani), cranial nerves XI and XII, fat
Submaxillary space	Superficial portion of the submandibular gland, anterior bellies of the digastric muscles, level I lymph nodes, facial artery, facial vein, fat

THE SPACES OF THE NECK AND THEIR CONTENTS *Continued*

Space or Anatomic Region	Major Structures Either Within or Bordering Each Space
Masticator Space	Medial pterygoid muscle, lateral pterygoid muscle, masseter muscle, temporalis muscle, ramus of mandible, branches of V3, fat
Parapharyngeal Space	Fat, ascending pharyngeal artery, internal maxillary artery, pterygoid venous plexus, branches of V3, cervical sympathetic trunk, minor salivary glands. Deep portion of parotid gland
Peritonsillar Space	Fat, palatine tonsil medially, parapharyngeal space laterally
''Paravertebral'' Space	Anterior middle and posterior scalene muscles, levator scapulae muscle, splenius capitus and splenius cervicus muscles, brachial plexus (roots), vertebral artery, vertebral vein, fat
''Posterior Triangle'' Space	Fat, cranial nerve XI, brachial plexus (trunks, divisions, and chords), dorsal scapular and long thoracic nerves, cutaneous nerves of the cervical plexus, level V lymph nodes

Table 34-2
THE SPACES OF THE NECK AS A BASIS FOR DIFFERENTIAL DIAGNOSIS

Space or Anatomic Region	Differential Diagnosis
Superficial Fascia (subcutaneous tissues)	Keloids; scars; subcutaneous fat necrosis of the newborn; lipomas; obstructed lymphatics and venules from edema, cellulitis, radiation therapy, surgery; schwannomas; neurofibromas, plexiform neurofibromas, pilomatrixoma, Merkel cell tumor; lymphoma, squamous cell and basal cell carcinomas
Visceral Compartment	
Retropharyngeal space	Medial and lateral retropharyngeal lymph adenopathy, cellulitis, phlegm, abscess, extension of goiter, extension of pharyngeal tumor
Retrovisceral space	Cellulitis, phlegm, abscess, extension of goiter, extension of esophageal tumor, extension of thyroid tumor
Pretracheal space	Tracheal, thyroid, laryngeal, and parathyroid tumors, goiter, recurrent laryngeal nerve or sympathetic trunk schwannomas, level VI lymph adenopathy, cellulitis, phlegm, abscess
Danger Space	Phlegm, abscess
Prevertebral Space	Cervical vertebral and disc disease, longus coli and longus capitis muscle tumors, phrenic nerve schwannoma, minor salivary gland tumors, cellulitis, phlegm, abscess
Carotid Sheath	Carotid artery arteritis, aneurysm, or dissection, internal jugular vein thrombosis or phlebitis, cranial nerve IX, X, XI, and XII schwannomas, paragangliomas, level II, III, and IV lymph adenopathy, cellulitis, phlegm, abscess
Space of the Body of the Mandible	Mandibular and odontogenic disease, cellulitis, phlegm, abscess
Space of the Submandibular Gland	Submandibular gland disease, cellulitis, phlegm, abscess
Space of the Parotid Gland	Parotid gland disease, facial nerve schwannoma, parotid lymph adenopathy, external carotid artery aneurysm, retromandibular (posterior facial) vein thrombosis and disease
Submandibular Space (sublingual space)	Sublingual gland disease, especially ranula, dermoid, lingual artery aneurysm, lingual nerve schwannoma, cranial nerve XI and XII schwannomas, lymphangioma, level I lymph adenopathy, facial artery and facial vein disease
Masticator Space	Medial pterygoid, lateral pterygoid, masseter, and temporalis muscle inflammatory disease and tumors, mandibular disease, V3 retrograde tumor or schwannoma, cellulitis, phlegm, abscess
Parapharyngeal Space	Deep portion of parotid gland tumors, V3 schwannomas, cervical sympathetic trunk disease, minor salivary gland tumors, paragangliomas, cellulitis, phlegm, abscess
Peritonsillar Space	Phlegm, abscess, extension of tonsillar tumor
''Paravertebral'' Space	Anterior middle and posterior scalene muscles, levator scapulae muscle, splenius capitus and splenius cervicus muscle disease, brachial plexus (roots) schwannomas, vertebral artery aneurysm, vertebral vein thrombosis, metastasis
''Posterior Triangle'' Space	Cranial nerve XI or brachial plexus (trunks, divisions, and chords) schwannomas, lymphangioma, level V lymph adenopathy

INTRODUCTION

In the proper clinical setting, congenital lesions must be considered in the differential diagnosis of a neck mass. Because there is a wide age range over which these congenital lesions can be identified, varying from the newborn to the older adult, it is important for the physician to be familiar with the specific anatomic and clinical presentations of these lesions so that appropriate and, when necessary, early therapy can be instituted. This chapter will discuss anomalies, and in particular cysts, related to the branchial, thymic, thyroid, parathyroid, and lymphatic primordia. In addition, hemangiomas, vascular malformations, teratoma/epidermoid/dermoid cysts, and other rare lesions including abnormalities of the sternocleidomastoid muscle are discussed.

THE BRANCHIAL ANOMALIES

The most accepted theories to explain the development of branchial abnormalities propose that they are either vestigial remnants resulting from incomplete obliteration of the branchial apparatus or the result of buried epithelial cell rests.[1, 2] A cell rest is a collection of displaced fetal cells embedded within tissue of another character. The vestigial remnant theory suggests that if any portion of the cervical sinus (of His), a branchial pouch, or a branchial cleft fails to

Copyright © 2003, Mosby, Inc. All rights reserved.

obliterate during embryogenesis, it can result in a cyst, sinus, or fistula. The cell rest theory suggests that if cells become trapped anywhere in the branchial apparatus during embryogenesis, they can grow and canalize to form branchial cysts, sinuses, or fistulas later in life.

The branchial anomalies are classified as either first, second, third, or fourth according to their proposed pouch or cleft of origin. A fifth-sixth branchial anomaly has never been reported. In most cases, surgical confirmation of the branchial arch involved is achieved by identification of the course of an associated fistula or sinus tract. However, in some cases without such surgical confirmation, the cysts may be less accurately classified on the basis of their anatomic location. Subtypes of some cysts have been proposed based on even more detailed anatomic considerations.[3, 4]

The malformations of the branchial apparatus are best understood as representing a spectrum of developmental anomalies that includes fistulas, sinuses, and cysts. As discussed in Chapter 33, the cervical sinus of His is formed shortly after the branchial arches appear by accelerated mesodermal growth cranially of the first arch and a portion of the second arch and caudally by growth of the epipericardial ridge, which develops from the mesoderm lateral to the fifth-sixth arch. As a result of these growths, within the cervical sinus of His are the caudal portion of the second arch and the third and fourth arches with their associated closing membranes. Continued growth around the cervical sinus of His narrows the external opening to the sinus into the channel-like cervical duct. Normally, the cervical duct and the ectoderm-lined cervical sinus of His are obliterated at about the seventh fetal week, resulting in a smooth, uniform contour to the external surface of the neck. In the adult, the cervical sinus of His is located at the angle between the dorsal surface of the infrahyoid strap muscles and the anterior margin of the sternocleidomastoid muscle.[5, 6]

Of specific interest is the observation that the epipericardial ridge, which forms the caudal aspect of the cervical sinus of His, contains the rudiments of the sternocleidomastoid muscle and the hypoglossal nerve (XII). Thus, based on this embryology, any communication persisting between the cervical sinus of His and the skin or the pharynx must lie ventral to the derivatives of the epipericardial ridge, namely, the sternocleidomastoid muscle and the hypoglossal nerve. In addition, the rare congenital absence of the sternocleidomastoid muscle is related to maldevelopment of the epipericardial ridge.[7, 8]

Branchial fistulas result when there is persistence of both a branchial cleft and its corresponding pharyngeal pouch forming an epithelium-lined single communication.[9] Such a communication never occurs during the normal development of a human embryo. The branchial fistula is thus a malformation that connects the skin to the lumen of the foregut. Since a fistula is formed from the cleft and pouch of a particular arch, and since the arch is always cranial to its cleft and pouch, the fistula must lie caudal to the structures derived from that arch. A branchial fistula may or may not communicate with a branchial cyst.

A branchial sinus is, in effect, a partial fistula that may open either externally or internally. Most often the sinus communicates externally; only rarely does it open internally. It may or may not communicate with a branchial cyst.

Branchial cysts are believed to be remnants of the cervical sinus of His, and a pure cyst has no internal or external communication. Branchial cysts are lined by stratified squamous epithelium of ectodermal origin. Less commonly, cysts can arise from branchial pouch endoderm; in this case, they are lined by columnar epithelium. Virtually all cysts have mesodermally derived lymphoid tissue in their walls. Thus, branchial cysts, fistulas, and sinuses can be lined by either stratified squamous, ciliated, or columnar epithelium, and all usually have lymphoid tissue in their walls.[10]

Branchial cysts typically present as recurrent tender masses, enlarging within days after an upper respiratory tract infection. Often initially treated with antibiotics, the cyst may resolve both to physical palpation and on imaging, only to enlarge again after the next infection. Alternatively, the cyst may be aspirated and disappear clinically for months, enlarging again when an upper respiratory tract infection develops. The patient's history often includes multiple such episodes before the diagnosis is finally established.

FIRST BRANCHIAL ANOMALIES

Of the first branchial cleft anomalies, which account for up to 8% of all branchial anomalies, 68% are cysts, 16% are sinuses, and 16% are fistulas.[5, 11, 12] They may be the most difficult anomalies to conceptualize because of the complex role played by the first branchial apparatus in the embryology of facial development, as discussed in Chapter 1. Possibly because of this complicated embryologic role, the anatomic locations of the first arch anomalies are less predictable than those of the second, third, and fourth branchial arches. Arnot in 1971 suggested that there are two types of anomalies.[3] He defined a type I anomaly as a cyst or sinus in the parotid gland lined with squamous epithelium and clinically appearing in early adult life. His type II anomaly was a sinus or cyst in the anterior triangle of the neck that had a communicating tract to the external auditory canal. In 1972, Work reclassified the first arch anomalies into two types.[4] He defined a type I anomaly to be of ectodermal origin, and he considered it a duplication of the external auditory canal. His type II anomaly was a duplication anomaly of the membranous external auditory canal and pinna that contained both ectodermal (skin) and mesodermal (cartilage) derivatives. Both types of anomalies are related to the parotid gland.[5] Of these two classifications, Work's is more widely accepted today. However, in 1980, Olsen et al. reviewed 38 cases and concluded that it was difficult to subclassify all of the anomalies into one of these subtypes, and that it was probably better to consider the locations of first arch anomalies as a spectrum of malformations.[13, 14] Nonetheless, today most physicians consider a type I first branchial anomaly as a lesion in the preauricular region whose distal portion may be either anterior or posterior to the pinna. These lesions tend to be parallel to the external auditory canal, lateral to the facial nerve (VII), and they may be embedded in the parotid gland (Fig. 35-1A). There can be a cyst, sinus, or fistula, with a tract connecting to the external auditory canal. A type II first branchial cleft anomaly is usually situated immediately posterior or inferior

FIGURE 35-1 **A**, Oblique drawing of an embryo showing the location of a first branchial cyst located in the upper portion of the parotid gland. This is classified as a type I first branchial cyst. **B**, Oblique drawing of an embryo showing a first branchial cleft cyst located in the lower portion of the parotid gland. This is classified as a type II first branchial cyst.

to the angle of the mandible; it may lie lateral to, medial to, or between the branches of the facial nerve within the parotid gland (Fig. 35-1B). Its tract connects to the external auditory canal. Because of this relationship to the parotid gland, complete excision usually requires that a superficial parotidectomy be performed to expose the branches of the facial nerve.

The sinuses, fistulas, and cysts related to the first arch most often originate along the course of the external auditory canal, but have rarely been reported to originate in the middle ear cavity or nasopharynx. The anomalies that approach or involve the external auditory canal most commonly terminate at the junction of the cartilaginous and bony portions of this canal and can extend either anterior or posterior to the pinna.[2, 15] This variable position relative to the pinna is explained by the fact that the pinna itself has a multifocal origin, arising from the union of six mesenchymal proliferations or hillocks, three on either side of the first pharyngeal cleft. In addition, once formed, the pinna migrates from its initial location on the caudal and ventral side of the face to its final more cranial and dorsal adult location. Thus, the pinna has contributions from the first and second arches and the first branchial groove, which are the sites of origin of these anomalies. That is, the pinna lies in the center of this development and migration. Since conceptually a first branchial malformation may occur anywhere along the course of migration of the pinna, the rare occurrence of a first arch anomaly near the angle of the mandible is explained by its location near the initial site of pinna development.

As discussed in Chapter 33, between the sixth and eighth weeks of fetal development, the parotid gland forms from ectoderm within the mouth that branches dorsally and cranially toward the ear. At the same time, the facial nerve and associated second arch musculature are migrating ventrally and caudally. Because the facial nerve and parotid gland have a somewhat later embryologic development, a vestigial first branchial anomaly can insinuate itself in a variable relationship to the parotid gland and the facial nerve. Thus, these anomalies have been reported to be within, superficial to, or deep to the parotid gland.

Occasionally, isolated cysts may occur within the parotid gland. Such cysts may represent a first branchial cyst without a sinus or fistulous tract. However, as discussed in Chapter 39, such a cyst may also represent a lymphoepithelial cyst, presumably developed in response to chronic inflammation.[16]

On imaging, these first branchial cysts are usually related to the parotid gland and/or the lower margin of the pinna (Figs. 35-2). If a tract directed toward the external auditory canal can be identified, the diagnosis is established. However, if a tract is not seen and the cyst lies within the parotid gland, the final diagnosis could be either a first branchial cyst, a lymphoepithelial cyst, or a rare localized obstructive mucocele or sialocele. In all of these cases, the cyst contents usually are of mucoid attenuation on CT (10 to 25 HU), while on MR imaging there usually is low to intermediate T1-weighted and high T2-weighted signal intensity. If the cyst is infected and has a tract, coronal T2-weighted and postcontrast T1-weighted, fat-suppressed MR images may best demonstrate the tract. It is only on the contrast-enhanced images that the cyst wall can be clearly identified on MR imaging.

GENERAL CONCEPTS REGARDING SECOND, THIRD, AND FOURTH ARCH ANOMALIES

As Bailey had suggested in 1929, to best understand the second, third, and fourth branchial anomalies, they should be considered to represent a spectrum of manifestations that range from a fistula to an isolated cyst.[17] According to Fraser, the only way to truly determine the branchial level of origin of these vestigial structures is by careful anatomic examination, the most important considerations for each cyst, sinus, or fistula being (1) its connection with the foregut derivatives and (2) its relationship to both the main vascular (the carotid arteries and the aorta) and neural components (cranial nerves IX, X, XI, and XII).[18] Thus, if the arteries have a normal embryologic development, these relationships are absolutely fixed, and one can reliably predict the branchial level of origin of the malformation. Therefore, for each of the second, third, and fourth arch anomalies, the course of the entire fistula will be discussed, realizing that a branchial cyst can occur anywhere along each described course. These cysts are usually filled with turbid straw-colored fluid that contains cholesterol products.

SECOND BRANCHIAL ANOMALIES

Between 92% and 99% of branchial anomalies arise from the second branchial apparatus, and cysts are far more common than sinuses or fistulas.[9, 19] When a sinus or fistula is present, nearly 80% of the time the opening is to the skin. The external opening for a second branchial fistula is typically along the anterior border of the sternocleidomastoid muscle at the junction of its middle and lower thirds. The tract runs deep to the platysma muscle, ascends lateral to the carotid sheath, and courses lateral to and above the hypoglossal nerve (XII) and the glossopharyngeal nerve (IX). It then passes between the external and internal carotid arteries to end in the region of the palatine tonsillar fossa, a second pouch derivative (Fig. 35-3).[5] The fistula's relationship to the carotid arteries is explained embryologically by noting that when the first and second arch vessels disappear, the third arch vessel, which becomes the common carotid artery and proximal internal carotid artery, remains as the most cephalic vessel to persist.[15] The more distal internal carotid artery is formed by the dorsal aorta. Because the external carotid artery arises from a persistence of the ventral aorta or the surrounding mesenchyme, a second branchial fistula, which is formed above the third arch, must pass between the internal and external carotid arteries.

Bailey classified second branchial cleft cysts into four types.[17, 20] A type I cyst lies beneath the platysma and cervical fascia but anterior to the sternocleidomastoid muscle. It is believed to originate from a remnant of the tract connecting the cervical sinus of His to the skin. The type II cyst, which is the most common, originates from persistence of the cervical sinus of His and therefore technically could be considered a cyst of the combined second, third, and fourth branchial arches. It characteristically lies adjacent to the great vessels and may be adherent to them. The type III cyst courses between the internal and external carotid arteries and extends to the lateral wall of the pharynx. The type IV cyst, a columnar-lined cyst lying against the

FIGURE 35-3 Lateral drawing of a second branchial cyst. Note that its tract enters in the region of the palatine tonsil.

pharyngeal wall, is believed to form from a remnant of the pharyngeal pouch. Type III and IV cysts can occasionally grow large, with elongations coursing cranially as far as the base of the skull.

Most second branchial cysts are first diagnosed when patients are between the ages of 20 and 40 years. Most often these cysts develop shortly after an upper respiratory tract infection, secondary to stimulation of the lymphoid tissue present in the cyst wall. Typically, the cyst is located in the lateral neck, superficial to the carotid sheath, dorsal to the submandibular gland, and ventral to the anterior edge of the sternocleidomastoid muscle. As these cysts enlarge, they may displace the submandibular gland anteriorly, while posteriorly the cysts extend deep to the sternocleidomastoid muscle (Fig. 35-4).

On CT, a noninfected cyst typically appears as a mucoid attenuation (10 to 25 HU) cyst with a uniformly thin, smooth wall. On MR imaging, the cyst typically has a low to intermediate T1-weighted and a high T2-weighted signal intensity. However, some cysts can have high T1-weighted signal intensity that may be related to chronic infection (Fig. 35-5). These variations in signal intensity reflect alterations in the protein content of the cyst.

If infected, the cyst wall becomes thickened and irregular, and it enhances with contrast (Fig. 35-6). Without clinical correlation, the imaging appearance is similar to that of a suppurative or metastatic lymph node (Fig. 35-7). Rarely, the inflamed walls of a sinus or fistulous tract can be seen, and there may be an associated thickening of the ipsilateral palatine tonsillar fossa (Fig. 35-6A).

Occasionally, septations can be seen on imaging within the cyst contents. Although septations usually occur after aspirations of the cyst, they can also be seen in nonmanipulated cysts. In addition, bleeding can occur into a cyst, usually correlating with a sudden enlargement of the cyst. The blood can increase the CT attenuation over that of muscle. On MR imaging, both the T1- and T2-weighted signal intensities are high.

THIRD BRANCHIAL ANOMALIES

The remaining branchial anomalies are rare. A complete third branchial fistula has a cutaneous opening along the anterior border of the sternocleidomastoid muscle, usually more caudal than the opening for a second branchial anomaly. The tract then courses cranially and dorsal to the common or internal carotid artery, cranial to the hypoglossal nerve (XII), and caudal to the glossopharyngeal nerve (IX), and then extends medially to pierce the posterolateral thyrohyoid membrane and open into the upper lateral piriform sinus. The tract opening into the thyrohyoid membrane is most often superior to the opening for the internal branch of the superior laryngeal nerve (Fig. 35-8).

The position of the tract dorsal to the proximal common carotid artery is a result of its cleft and pouch precursors arising dorsal to this vessel's origin from the ventral aorta. In addition, as noted earlier, the structures derived from a branchial arch lie cranial to the cleft and thus cranial to a fistula of the same arch. Involution of the dorsal aorta, a posterior structure between the third and fourth arches, enables a third branchial fistula to pass posterior to the distal common carotid and proximal internal carotid arteries. The tract passes anterior to the vagus nerve (X) and above the hypoglossal nerve (XII) but below the glossopharyngeal nerve (IX). This is to be expected since the glossopharyngeal nerve innervates the third arch derivatives and must therefore lie cranial to them. The tract ends in the thyrohyoid membrane, which extends between the third arch derivative hyoid bone (inferior portion of the body and greater cornua) and the fourth arch derivative thyroid cartilage, precisely at the level of the third pouch. The fistula then enters the piriform sinus and, as can be expected, lies above the internal branch of the superior laryngeal nerve—the nerve of the fourth branchial apparatus.

On imaging, the third branchial cyst is identified either in the same region as a second branchial cyst or slightly lower in the neck along the anterior edge of the sternocleidomastoid muscle and lateral to the carotid sheath. If the cyst is infected, there may be localized edema of the ipsilateral hypopharyngeal wall (Fig. 35-9). Its other imaging characteristics are similar to those of a second branchial cyst.

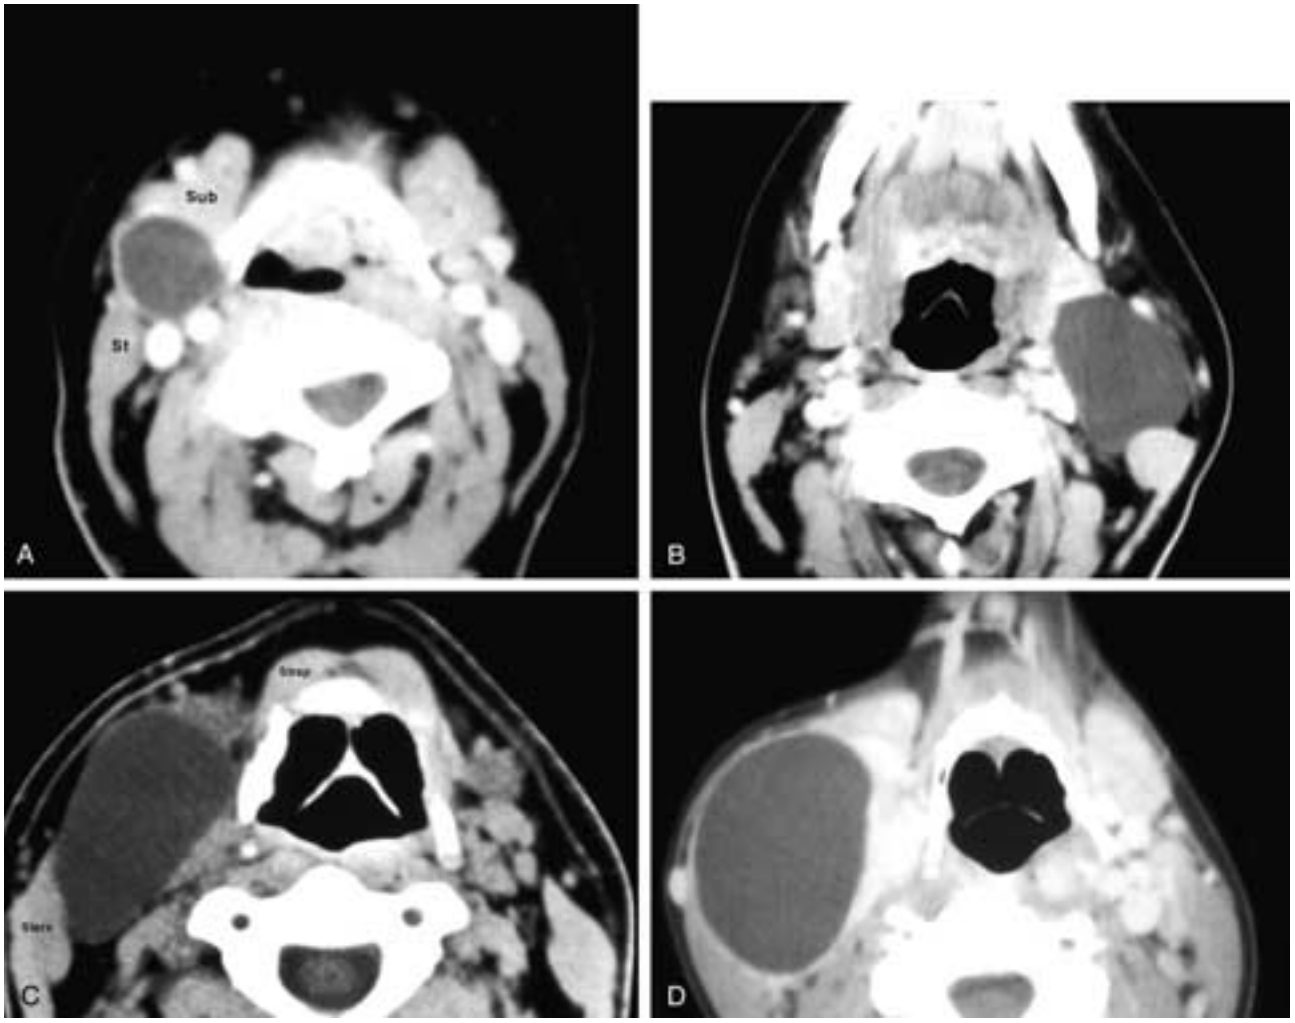
Thymic Anomalies

The normal development of the thymus, a third pouch derivative, is discussed in Chapter 33. Several anomalies of the thymus are attributed to abnormal embryologic descent of the thymic primordium into the mediastinum. These

Copyright © 2003, Mosby, Inc. All rights reserved.

anomalies can result from incomplete descent of the thymus into the chest, sequestration of thymic tissue being retained along the normal thymic pathway during descent, or failure of involution of the thymopharyngeal duct. Thymic tissue may be associated with an epithelial tract that communicates with the pharynx through the thyrohyoid membrane or it may maintain a connection with the thymus gland in the mediastinum. Thymic tissue may occur in the lateral neck, anterior or deep to the sternocleidomastoid muscle, and as such, it may be clinically similar to a branchial cyst. It also may occur as a mass in relationship to the piriform sinus. Thymic cysts are diagnosed by the presence of thymic tissue on histologic examination.[5, 21–26]

Two theories exist concerning the pathogenesis of aberrantly located thymic cysts. One theory suggests that the cysts result from acquired progressive cystic degeneration of epithelial remnants or Hassall corpuscles.[4] Histologically, there are Hassall corpuscles in a thymic cyst wall; however, the cause of such presumed degeneration is uncertain. The other, more popular theory states that the cysts represent persistence of portions of the thymopharyngeal duct and, uncommonly, a cyst may occur that extends from the upper neck caudally into the lower neck or even the anterior mediastinum. Such cysts are referred to as thymopharyngeal cysts, presumably following the course of a nonresorbed thymopharyngeal duct. It is interesting to note that the majority of these anomalies are found on the left side of the neck.



VIEW IMAGE

FIGURE 35-4 **A**, Axial contrast-enhanced CT scan shows a uniformly thin-walled right neck cyst positioned lateral to the carotid sheath structures, behind the right submandibular gland (*Sub*), and along the anterior border of the sternocleidomastoid muscle (*St*). This second branchial cleft cyst was located just caudal to the angle of the mandible. **B**, Axial contrast-enhanced CT scan shows a left neck cyst just behind the submandibular gland, lateral to the carotid sheath structures, along the anterior border of the sternocleidomastoid muscle, at or just caudal to the level of the angle of the mandible. This was a first branchial cleft cyst. **C**, Axial CT scan shows a large right neck cyst behind the submandibular gland, lateral to the carotid sheath structures, and just caudal to the level of the angle of the mandible. As this second branchial cleft cyst enlarges, the unseen superficial layer of the deep cervical fascia (extending from the sternocleidomastoid muscle (*Stern*) to the strap muscles (*Strap*) puts pressure on the cyst and pushes it dorsally deep to the Stern muscle. **D**, Axial contrast-enhanced CT scan shows a huge right second branchial cleft cyst lateral to the carotid sheath structures, behind the submandibular gland, just caudal to the level of the angle of the mandible, and partially deep to the sternocleidomastoid muscle (see **B**).

FIGURE 35-7 Axial contrast-enhanced CT scan shows a ''cyst'' in the right neck, completely deep to the sternocleidomastoid muscle, dorsal to the carotid sheath structures, and not touching the submandibular gland. Clinically, this was thought to be a second branchial cleft cyst, but the location of the lesion on the image is not that of a second branchial cleft cyst. This was a metastatic papillary thyroid carcinoma lymph node.

About two thirds of the cases of cervical thymic cyst occur in the first decade of life, and the remaining cases are distributed over the second and third decades. They can present anywhere in the neck from the angle of the mandible to the sternum, usually paralleling the sternocleidomastoid muscle. Most occur in the lower neck as a slowly enlarging mass, and sudden enlargement usually signifies hemorrhage into the cyst. The cysts may be isolated from the normal thymic tissue or attached to it by a fibrous band. Unlike mediastinal thymic cysts, cervical thymic cysts are not associated with myasthenia gravis.[27]

On imaging, a cervical thymic cyst usually appears as a solitary, off-midline, low anterior neck cyst, either adjacent to the lower piriform sinus or just caudal to the thyroid gland (Fig. 35-10). There usually is no demonstrable connection to the thymus in the anterior mediastinum. The cyst wall is thin and uniformly smooth, and the cyst contents are of mucoid attenuation (10 to 25 HU) on CT. On MR imaging, the cyst contents usually have low to intermediate T1-weighted and high T2-weighted signal intensity.

Although the inferior parathyroid glands develop from the third pharyngeal pouch endoderm, for the sake of brevity the abnormalities of the parathyroid glands will be discussed with the fourth arch anomalies, since the fourth arch contributes to the superior parathyroid glands.

FOURTH BRANCHIAL ANOMALIES

There are only a few documented complete fourth branchial fistulas. In 93% of the reported cases, the anomaly occurred on the left side and recurrent episodes of a low neck abscess or thyroiditis suggested the diagnosis.[28] The anomaly is most often diagnosed in a child, although it can present in an adult. The cutaneous opening is along the anterior border of the sternocleidomastoid muscle, usually along the lower third of the muscle and caudal to the openings of the second and third arch anomalies. On the left side, the tract courses superiorly to loop over the hypoglossal nerve (XII), extends between the internal and external carotid arteries, descends in the neck posteriorly to the common carotid artery, loops posteriorly around the aortic arch, and then ascends lateral to the trachea and the recurrent laryngeal nerve to end in the apex of the piriform sinus. On the right side, the fistula passes beneath the subclavian artery and then ascends to the apex of the piriform sinus (Fig. 35-11). These varied courses are explained by noting that a branchial fistula must pass inferior to its arch structures and the associated nerves and vessels of the same arch. Because the left fourth arch artery forms the aorta while the right fourth artery forms the subclavian artery, the fistulas descend respectively beneath the arch or subclavian artery anteriorly, then loop around the vessel posteriorly to extend cranially. Because the superior laryngeal nerve develops in association with the fourth arch and the recurrent laryngeal nerve with the sixth arch, a complete fourth branchial fistula passes inferior to the superior laryngeal nerve and superior to the recurrent laryngeal nerve.[29] It penetrates the thyrohyoid membrane behind the internal branch of the superior laryngeal nerve, unlike the more anterior third branchial fistula.[30] The tract then empties into the apex of the piriform sinus, more caudal than its third branchial counterpart.[31–35]

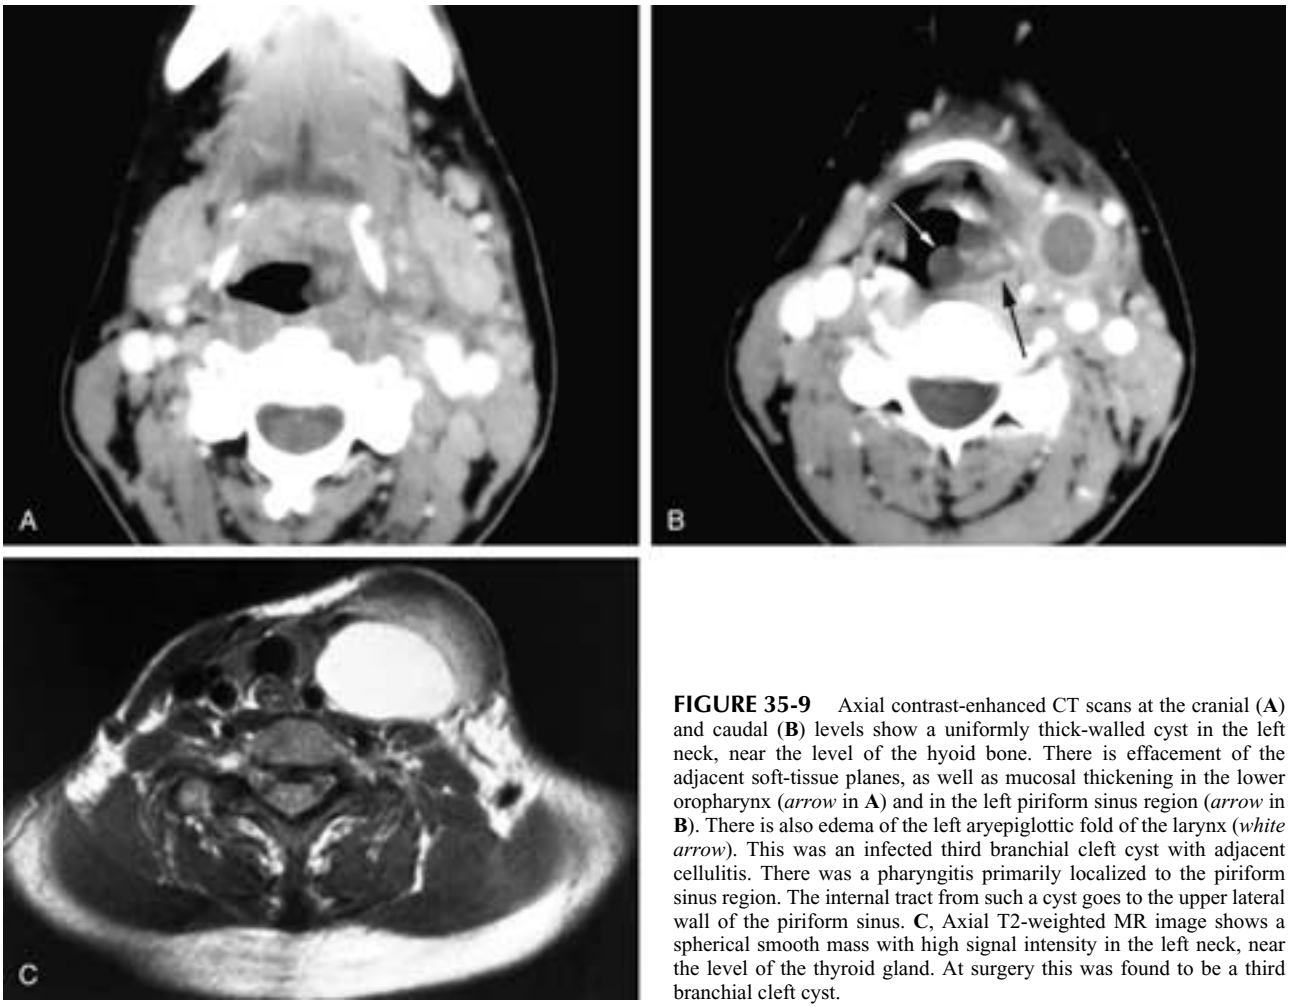

FIGURE 35-9 Axial contrast-enhanced CT scans at the cranial (**A**) and caudal (**B**) levels show a uniformly thick-walled cyst in the left neck, near the level of the hyoid bone. There is effacement of the adjacent soft-tissue planes, as well as mucosal thickening in the lower oropharynx (*arrow* in **A**) and in the left piriform sinus region (*arrow* in **B**). There is also edema of the left aryepiglottic fold of the larynx (*white arrow*). This was an infected third branchial cleft cyst with adjacent cellulitis. There was a pharyngitis primarily localized to the piriform sinus region. The internal tract from such a cyst goes to the upper lateral wall of the piriform sinus. **C**, Axial T2-weighted MR image shows a spherical smooth mass with high signal intensity in the left neck, near the level of the thyroid gland. At surgery this was found to be a third branchial cleft cyst.

VIEW IMAGE

A fourth branchial pouch cyst adjacent to the larynx, like a third branchial pouch cyst, must be clinically differentiated from a laryngocele. As mentioned, the literature supports the belief that a branchial cyst arising from the apex of the piriform sinus is more likely to be a fourth pouch remnant. Branchial cysts in the mediastinum without a connection to the larynx or the neck have also been described.[36] Such a cyst could represent either a fourth or fifth-sixth branchial remnant, depending on whether the remnant passes clearly beneath the aorta (fourth arch) or the pulmonary artery (fifth-sixth arch), respectively.

On imaging, a fourth branchial cyst usually appears as a solitary, often infected, cyst just anterior to the thyroid gland, usually on the left side. The adjacent thyroid lobe is involved, and on CT it has a lower attenuation, reflecting infection and the loss of iodine concentration (Fig. 35-12). On MR imaging, as a result of infection, there usually is high T2-weighted signal intensity within the involved thyroid. Rarely, there can be swelling of the ipsilateral hypopharynx reflecting a pharyngitis.

Parathyroid Anomalies

The normal development of the parathyroid glands was discussed in Chapter 33. As a result of that embryology, parathyroid cysts or aberrant glands can be located anywhere around the thyroid gland and are most commonly found inferior to the gland. Because of their proximity to the thymic primordia (particularly for the inferior parathyroid glands), these anomalies can be situated anywhere a thymic anomaly can be found, including the mediastinum.

Various theories have been proposed to explain the pathogenesis of parathyroid cysts, suggesting that these cysts arise from embryologic remnants of third and fourth pharyngeal pouches, cystic degeneration of parathyroid adenomas, gradual enlargement of microcysts as a result of accumulation of secretions, or fusion or coalescence of smaller microcysts. Although most parathyroid cysts are not associated with biochemical anomalies, nearly one third of them have been reported to be functioning and associated with hyperparathyroidism.[27, 37, 38]

Parathyroid cysts comprise only 0.6% of all thyroid and parathyroid masses. Although most patients present with an asymptomatic low neck mass, tracheal and esophageal compression can occur, as can hoarseness secondary to recurrent laryngeal nerve compression. Pain associated with hemorrhage into the cyst has also been reported.[39] Nearly 95% of parathyroid cysts occur below the level of the inferior thyroid border, and 65% are associated with the inferior parathyroid glands. However, these cysts can occur

Copyright © 2003, Mosby, Inc. All rights reserved.

anywhere from the angle of the mandible down to the mediastinum.[40, 41]

The cyst wall usually is composed of a solitary layer of cuboidal or low columnar epithelium, with scattered chief or oxyphil parathyroid cells. Some cysts have no parathyroid tissue in their wall, but analysis of the fluid content shows elevated parathyroid hormone levels.

The nonfunctioning cysts affect patients with a mean age of 43.3 years and are three times more likely to occur in women than in men. These cysts almost always involve the inferior parathyroid glands.[39] The functioning cysts, which represent about one third of these cysts, occur more commonly in men by a ratio of 1.6:1, affect patients with a mean age of 51.9 years, and tend to occur in the superior parathyroid glands or in ectopic locations.

On imaging, although both multiloculated and multiple cysts can occur, most often there is a solitary unilocular cyst just inferior to the thyroid gland in the anterior neck, varying in size from 1 to 10 cm (Fig. 35-13). A cleavage plane usually is seen between the cyst and the thyroid gland, making excision relatively easy. The cysts contain mucoid attenuation (10 to 25 HU) material and have a thin, uniform rim. On MR imaging, the signal intensities vary from low to high on T1-weighted images, and there is a high T2-weighted signal intensity. Rarely, an adenoma can be visualized within the cyst.[27]

FOURTH TO SIXTH BRANCHIAL ANOMALIES

Laryngeal Anomalies

The fourth branchial apparatus contributes to the embryology of the larynx, and the development of this structure is discussed in Chapter 33. The congenital abnormalities of the larynx are discussed in detail in Chapters 30 and 31.

NONBRANCHIAL ANOMALIES

Thyroid Anomalies

The embryology of the thyroid gland is discussed in detail in Chapter 33. The anomalies of the gland are varied and can present as complete or unilateral agenesis, an abnormality due to altered migration or incomplete degeneration, or an abnormality resulting from incomplete glandular descent that can lead to remnants of ectopic thyroid tissue anywhere along the course of the thyroglossal duct. During embryologic descent of the thyroid anlagen, the forming gland interacts with the developing branchial pouches, particularly the third and fourth pouches from which the parathyroid glands originate, as well as the ultimobranchial body, which is thought to contribute to the lateral thyroid

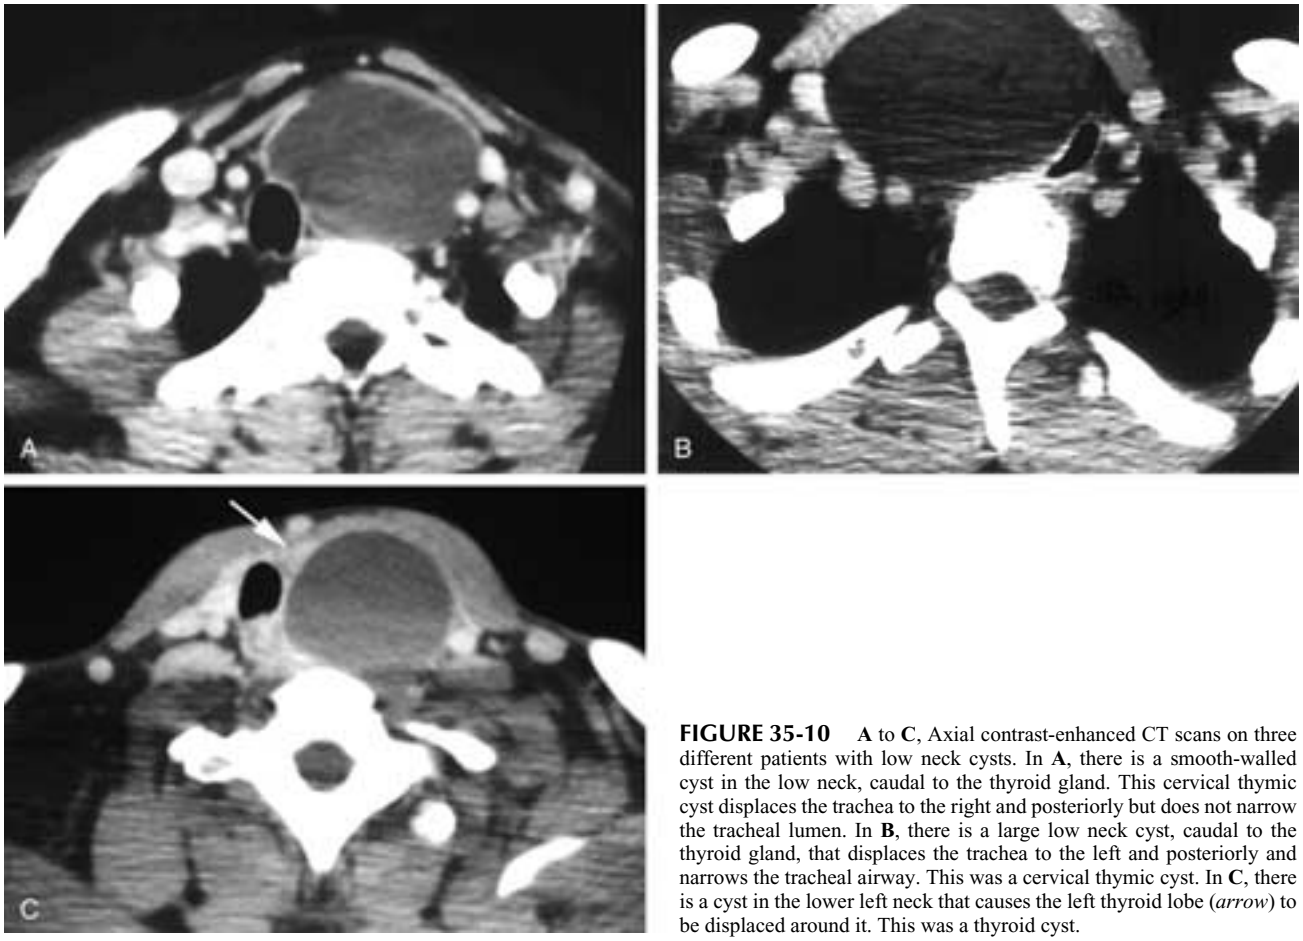

FIGURE 35-10 **A** to **C**, Axial contrast-enhanced CT scans on three different patients with low neck cysts. In **A**, there is a smooth-walled cyst in the low neck, caudal to the thyroid gland. This cervical thymic cyst displaces the trachea to the right and posteriorly but does not narrow the tracheal lumen. In **B**, there is a large low neck cyst, caudal to the thyroid gland, that displaces the trachea to the left and posteriorly and narrows the tracheal airway. This was a cervical thymic cyst. In **C**, there is a cyst in the lower left neck that causes the left thyroid lobe (*arrow*) to be displaced around it. This was a thyroid cyst.

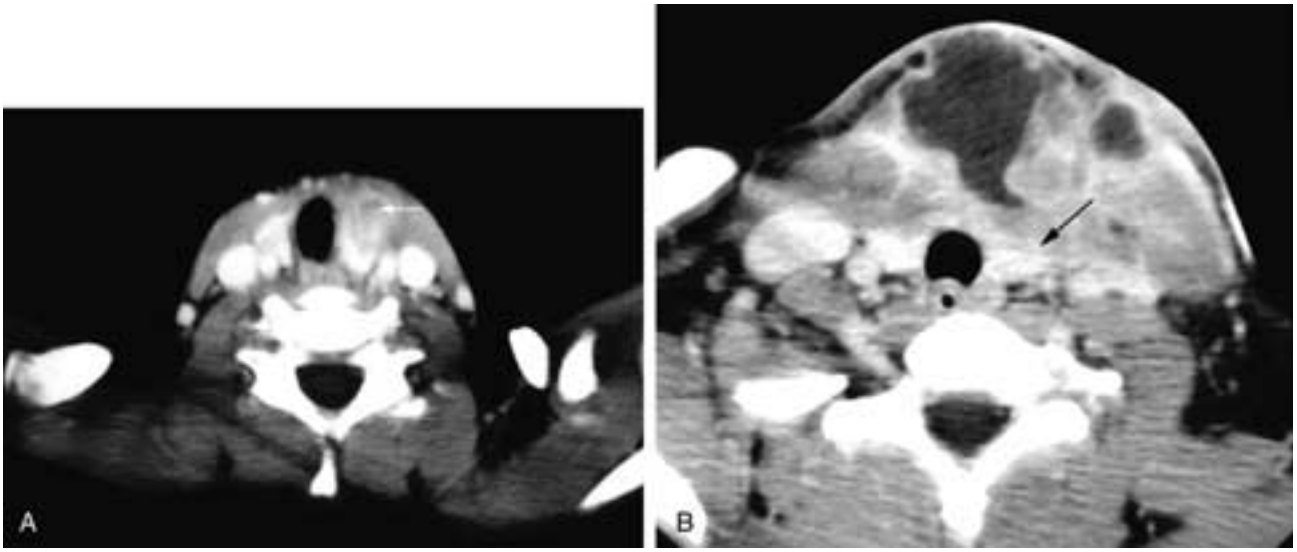
anlage. Possibly as a result of the early embryologic position of the heart and great vessels relative to the developing branchial region, ectopic thyroid tissue may become located in the larynx, esophagus, lateral neck, mediastinum, pericardium, or heart.

Complete absence or agenesis of the thyroid gland is poorly understood because of the lack of any morphologic information. The complete lack of a thyroid gland at birth can be due either to congenital absence or possibly destruction in utero secondary to maternal antithyroid antibodies.[42, 43] When there is a congenitally absent thyroid, this anomaly appears to be quite specific, and there are no other associated anomalies of the branchial region.



VIEW IMAGE

FIGURE 35-12 In **A**, there is a low-attenuation region (*arrow*) in the left neck. Associated with this process is effacement of the adjacent soft-tissue planes and extension of the process into the left thyroid lobe. The patient was a young child with a recurrent low neck abscess and clinical thyroiditis. At surgery, the lesion was found to be an infected fourth branchial cleft cyst with a tract extending to the apex of the left piriform sinus. In **B**, there is a low-attenuation region with an enhancing rim in the left side of the neck. There is associated cellulitis involving the anterior neck and the left thyroid lobe (*arrow*) is affected, having slightly lower attenuation than the normal right thyroid lobe. The patient was a young child with a recurrent low neck abscess and clinical thyroiditis. At surgery, the lesion was found to be an infected fourth branchial cleft cyst with a tract extending to the apex of the left piriform sinus.

The term *congenial hypothyroidism* refers to hypothyroidism present at birth. The etiologies are diverse and can be either congenital or acquired. One of the more common congenital etiologies is congenital dyshormonogenesis, which is caused by an enzyme defect in the synthesis of thyroglobulin, the matrix protein for thyroid hormone synthesis in the thyroid gland.[44] Other causes include thyroid agenesis or dysgenesis, congenital goiter due to maternal drug ingestion or the ingestion of iodide, genetic defects in thyroid hormone synthesis and metabolism, congenital endemic goiter, familial transient hypothyroidism secondary to transplacental thyrotropin-blocking antibodies, transient primary hypothyroidism in a sick premature newborn, and familial thyroid-stimulating hormone deficiency.[45, 46]

The adult thyroid gland can vary in both form and size.[47] Asymmetry in the size of the two lobes is very common, with the right lobe usually being longer than the left. True thyroid hemiagenesis is reported to be very uncommon and usually occurs on the left side.[48] More commonly, there are a variety of pathologic conditions that can render a lobe nonfunctioning, mimicking hemiagenesis on a radionuclide thyroid scan. Thyroid pathology is discussed in Chapter 40.

Thyroglossal Duct Anomalies

For a short time, the developing thyroid gland is connected to the tongue by a narrow tube, the thyroglossal duct. This duct courses from the region of the junction of the anterior two thirds and posterior one third of the tongue to the hyoid bone and then farther caudally to the region of the thyroid bed (Fig. 35-14). The thyroglossal duct begins to degenerate or atrophy between the fifth and sixth fetal weeks, and the foramen cecum of the tongue and the pyramidal lobe of the thyroid gland are the normal remnants of this duct, respectively occurring at its most proximal and most distal portions. The pyramidal lobe is a band of thyroid tissue that can be attached to the isthmus in the midline or project off either thyroid lobe, more often on the left side. It can extend up to the hyoid bone. Uncommonly, the pyramidal lobe can be detached from the main thyroid gland or it can be divided into two or more parts. The distal thyroglossal duct can also differentiate into fibrous tissue or even into a muscle referred to as the levator glandulae thyroidae, originating in the midline above at the body of the hyoid bone and extending either to the isthmus of the thyroid gland or to the pyramidal lobe.

VIEW IMAGE

FIGURE 35-14 Lateral diagram traces the course of the thyroglossal duct cyst from the foramen cecum (*F*) downward, at first ventral to the hyoid bone and then dorsal to the hyoid bone. The duct then descends in the neck to the level of the normal thyroid bed (*T*).

The most common congenital neck mass is the thyroglossal duct cyst, which accounts for nearly 90% of nonodontogenic congenital cysts.[10, 49] This usually midline or near-midline lesion can occur anywhere along the path of the duct and probably is due to a rest of secretory epithelial cells that fails to involute and, when stimulated by an inflammatory process, causes a cyst to develop. The distribution of these cysts in the neck is 20% to 25% in the suprahyoid neck, 15% to 50% at the level of the hyoid bone, and 25% to 65% in the infrahyoid neck.[10] Thus, these cysts most commonly occur near the hyoid bone, and they can be either superior, anterior, inferior, or posterior to this bone. This is explained by noting that during its maturation, the hyoid bone rotates (in a counterclockwise direction, as seen from the left side) before assuming its final adult position. During this rotation, the thyroglossal duct, which is adherent to the hyoid along its anterior inferior edge, may be drawn posteriorly and cranially to lie behind the body of the hyoid bone.[50] Rarely, the duct can be incorporated into the hyoid bone, presumably trapped between the second and third arch components of the hyoid's body.[51] Noting this close relationship between the thyroglossal duct and the body of the hyoid bone, Sistrunk proposed that the body of the hyoid bone should be removed during surgical resection of a thyroglossal duct cyst. When this was done, recurrences were reduced from nearly 50% to less than 4%.[52]

As mentioned, thyroglossal duct cysts are the most common midline neck mass, and 75% of them occur near the midline.[10] The lining of the cyst may be stratified squamous, pseudostratified ciliated, simple cuboidal, or columnar epithelium, and there may be residual thyroid tissue in the cyst wall.[53] The typical history is that of a gradually enlarging mass in the midline of the neck. The size of the mass may fluctuate with cyst infection, and fistulas are rare in patients who have not been operated on. Rarely, the cyst can rupture, and occasionally a residual portion of the duct can form a sinus or even a branched sinus tract.[54, 55] Although these are congenital lesions, with nearly 50% of patients being diagnosed before the age of 30 years, 15% are diagnosed in patients older than 50 years.

On imaging, those cysts that occur in the suprahyoid neck are almost always in the midline, and most lie immediately adjacent to the hyoid bone, often remodeling it (Fig. 35-15). Rarely, a lateral suprahyoid thyroglossal duct cyst can occur, clinically mimicking a second branchial cyst. However, these thyroglossal duct cysts have a medial tail-like component that ''dives'' into the hyoid bone, thus differentiating them from a branchial cyst (Fig. 35-16). If the cyst occurs just caudal to the hyoid bone, it lies at the level of the

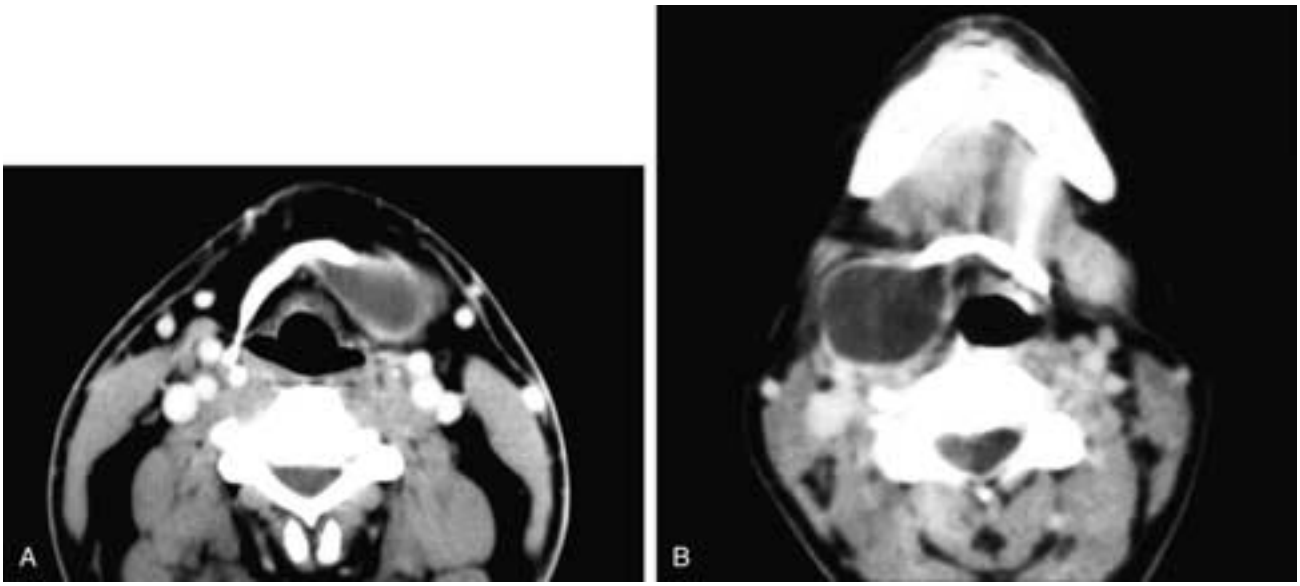
FIGURE 35-15 Axial contrast-enhanced CT scans at the cranial level (**A**) and a more caudal level (**B**). There is a midline thin-walled cyst in the region of the floor of the mouth. The caudal aspect of the cyst touches the hyoid bone and slightly remodels the anterior margin of this bone. This was a thyroglossal duct cyst.

thyrohyoid membrane of the larynx. These cysts can stretch this membrane, bowing it posteriorly, so that on imaging the cyst appears to lie in the preepiglottic space of the larynx (Fig. 35-17). In fact, the cyst remains outside the larynx, and at surgery, once a dissecting plane around the cyst can be identified, the cyst can be separated from the larynx without entering the larynx itself. In rare cases, such a cyst, occurring at the level of the larynx, can grow so large that it appears to destroy the laryngeal cartilages, and may initially appear both on imaging and clinically to be a submucosal supraglottic laryngeal tumor (Fig. 35-18). In actuality, the cyst has simply remodeled (and deossified) the laryngeal cartilages without destroying them. At surgery, once a dissection plane can be identified, the larynx again need not be entered. The imaging appearance of such a cyst, usually deforming the hyoid bone as well as the larynx, should lead to the correct diagnosis.[56]

In the infrahyoid neck, a thyroglossal duct cyst also has a classic imaging appearance. It is a cyst the lies just off of the midline, adjacent to the outer surface of the thyroid cartilage and deep to the infrahyoid strap muscles (Figs. 35-19 and 35-20). Once it is so identified on imaging, the diagnosis is established. Rarely, these cysts can occur in the lower neck, either in the midline or just off to one side (Fig. 35-21).

Regardless of their location in the neck, on imaging these cysts have a thin, smooth rim when not infected. If they are infected, the cyst wall thickens and enhances. On CT, the cyst contents usually have a mucoid attenuation (10 to 25 HU); however, if there has been previous infection or hemorrage, the attenuation of the cyst contents can approach



VIEW IMAGE

FIGURE 35-17 Axial contrast-enhanced CT scans at the cranial level (**A**) and a more caudal level (**B**). There is a slightly lobulated midline cyst that extends from the lower posterior margin of the hyoid bone (**A**), indents the thyrohyoid ligament, and projects into the superior thyroid notch of the thyroid cartilage of the larynx (**B**). Such a thyroglossal duct cyst was an incidental finding on this scan of the neck done for another reason. These cysts indent the thyrohyoid membrane but do not actually enter the preepiglottic space of the larynx.

that of muscle. On MR imaging, the T1-weighted signal intensity can vary from low to high, while the T2-weighted signal intensity remains high (Fig. 35-22). These variations in signal intensity reflect the variable protein content of the cyst.[57] As with branchial cysts, septations can occur within the cyst, with or without prior needle aspirations.

MR imaging also allows distinction from a vallecula cyst (Fig. 35-22C and D), which is a retention cyst on the mucosal margins, not along the thyroglossal duct tract.

Ectopic Thyroid Arising from the Median Anlage

Ectopic thyroid tissue occurs more commonly in females (7:1) and presents symptomatically during adolescence in approximately 78% of cases, often being attributed to hormonal disturbances that occur during puberty and pregnancy.[58] In autopsy studies, ectopic thyroid tissue measuring less than 3 mm in size was found in 10% of the normal population.[59] An understanding of the anatomic locations in which ectopic thyroid tissue can occur is based on knowledge of the embryologic course of the thyroglossal duct, as described in Chapter 33. If the gland fails to descend, it can actually ascend secondary to the growth of the developing tongue. For this reason, a thyroid in the tongue, the most common ectopic location (90% of cases), is by strict embryologic criteria an abnormally ascended gland. Partial failure of the gland to descend causes a prelaryngeal thyroid gland. Failure of the thyroglossal duct to degenerate completely can result in persistent thyroid tissue occurring anywhere along the course of this duct. However, when this happens, the thyroid tissue is usually normal and is most often in or near the location of a normal thyroid gland. To be

This patient presented with altered voice quality, and the clinical examination showed a large submucosal supraglottic mass that was thought to be a tumor. In **B**, the large cyst is seen apparently destroying the right side of the thyroid cartilage and bulging into the larynx deep to the mucosa (*arrowhead*). However, in **A**, the cranial aspect of the cyst not only touches the hyoid bone but remodels and widens the dorsal concavity of this bone. It is this latter finding that confirms the diagnosis of a huge thyroglossal duct cyst. This cyst was surgically elevated away from the larnyx without entering the larynx. The thyroid cartilage was only deossified from pressure exerted by the cyst.

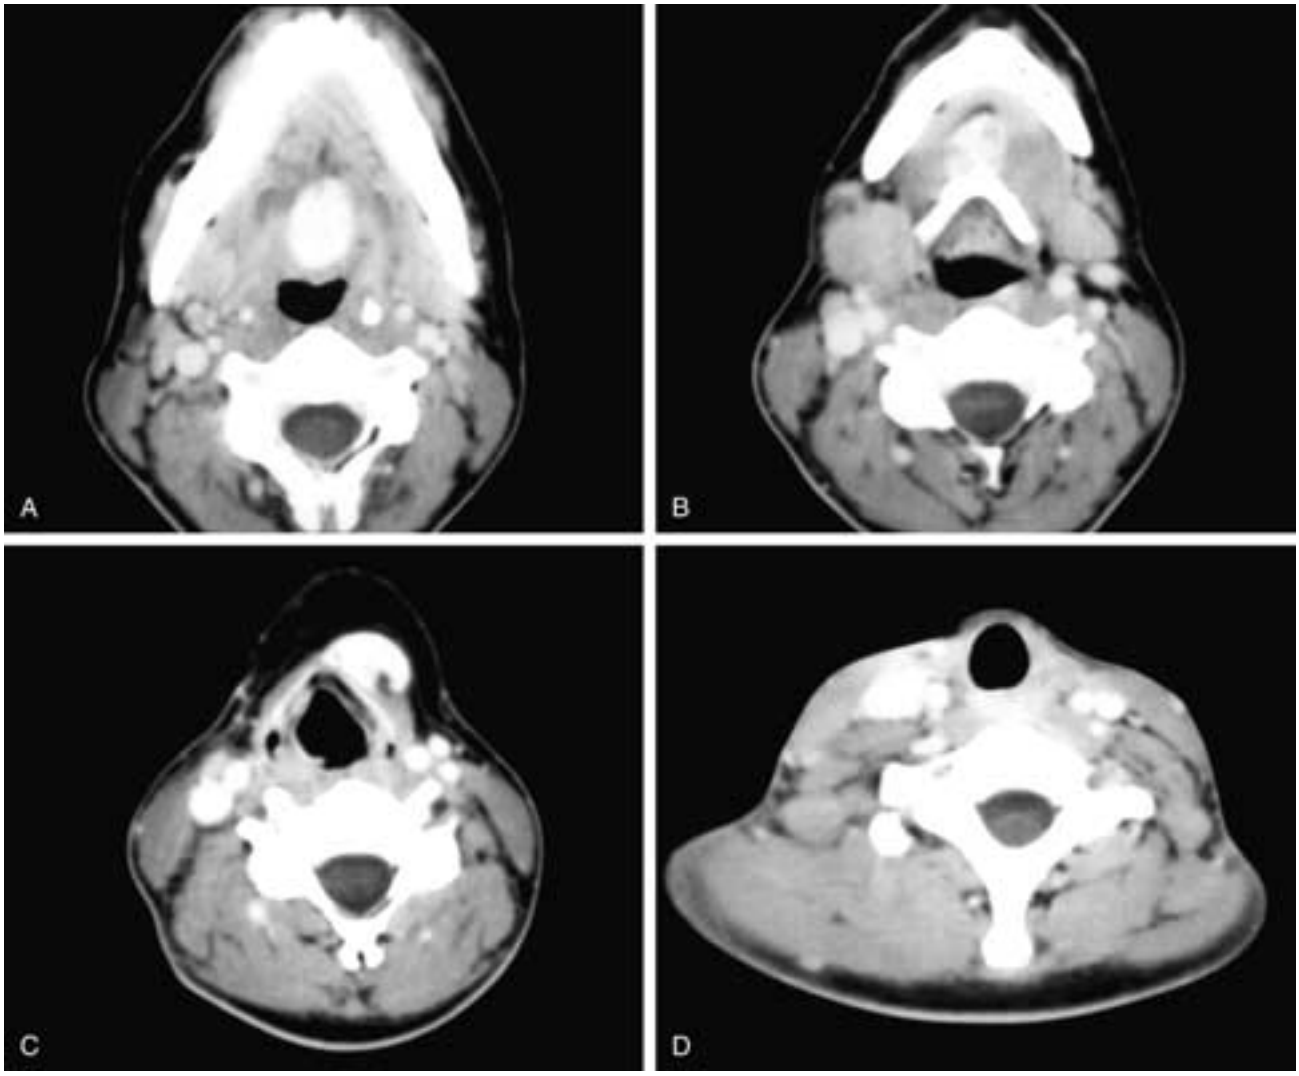
truly considered ectopic thyroid tissue, there must be no connection between the ectopic tissue and the normal thyroid bed.[60]

During normal embryogenesis, the thyroid anlage is adherent to the aortic root, which enables the thyroid tissue to descend until it interacts with the laryngeal primordia. These thyroid cells can become trapped within the developing laryngeal cartilages, the membranes, or the surrounding pharyngeal constrictor muscles.[61] Abnormal adherence of thyroid cells to the developing heart can lead to deposition of thyroid tissue anywhere along the descent of the heart into the thorax, including the low neck, mediastinum, pericardium, or even within the heart itself.[62, 63] Thyroid cells adhering to the developing tracheoesophageal bud can also contribute thyroid tissue adjacent to the diaphragm.

In a patient with a lingual thyroid, especially one in a stressful situation such as pregnancy, a goiter may develop and present clinically as dysphagia, dysphonia, stridor, dyspnea, hemorrhage, or hoarseness.[64–67] The actual development of a malignancy in lingual thyroid tissue is considered to be rare. The topic of thyroid disease is discussed in detail in Chapter 40.

On CT, ectopic thyroid tissue usually has high attenuation because normally functioning thyroid tissue has an active transport mechanism that concentrates iodine about 100 times over the serum concentration (Figs. 35-23 to 35-26). In addition, on contrast CT studies, the normally hypervascular thyroid tissue strongly enhances. The diagnosis is somewhat more difficult on MR imaging since the thyroid tissue is not as distinctly identified as on CT. On MR imaging, thyroid tissue is isointense to slightly hyperintense relative to muscle on both T1- and T2-weighted images and, as with CT, the thyroid does enhance strongly after contrast administration.



VIEW IMAGE

FIGURE 35-23 Serial axial contrast-enhanced CT scans from cranial (**A**) to caudal (**D**). In **A**, an enhancing mass is seen in the midline of the tongue. This was lingual thyroid tissue. In **B**, similar tissue is seen in the midline at the level of the hyoid bone. In **C**, similar tissue is seen adjacent to the outer contour of the thyroid cartilage and partially deep to the strap muscles. In all of these cases this was ectopic thyroid tissue, paralleling the location of the thyroglossal duct cysts in Figures 35-14 to 35-21. In **D**, there was no thyroid tissue in the normal location of the thyroid bed. This occurs in about 80% of patients with lingual thyroid tissue.

VIEW IMAGE

FIGURE 35-24 Axial contrast-enhanced CT scan (**A**) and a sagittal T1-weighted MR image (**B**) on a woman who developed dysphagia 1 week after delivering her first child. There is an enhancing mass in the midline base of the tongue. This was a goiter in a lingual thyroid, a fairly common occurrence in pregnant women. After surgery, pathologic examination revealed a focus of papillary thyroid carcinoma within the goiter.

Once a lingual thyroid is identified, one should always check the normal thyroid bed for the presence of any thyroid tissue. In 70% to 80% of these cases, the lingual thyroid is the only functioning thyroid tissue. Thus its complete removal, without any thyroid tissue reimplantation, will lead to permanent hypothyroidism and the need for thyroid replacement medication for the remainder of the patient's life. Nuclear thyroid scanning, usually with technetium 99m pertechnetate, can also identify the location of any ectopic thyroid tissue. Such imaging will visualize a small site of ectopic thyroid, provided that no dominant normal thyroid tissue is present in the neck. The presence of such normal thyroid tissue will trap virtually all of the radionuclide, making isotopic identification of ectopic thyroid tissue unlikely.

Ectopic Thyroid Originating from the Lateral Anlage

Ectopic thyroid tissue arising from the lateral anlage is extremely rare. As previously described, the lateral lobes of the thyroid receive contributions from the ventral aspect of the fourth through sixth branchial pouches. They migrate laterally around the developing laryngeal primordia to adhere to the median bilobed thyroid anlage. Although unproven, one theory postulates that endoderm originating from the caudal pharyngeal complex does not form thyroid tissue unless there is an interaction with the median anlage. The lateral thyroid anlage also has a less complicated embryology than the median thyroid anlage, including a

shorter distance to travel during development. These concepts could account for the rarity of ectopic tissue arising from the lateral thyroid anlage. Their pathogenesis is similar to that of the median anlage, and abnormal migration can lead to thyroid cells being left behind in the lateral neck or lateral floor of the mouth.[68] Lateral thyroid anlagen can also adhere to, or be trapped by, the developing neck musculature, vessels, lymph nodes, or laryngeal primordium. When trapped by the developing cartilages, membranes, and musculature of the laryngotracheal primordia, these ectopic clusters of thyroid tissue can migrate abnormally to the posterolateral wall of the trachea, the esophagus, or even the retroesophageal region.[61, 69, 70] Cells can also adhere to the developing nasopharyngeal diverticulum, which originates at the posterior aspect of the cervical foregut. This can lead to abnormal migration of ectopic thyroid to the nasopharynx.

Lateral ectopic thyroid tissue poses a unique problem in the setting of a known thyroid malignancy.[62] In some circumstances, exclusion of metastasis is straightforward. If an ectopic thyroid nodule is attached to the gland by a fibrous band, it can be considered a congenital group of cells pulled away from the thyroid during development. Similarly, thyroid tissue within the neck, not attached to the thyroid gland or lymph nodes, can be considered ectopic and due to abnormal migration of the lateral anlage. However, the presence of thyroid tissue within lymph nodes is a less clear-cut issue. It is well known that differentiated thyroid malignancy can frequently metastasize to lymph nodes. Although it is possible for ectopic thyroid tissue to be incorporated into a lymph node during normal embryogenesis, whenever such tissue is identified, it should be considered metastatic disease until proven otherwise.

Neoplasms Arising within Thyroglossal Duct Cysts

The literature on this subject was reviewed in 1988 by McNicoll et al.[71] Of the 133 reviewed cases, 89% were papillary or mixed papillary-follicular carcinoma, 7% squamous cell carcinoma, 2% adenocarcinoma, 1% follicular carcinoma, and 1% anaplastic carcinoma. Overall, carcinoma arising in a thyroglossal duct cyst occurs in less than 1% percent of the cases, and the diagnosis of malignancy is usually made postoperatively.[72, 73] If the malignancy is entirely within the resected cyst, simple cyst resection is considered adequate surgical treatment. Wider excision is considered necessary if the neoplasm extends beyond the cyst wall. Treatment remains controversial. Of the patients who underwent thyroidectomy for papillary or follicular carcinoma within a thyroglossal duct cyst, 11% had carcinoma in the native thyroid gland. The prognosis appears to be similar to that of the same malignancy when it occurs in normally located thyroid tissue.[72, 73]

On imaging, most of these cases appear to be normal cysts, with no evidence of a malignancy. However, a localized mass visualized in a portion of the cyst wall should suggest the possibility of a malignancy, while invasion of the adjacent soft tissues, without a history of infection, should strongly suggest that a neoplasm is present within the cyst (Fig. 35-27).

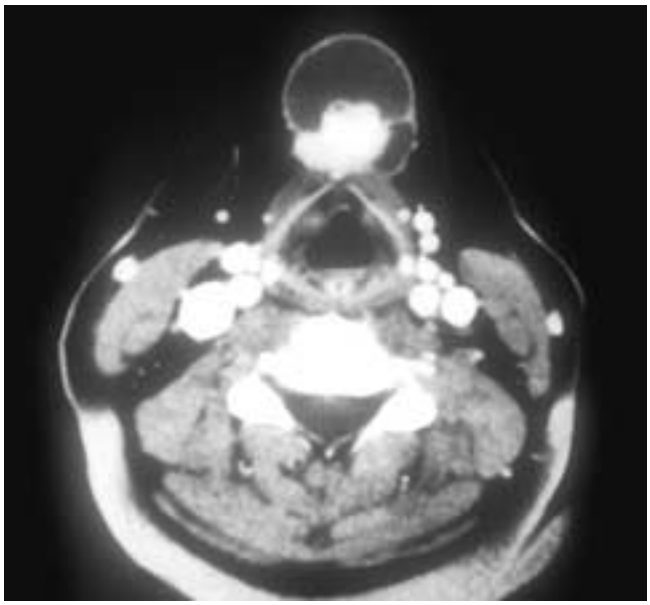

FIGURE 35-27 Axial contrast-enhanced CT scan shows a midline cyst just caudal to the level of the hyoid bone. Within the cyst is an enhancing nodule and there is some infiltration of the adjacent strap muscles. This was a papillary thyroid carcinoma within a thyroglossal duct cyst. At surgery, there was extension of the tumor into the strap muscles.

VIEW IMAGE

Neoplasms Arising within Ectopic Thyroid

Carcinoma arising in ectopic thyroid tissue is extremely rare.[74] Although the reported cases are few, they appear to involve the same cell types that affect the thyroid gland. Almost all reported cases are mixed papillary and follicular carcinoma.

The neural crest cells migrate to many areas in the body and are the origin for many polypeptide- or hormone-producing cells including those of the adrenal medulla.[75, 76] As described in Chapter 33, the parafollicular C cells of the lateral lobes of the thyroid gland are neural crest derivatives that secrete calcitonin, and medullary thyroid carcinoma arises from these cells. Most such tumors arise spontaneously, but they can also be part of the familial (autosomal dominant) multiple endocrine neoplasia syndromes (MEN types II and III). Medullary thyroid carcinoma is discussed in detail in Chapter 40.

Imaging the Postoperative Sistrunk Procedure

If a patient has had a Sistrunk procedure, on imaging a portion of the hyoid bone will have been resected and the space filled with fibrofatty tissue (Fig. 35-28). When seen, this classic imaging appearance indicates that the patient had surgery for a thyroglossal duct cyst.

CONGENITAL MALFORMATIONS OF THE CERVICAL LYMPHATIC SYSTEM

Lymphangiomas are congenital lymphatic malformations that comprise 5.6% of all benign lesions of infancy and childhood. They have no predilection for either sex or any

Copyright © 2003, Mosby, Inc. All rights reserved.

race.[77–79] From 50% to 60% of these lesions are present at birth, and nearly 80% to 90% are detected by the age of 2 years. Although the lesions that occur within the first 2 years of life may be unilocular, most are multilocular. In up to 10% of patients, lymphangiomas may not be discovered until adulthood, and only a few cases have been reported as late as the fifth decade of life. These latter lesions are most often unilocular, and there is some evidence that these adult lymphangiomas may not be congenital but rather posttraumatic in origin. They frequently present as a painless soft or semifirm mass.

Hemorrhage into the cystic spaces may cause rapid enlargement, and the mass effect of the lesion may cause compression of adjacent structures and lead to symptoms such as dysphagia, dyspnea, stridor, or pain.[5] Although the lesion tends to surround and sometimes invade normal anatomic structures, it has no malignant potential. Surgical excision is the treatment of choice, with a recurrence rate of up to 15%. More recently, new attempts to sclerose these lesions with agents such as OK-432 have met with more success than in the past.[80]

Typical lymphatic malformations cause little serious threat to life. However, due to aberrant peripheral lymphatics, nuchal cystic hygromas discovered in utero may have a poor prognosis when associated with Turner's syndrome and fetal hydrops. It has also been suggested that involution of a cervical lymphangioma in utero may be the origin of the ''wed neck'' associated with Turner's syndrome.[19]

The embryology of the lymphatic system is discussed in detail in Chapter 33. Familiarity with it allows an understanding of the pathogenesis and imaging appearance of congenital lymphatic malformations (lymphangiomas).

Theories of Pathogenesis

Three major theories have been proposed to explain the pathogenesis of lymphangiomas, and each of these theories helps us better understand the imaging appearance of these lesions.[81] These theories are as follows:

1. Failure of the primordial lymphatic sacs to drain into the veins: According to this theory, failure of the lymphatic sacs to drain into the veins results in dilation of the isolated lymphatic channels, which may eventually form lymphangiomas, particularly the larger, more central cystic hygromas.[81]
2. Abnormal sequestration of lymphatic tissue: According to this theory, abnormal sequestration of lymphatic tissue occurs early in embryogenesis.[82] This tissue subsequently fails to join the normal, more central lymphatic channels, and consequently lymphangiomas are formed. This theory helps explain the morphology of the more peripheral lesions such as capillary and cavernous lymphangiomas. The smaller lymphatic channels and the smaller overall size of these lesions are likely related to their primordium, which is a fine meshwork of lymphatic channels, the terminal branches of the lymphatic system.
3. Abnormal budding of the lymphatics: According to this theory, these aberrant buds lose their connections with the lymphatic primordia and eventually canalize to form lymph-filled cysts.[83] These cysts maintain their ability to branch and grow, and do so in an uncontrolled, disorderly manner. They have a strong tendency to penetrate and destroy normal anatomic structures. This theory helps explain the branching and permeative growth pattern of many lymphatic malformations, particularly the cavernous lymphangiomas. An aberrant primary bud arising directly from a primordial lymphatic sac is the likely explanation for the formation of a cystic hygroma near, but not in, the exact location of a primordial lymphatic sac.

VIEW IMAGE

Classification of Lymphangiomas

There are four histologic types of lymphangioma: cystic hygroma or lymphangioma, cavernous lymphangioma, capillary or simple lymphangioma, and vasculolymphatic malformation or lymphangiohemangioma. For at least two reasons, it is best to consider these four types of lymphangioma under a unified concept, as representing a spectrum of manifestations of the same pathologic process. First, combinations of these four types can often be seen in a single lesion. Second, these four types are differentiated from one another merely on the basis of the size of their lymphatic spaces. In all other respects, they are virtually pathologically identical, as all four types are composed of endothelium-lined lymphatic channels that are separated by connective tissue stroma.

The anatomic location of the lymphatic abnormality may also be very important in determining the histologic characteristic. Bill and Summer suggested that the loose fatty tissue in the axilla, neck, and chest may allow relatively unlimited growth of the lymphatic anomaly, leading to the formation of a cystic hygroma.[84] The subcutaneous portions of the lips, cheek, and tongue, however, permit only a more limited expansion, possibly resulting in a cavernous lymphangioma. Finally, in the tougher dermal and epidermal elements, expansion is further limited, possibly result-

ing in the formation of a capillary lymphangioma (e.g., lymphangioma circumscription congenitale).

Cystic Hygroma

Cystic hygroma, or cystic lymphangioma, is the most common form of lymphangioma. It consists of hugely dilated cystic lymphatic spaces. As mentioned, 75% of these malformations occur in the neck, particularly within the posterior triangle of the neck, and up to 10% of these nuchal hygromas may extend into the mediastinum. An additional 20% of these lesions are found in the axilla, and 5% arise in the mediastinum. Rarer locations include the retroperitoneum, abdominal viscera, and groin, although they can arise in any portion of the lymphatic system. These malformations tend to occur in or near the location of the primordial lymphatic sacs from which they presumably arise (jugular, axillary, internal thoracic, etc).

Cystic hygromas are often isolated malformations in which the remainder of the lymphatic system is normal. They may, however, be associated with a more generalized process, including an abnormally developed peripheral lymphatic system.

Fetal cystic hygromas occur most commonly in the posterior triangle of the neck. They are associated with abnormal peripheral lymphatics and varying degrees of lymphedema, and the prognosis worsens in the presence of fetal hydrops. They are frequently seen in aborted fetuses with Turner's syndrome. Smith believed that fetal cystic hygromas form when the juguloaxillary lymphatic sac fails to drain into the internal jugular vein.[85] He suggested that the accumulation of lymphatic fluid within a progressively dilating juguloaxillary lymph sac leads to the formation of the cystic hygroma. Secondary dilatation of the lymphatic channels draining the chest and extremities occurs, and peripheral edema and hydrops result. This series of events has been termed the *jugular lymphatic obstruction sequence*.[85] As previously noted, if lymphatic drainage is established prior to fetal death, the cystic hygroma may regress and the neck webbing characteristic of Turner's syndrome can result.[86]

Van der Putte studied aborted fetuses with cervical cystic hygroma and Turner's syndrome and confirmed that no lymphaticovenous communications were present near the jugulosubclavian junctions on either side.[87] He also found no communication between the juguloaxillary sac and the internal thoracic sac, paratracheal sac, or thoracic duct. Shaub and Wilson also helped prove this cause-and-effect relationship between failed lymphaticovenous communication and generalized lymphatic defects.[88] They described a fetus with a unilateral left cystic hygroma and edema of all body parts except the right arm. This pattern suggested that the left juguloaxillary lymph sac and the thoracic duct that emptied into it failed to communicate with the venous system, whereas the corresponding sac on the right and its tributaries formed normally due to adequate drainage into the venous system.

Van der Putte also noted that the peripheral lymphatics have a variable appearance in fetuses with nuchal cystic hygroma and Turner's syndrome. Increased numbers of very wide, valveless lymph vessels were seen in some fetuses, while in others, the extremities were devoid of lymphatic structures. Van der Putte concluded that the time in embryonic life at which the maldevelopment of the lymphaticovenous communication occurs is important in ultimately determining which portions of the lymphatic system will be hypoplastic. If the maldevelopment occurs early, a more hypoplastic system may be seen, since the wide, valveless lymphatic sprouts have not had time to reach the periphery. If the maldevelopment occurs late enough to allow these sprouts to reach the periphery but before further arborization occurs, the wide, valveless channels persist.[87]

Van der Putte also theorized that the disorder of lymphatic outgrowth is related to a chromosomal anomaly and mechanical factors. High pressures in the peripheral tissues have been shown to inhibit lymphatic growth, which sets up a vicious cycle of impaired lymph flow, lymphedema, and inhibition of lymphatic growth with a further diminution in lymph flow. Mechanical factors, however, are negligible in malformations of the juguloaxillary lymph sac, since the lower pressures within the loose, fatty connective tissue of the neck allow significant lymphatic sprouting and extension.

The differential diagnosis of a large neck mass identified in utero includes lymphangioma, teratoma, and possibly epidermoid.[89] Such imaging can be accomplished with either ultrasound or MR imaging and allows any compromise of the fetal airway to be assessed so that appropriate precautions for immediate intubation can be taken at the time of birth.

An isolated cystic hygroma may develop when one of several potential lymphaticovenous anastomoses fails to form. The resultant malformation is in or near the location of the primordial sac from which it arose. However, as long as the remainder of the lymphatic system is connected and the other lymphaticovenous anastomoses form, the remainder of the lymphatic system should drain well. Yet, an isolated cystic hygroma could develop even if the failed anastomosis involves the left juguloaxillary lymph sac, which is often responsible for the lymphatic drainage of most of the body. This is not unexpected, since the thoracic duct has more than one venous communication in 75% of all cases.[90] Connections with the venous system may also persist in other lymph vessels. These additional connections allow adequate lymphatic drainage for the rest of the body, thus preventing the jugular lymphatic obstruction sequence and fetal death.

An isolated cystic hygroma can also form if an aberrant bud loses its connection with the primordial lymph sac from which it arose. In conjunction with a normal lymphaticovenous communication, this situation also leads to the development of an isolated cystic hygroma in a patient with an otherwise normal lymphatic system.

In adults, solitary cystic hygromas can occur in the posterior triangle of the neck and in the submandibular triangle. These isolated lesions are cured by surgery and may be posttraumatic in origin.

On imaging, cystic hygromas typically are multiloculated cystic masses in the posterior triangle of the neck in a child or young adult. Rarely in uncomplicated cases is a cyst wall actually seen. However, if there has been infection within the lesion, the cyst wall thickens and enhances, and there is inflammatory infiltration of the adjacent fat planes (Figs. 35-29 through 35-31). On CT, the cyst content is typically of mucoid attenuation (10 to 25 HU) (Fig. 35-29). Fluid-fluid

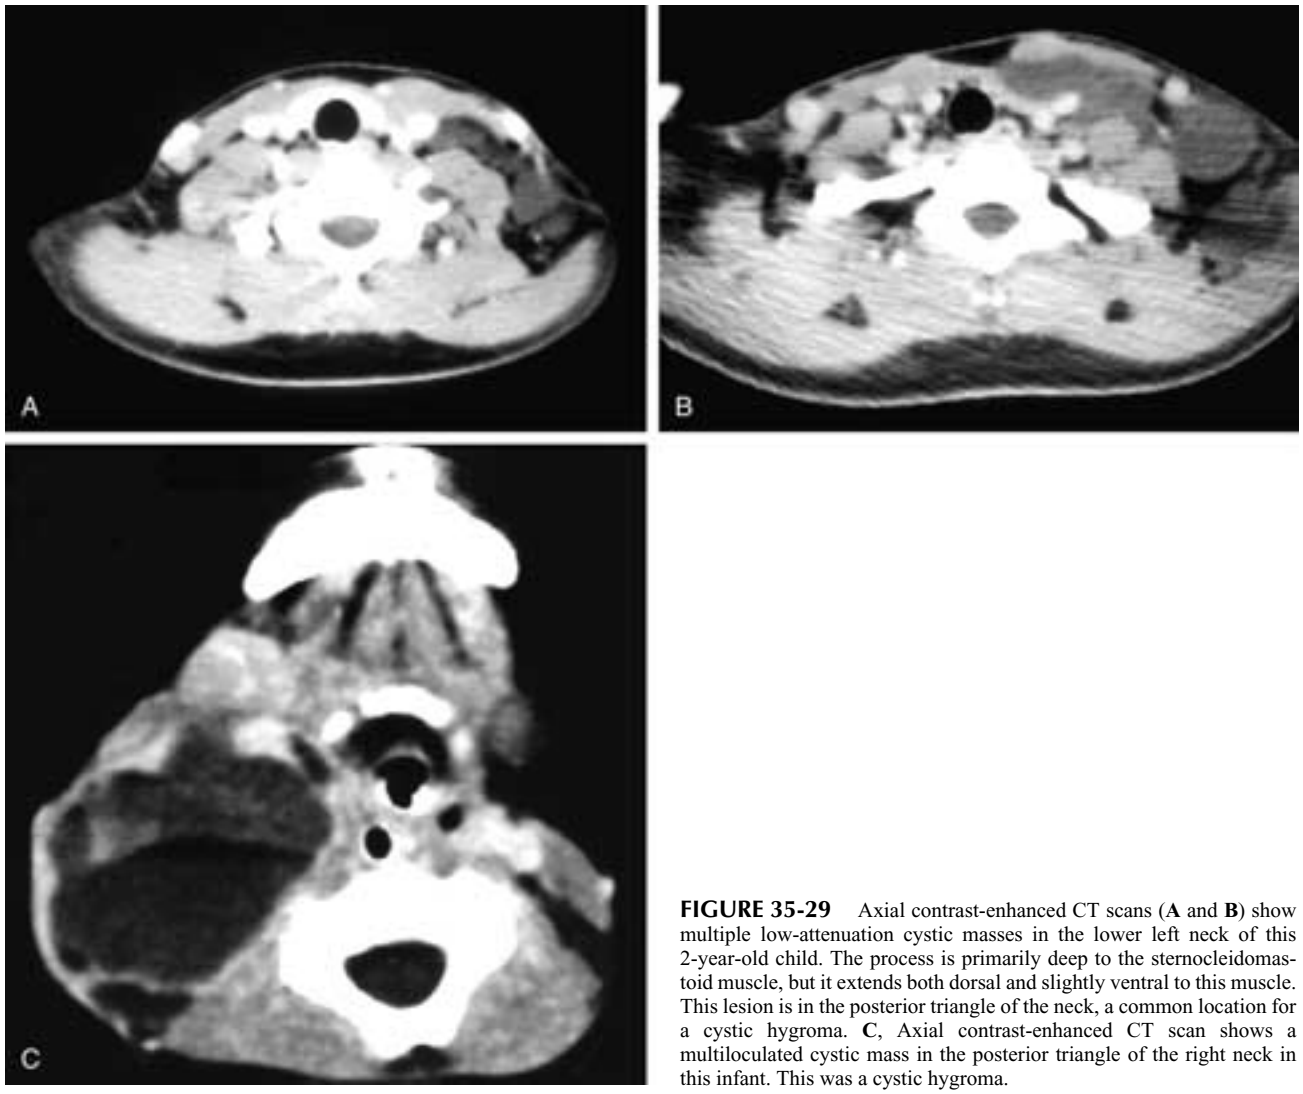

FIGURE 35-29 Axial contrast-enhanced CT scans (**A** and **B**) show multiple low-attenuation cystic masses in the lower left neck of this 2-year-old child. The process is primarily deep to the sternocleidomastoid muscle, but it extends both dorsal and slightly ventral to this muscle. This lesion is in the posterior triangle of the neck, a common location for a cystic hygroma. **C**, Axial contrast-enhanced CT scan shows a multiloculated cystic mass in the posterior triangle of the right neck in this infant. This was a cystic hygroma.

VIEW IMAGE

levels may be seen after hemorrhage into the lesion. On MR imaging, typically there is low T1-weighted signal intensity, but this may vary between low and high signal intensity. There almost always is high T2-weighted signal intensity. If hemorrhage has occurred, fluid-fluid levels are best seen on MR imaging; in fact, the appearance of a multicystic mass with fluid-fluid levels is characteristic of this lesion (Fig. 35-32).[77, 78, 91] Since blood entering these cysts does not clot, the fluid-fluid levels actually represent separation of fluids based on specific gravity. If a parotid lymphangioma hemorrhages, the lesion can become sufficiently rigid to cause facial nerve paresis and simulate an aggressive tumor (Fig. 35-33).[92] This subject is discussed in more detail in Chapter 39.

Cavernous Lymphangioma

Cavernous lymphangioma is a subcutaneous lesion composed of mildly dilated cavernous lymphatic spaces that are smaller than those of a cystic hygroma but larger than those of a capillary lymphangioma. These lesions also tend to be larger than capillary lymphangiomas. Cavernous lymphangioma commonly occurs in the tongue, floor of the mouth, or salivary glands. The margins of the lesion are not discrete, and the lesion tends to penetrate but not destroy contiguous structures such as muscles, glands, vessels, and nerves (Fig. 35-34).

These lymphatic malformations form during the last phase of lymphatic development, which occurs between the ninth and tenth weeks of gestation, when sprouts are sent in all directions to permeate all tissues. The lesion forms from an abnormally sequestered mesenchymal bud that loses its connection with the more central lymphatic channels but maintains its ability to branch and grow. It is believed that the prevalence of these lesions in the tongue and parotid gland, and the relative absence of cystic hygromas in these regions, are secondary to the cavernous lymphangioma's being a lesion that arises from the more peripheral, finely branched portions of the lymphatic primordium, and the fact that the tongue musculature and glandular tissues offer more resistance to growth than do the loose fatty connective tissues of the neck in which cystic hygromas tend to form.

Copyright © 2003, Mosby, Inc. All rights reserved.

Capillary Lymphangioma

The capillary or simple lymphangioma (lymphangioma simplex) is the least common form of lymphangioma and has the most diminutive lymphatic channels. This lesion is composed of a network of small lymph vessels that can be differentiated from capillaries by the absence of red blood cells, pericytes, and a basement membrane. The lymphatic endothelial cell cytoplasm is also extremely thin. The lesion occurs predominantly within the epidermis and/or dermis as a wart or a group of small vesicles. Most of the vesicles are white or pink, but a few can have a more dark red or purplish color. These cutaneous lesions may be further subdivided into two main groups, classic and localized.[93]

Although the classic form can occur anywhere on the body, it tends to develop over the proximal portions of a limb and the adjacent trunk. Involvement of the upper arm, axilla, and adjacent chest is especially common. The superficial vesicles described above are connected via lymphatic channels to larger dilated lymphatic spaces called cisterns. These cisterns are often surrounded by a muscular coat, the contractions of which may cause further dilation of the superficial vesicles with which the cisterns communicate. The relatively smaller component on the skin surface can mask an underlying lesion that may reach considerable size.

The localized form has no predilection for any definite area. It also differs from the other lymphangiomas by presenting at any age. Twenty-five percent of the cases are first seen in patients older than 45 years of age. This superficial epidermal lesion typically involves a discrete area of approximately 1 cm^2. The term *lymphangioma circumscriptum* was formerly used to describe all cutaneous lymphangiomas, but now it is used to describe any localized capillary lymphangioma that measures less than 5 cm in diameter.[94] Some authors have also described a ''spongy'' form of lymphangioma that is now believed to be merely a localized capillary lymphangioma that occurs in mucous membranes, lips, eyelids, and the external auditory canal.[93, 95]

Capillary lymphangioma forms during the last part of embryonic development. As lymphatic sprouts follow the vasculature into the periphery, an abnormal bud encounters the relatively tougher connective tissue of the skin. This tends to inhibit subsequent growth of these lymphangiomas more so than do the musculature or glandular elements throughout which cavernous lymphangiomas grow. In addition, capillary lymphangiomas arise from the terminal branches of the lymphatic primordium, which constitute a fine meshwork of capillary-sized vessels.

After penetrating trauma, the heat of the penetrating object usually seals the lymphatic capillaries. However, if such a sealing does not occur, lymph can accumulate in the wound site and a posttraumatic lymphocyst can develop. Such cysts often become infected and on imaging thus have a thickened, enhancing rim (Fig. 35-35).

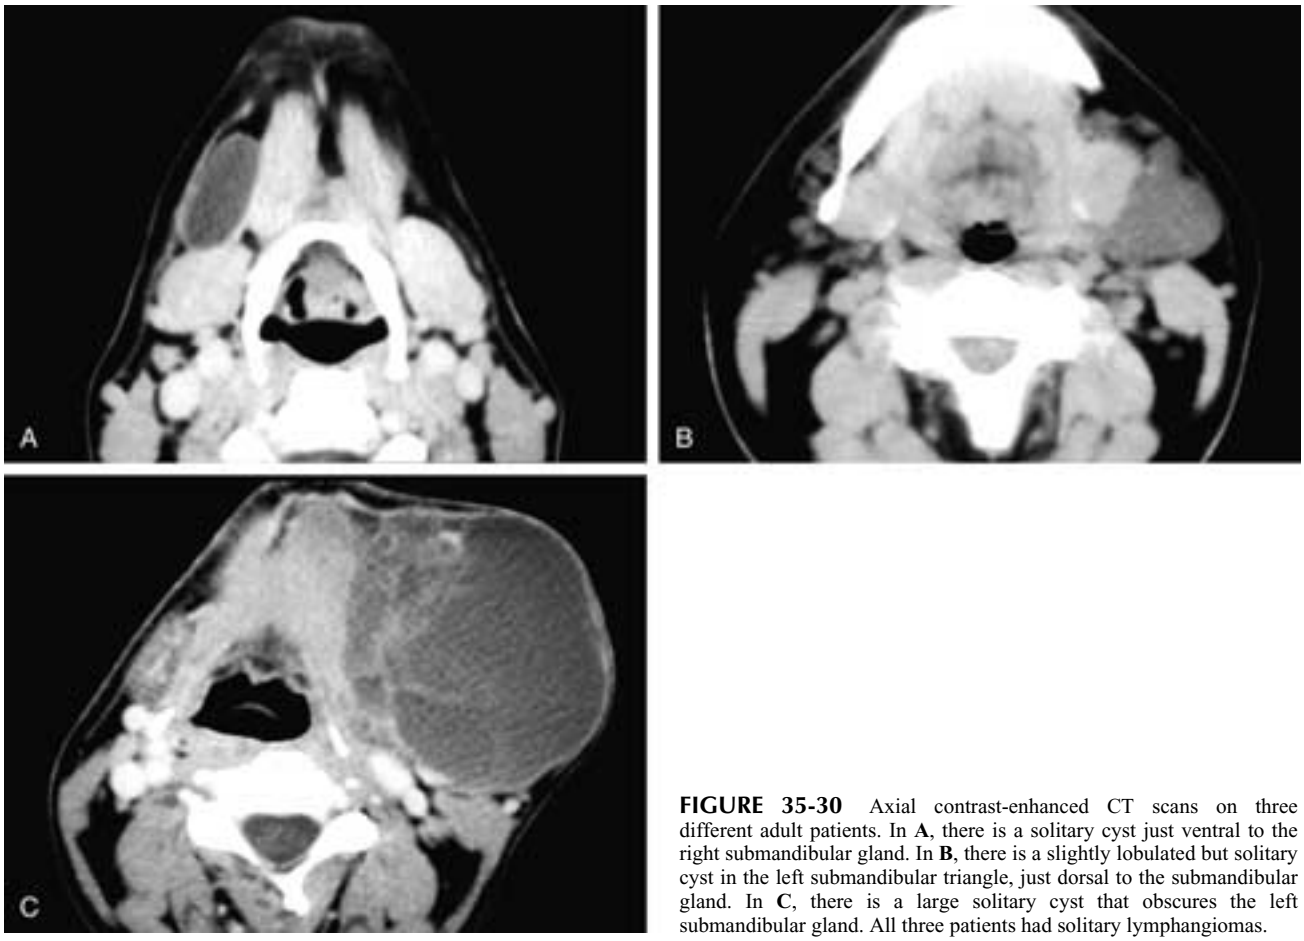

FIGURE 35-30 Axial contrast-enhanced CT scans on three different adult patients. In **A**, there is a solitary cyst just ventral to the right submandibular gland. In **B**, there is a slightly lobulated but solitary cyst in the left submandibular triangle, just dorsal to the submandibular gland. In **C**, there is a large solitary cyst that obscures the left submandibular gland. All three patients had solitary lymphangiomas.

FIGURE 35-31 Axial contrast-enhanced CT scans on three different adult patients. In **A**, there is a solitary cyst in the left neck, deep to the sternocleidomastoid muscle. In **B**, there is a solitary cyst in the right neck, deep to the sternocleidomastoid muscle. In **C**, there is a moderate-sized solitary cyst in the right neck, deep to the sternocleidomastoid muscle. In **D**, there is a huge cyst in the right neck, deep to the sternocleidomastoid muscle. All four patients had solitary lymphangiomas. The main imaging differential diagnosis is a lymphomatous lymph node.

Vasculolymphatic Malformations

Vasculolymphatic malformations are composed of both lymphatic and vascular elements, and lymphangiohemangioma is a prime example. These lesions likely form from an abnormal bud that retains its original venous communication. For this reason, the mesenchyme of the venous structure and some vascular characteristics are maintained.

VASCULAR LESIONS

The classification of vascular lesions of the head and neck has been somewhat confusing in that overlapping terminology has made it difficult to compare certain lesions, follow their natural history, and plan appropriate treatment. In 1982, Mulliken and Glowacki proposed a classification for these vascular lesions that was based on their natural history as well as their cellular structure. This nomenclature provides insight into the natural history and management of these vascular lesions.[96] The authors identified two main categories of lesions: hemangioma and vascular malformations. The vascular malformations were, in turn, further subdivided into capillary, venous, arteriovenous, and lymphatic types.

Hemangiomas

Hemangiomas are neoplastic and exhibit increased proliferation and turnover of endothelial cells, mast cells, fibroblasts, and macrophages.[97] They are the most common tumors of the head and neck in infancy and childhood, accounting for approximately 7% of all benign soft-tissue tumors.[5, 98] Utilizing the classification proposed by Mulliken and Glowacki, the term *hemangioma* should be reserved

Copyright © 2003, Mosby, Inc. All rights reserved.

for those lesions that present in early infancy, rapidly enlarge, and ultimately involute by adolescence.[96]

Although they are rarely present at birth, hemangiomas typically become apparent during the first month of life.[98] Ninety-six percent of hemangiomas are clinically evident by the age of 6 months and about 80% occur as single lesions, with females being more commonly affected (4:1). One half of all hemangiomas resolve completely by 5 years of age, and 70% resolve by 7 years of age.[99]

Previously termed *strawberry hemangiomas*, these primarily superficial cutaneous hemangiomas are usually diagnosed clinically with ease. However, they may also occur as subcutaneous hemangiomas that extend deeply through the skin to infiltrate the underlying muscles, usually presenting as nonspecific soft-tissue masses. Osseous deformity or skeletal hypertrophy may be associated with these lesions, but intraosseous invasion is extremely uncommon.[100, 101] Clinically, these lesions present as either a diffuse skin lesion or a soft ''cystic'' mass in the oral cavity, pharynx, parotid gland, or neck. The deeper lesions usually exhibit characteristics such as compressibility, bluish discoloration of the overlying skin, bruits, and a change in size during crying or straining, and there may be other associated hemangiomas elsewhere on the body.[5]

The association of hemangiomas with a variety of intracranial arterial vascular anomalies has been reported as

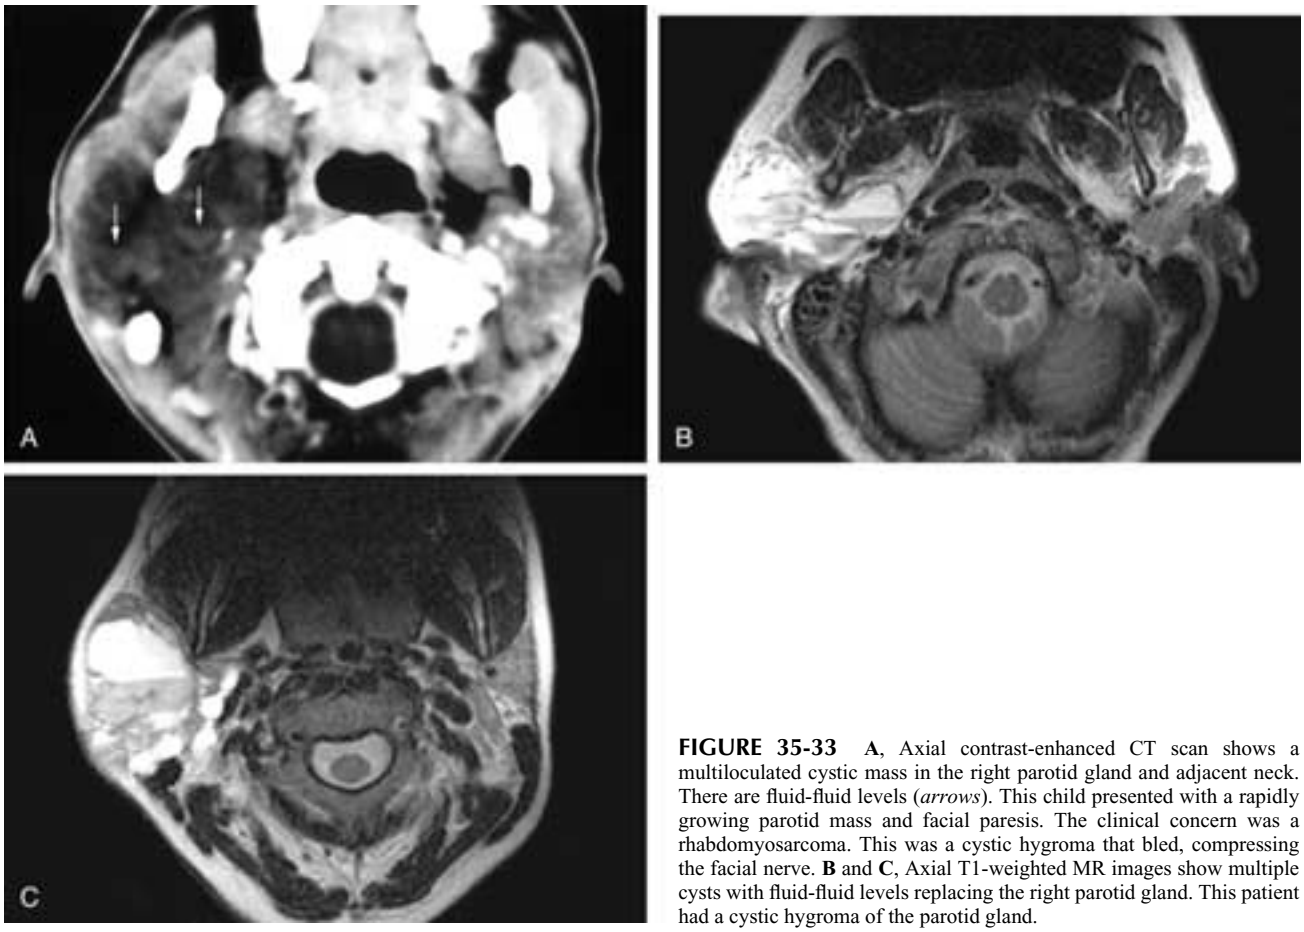

FIGURE 35-33 **A**, Axial contrast-enhanced CT scan shows a multiloculated cystic mass in the right parotid gland and adjacent neck. There are fluid-fluid levels (*arrows*). This child presented with a rapidly growing parotid mass and facial paresis. The clinical concern was a rhabdomyosarcoma. This was a cystic hygroma that bled, compressing the facial nerve. **B** and **C**, Axial T1-weighted MR images show multiple cysts with fluid-fluid levels replacing the right parotid gland. This patient had a cystic hygroma of the parotid gland.

VIEW IMAGE

the *cutaneous hemangioma–vascular complex syndrome*. There is an association between extensive craniofacial hemangiomas, these intracranial arterial vascular anomalies, and the presence of progressive occlusive cerebrovascular disease, with resultant cerebral infarction. One defined cluster of abnormalities associated with hemangiomas is referred to as the PHACE syndrome, consisting of posterior fossa abnormalities, facial hemangioma, arterial abnormalities, cardiovascular defects, and eye abnormalities, associated with a supraumbilical midline raphe.

Most hemangiomas require no treatment unless life-threatening complications occur. They usually present during the rapid proliferation phase and may be associated with a mortality rate as high as 20% to 30%. Complications may include Kasabach-Merritt syndrome (consumptive coagulopathy), compression of vital structures (i.e., airway), bleeding, and ulceration.

Hemangiomas are classified as high-flow lesions that are well circumscribed and angiographically exhibit a lobular pattern of intense, persistent tissue staining. The frequent arteriovenous shunting and high flow in these lesions may not permit their distinction from vascular malformations. On MR imaging, the solid component of the hemangioma demonstrates signal intensity isointense or slightly hyperintense to muscle on T1-weighted images, higher signal intensity on progressively more heavily T2-weighted scans, and enhancement following contrast administration (Fig. 35-36).[102, 103]

Vascular Malformations

Unlike hemangiomas, vascular malformations are not tumors. Rather, they are true congenital vascular anomalies that may not be clinically manifest until late infancy or early childhood. Their endothelial cell proliferation and turnover characteristics are normal, and they demonstrate slow, steady growth commensurate with the growth of the child. They also neither regress nor involute, and skeletal changes are more commonly associated with these vascular malformations (35%) than they are with hemangiomas. Rapid enlargement of these lesions is reported to occur in association with trauma, infection, or endocrine changes such as those occurring during puberty and pregnancy.[104, 105]

The vascular malformations are classified on the basis of their predominant type of anomalous vessels. Thus, there are the capillary, venous, arterial, and lymphatic malformations.[97, 101] A variety of therapies have been employed for the treatment of vascular malformations and rapidly enlarging hemangiomas, with varying degrees of success. These include steroid administration, laser photocoagulation, sclerotherapy, embolization, and surgical resection.[106–116]

Capillary Malformations

These lesions have been variably referred to as *port-wine stains, capillary hemangiomas*, and *nevus flammeus*.[117]

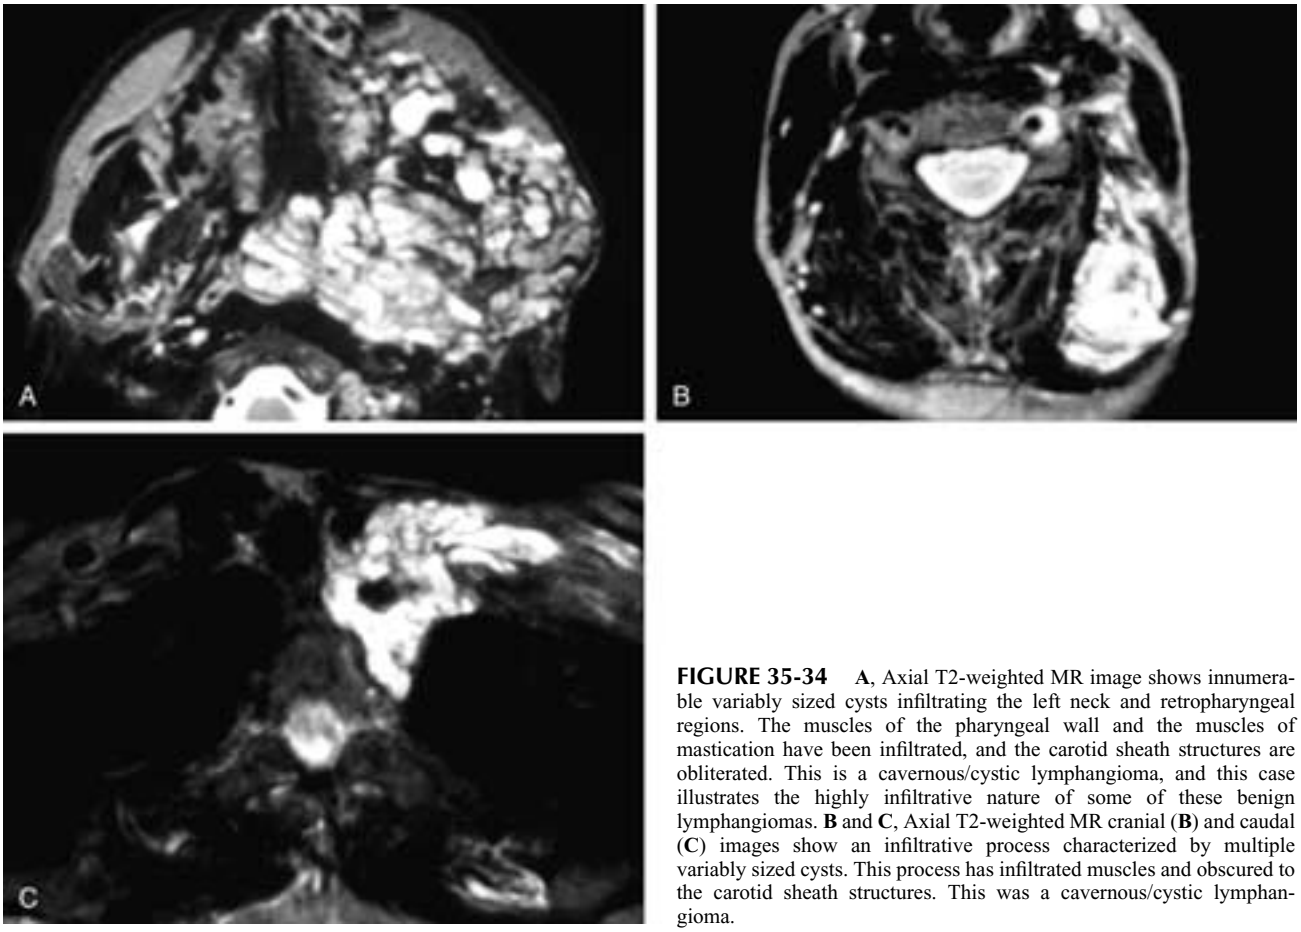

FIGURE 35-34 **A**, Axial T2-weighted MR image shows innumerable variably sized cysts infiltrating the left neck and retropharyngeal regions. The muscles of the pharyngeal wall and the muscles of mastication have been infiltrated, and the carotid sheath structures are obliterated. This is a cavernous/cystic lymphangioma, and this case illustrates the highly infiltrative nature of some of these benign lymphangiomas. **B** and **C**, Axial T2-weighted MR cranial (**B**) and caudal (**C**) images show an infiltrative process characterized by multiple variably sized cysts. This process has infiltrated muscles and obscured to the carotid sheath structures. This was a cavernous/cystic lymphangioma.

FIGURE 35-36 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show a large soft tissue mass replacing the ventral portion of the left parotid gland. Within the mass there are serpiginous vascular flow voids. This child had an hemangioma.

They are low-flow lesions that may be associated with the distribution of the trigeminal nerve as part of the Sturge-Weber syndrome. In this syndrome, these lesions also may involve, as an underlying vascular anomaly, the choroid plexus and leptomeninges. Other syndromes associated with capillary malformations include ataxia-telangiectasia (Louis-Barr) and Osler-Weber-Rendu (hereditary hemorrhagic telangiectasia), Wyburn-Mason (facial capillary malformation overlying retinal or optic pathway arteriovenous malformations), and Cobb (posterior thoracic capillary malformation overlying spinal cord arteriovenous malformations) syndromes.[97]

Venous Malformations

These lesions are occasionally erroneously termed *cavernous hemangiomas*, and unlike true hemangiomas, they may involve bone and they do not involute.[117] These lesions are the most common ones to affect the oral cavity and share many imaging features with subcutaneous hemangiomas. When located in the extracranial head and neck, these venous malformations may attain enormous size and cause airway compromise. Although they are predominantly soft-tissue masses, they may infiltrate deeply along fascial planes and, rarely, may be entirely intramuscular.[118, 119] Of all the skeletal muscle hemangiomas or venous malformations, approximately 14% occur in the head and neck region and in descending order involve the masseter, trapezius, and sternocleidomastoid muscles.[120, 121] On CT, these lesions typically show muscle attenuation on noncontrast images and variable patterns of enhancement on contrast studies.[122] Like their capillary counterparts, venous malformations are low-flow lesions that are supplied by small arteries. As a consequence of their slow blood flow, they may not demonstrate sufficient enhancement on CT to enable separation of their margins from the surrounding muscle, while angiographically, their arterial supply may not be identified.[123] On MR imaging, these lesions may appear very similar to deep hemangiomas in that they are either isointense or hyperintense to muscle on T1-weighted images, hyperintense to muscle on T2-weighted images, and typically enhance. The identification of discrete areas of homogeneous high signal intensity, representing venous lakes, or the presence of phleboliths may be extremely helpful in suggesting the diagnosis of a venous malformation (Figs. 35-37 and 35-38).[99, 123, 124]

Arterial Malformations

These lesions are high-flow malformations that result from abnormal blood vessel morphogenesis and arteriovenous malformations; fistulas are included in this category. The head and neck region is considered to be one of the more common sites for these congenital arterial malformations. Angiographically, arterial malformations are characterized by rapid flow and enlarged, tortuous arteries and draining veins. Parenchymal staining is unusual. On MR imaging, the enlarged arterial components appear as flow voids on T1- and T2-weighted images.

One subgroup of patients has combined vascular malformations with features of both high- and low-flow lesions.[100] These lesions may be highly invasive, become enormous in size with a tendency to involve the deep musculature and subcutaneous tissues, and be resistant to all forms of therapy. On MR imaging, these lesions demonstrate serpiginous flow voids, characteristic of arterial malformations, as well as a soft-tissue infiltrating component, typical of venous malformations (Figs. 35-39 and 35-40).[101]

There are other congenital vascular abnormalities that can occur in addition to the vascular malformations. Internal jugular vein phlebectasia is a rare entity that mostly involves the right side.[125, 126] It is usually discovered in childhood and is believed to be of congenital origin. Although it can occur at any age and can affect both genders, no case has been reported in a young adult male. The diagnosis is made clinically by noting a soft fullness in the lower neck that is most prominent when the patient is supine, or phonates in the erect position, and then disappears when the patient is erect and breathes normally. The diagnosis can be confirmed by Doppler ultrasonography, CT with contrast, and MR imaging.[125, 127] Even though most of these lesions have been excised surgically, the

FIGURE 35-39 Axial (**A**) and coronal (**B**) T2-weighted MR images show a noninfiltrating mass with overall high signal intensity in the fat of the posterior right neck, deep to the sternocleidomastoid muscle. There are vascular flow voids within this arteriovenous vascular malformation.

treatment of choice should be conservative as long as the patient is asymptomatic.

TERATOMAS, EPIDERMOID CYSTS, AND DERMOID CYSTS

The nomenclature of these lesions is confusing, and overlapping definitions exist. There are two main categorical systems that use either the teratoma or the dermoid as the basic lesion and then define the other lesions as variants.

A teratoma is a neoplasm composed of multiple tissues that are foreign to the part of the body in which the lesion arises. The term *teratoma* is often used in the generic sense to include both teratoid and dermoid lesions. As such, teratomas occur in 1 in 4000 births, and less than 10% involve the head and neck structures. Most often affected are the sacrococcygeal, mediastinal, retroperitoneal, and gonadal regions.[5] The teratomas have been classified into four groups, differentiated by the germ layers involved and the degree of tissue organization. The most common form of teratoma is the demoid cyst, which contains ectodermally

and mesodermally derived tissues. The teratoid cyst is composed of tissues derived from ectoderm, mesoderm, and endoderm. The teratoma differs from the teratoid cyst in that the teratoma has cellular differentiation into recognizable organs. Congenital teratoid cysts have been reported to occur primarily in the floor of the mouth, with or without a median fistula, and two cases have been reported in the nasopharynx.[79, 128–137] The epignathi represents the highest form of differentiation, containing fetal organs and limbs. This rare anomaly is virtually incompatible with life.[5]

The term *dermoid cyst* has also been applied to a variety of dysontogenic cystic lesions that can occur in the body. Despite Meyer's detailed classification of these lesions into epidermoid, dermoid, and teratoid forms, the term *dermoid cyst* continues to be commonly used in reference to all three types of lesions, without regard to their differing histologies.[138] Being so loosely defined, as mentioned above, dermoid cysts of the head and neck account for 7% to 10% of all dermoid cysts.[139] Pathologically, epidermoid cysts consist of simple squamous cell epithelium with a fibrous wall. Dermoid cysts have, in addition, a variable number of skin appendages such as hair follicles and sebaceous glands. Teratoid cysts contain any number of diverse tissues derived from all three germ cell layers.[140] All three varieties may be filled with a cheesy keratinaceous material.

The most popular theory regarding the etiology of these lesions suggests that they are derived from epithelial rests that become enclaved during midline closure of the first and second branchial arches.[141] This theory may help to explain the simultaneous occurrence of multiple such cysts.[142] The other popular theory suggests that isolation of pluripotential cells occurs during embryogenesis and that subsequently disorganized growth of these cells occurs.[5]

Approximately 80% of the dermoid cysts that occur in the head and neck develop in the orbit (~50%), the oral cavity region (~24%), and the nasal region (~13%). The remainder of these lesions occur in the neck, frontal or occipital midline scalp, lower lip, or palate. There is apparent sparing of the upper lip.[139]

Median dermoid cysts of the nose represent 3% of all dermoids and about 7.6% of head and neck dermoids. Although they usually are clinically evident shortly after birth, the average age of diagnosis and treatment is 12 to 13 years. There is a 2:1 male predominance. This topic is discussed further in Chapter 1. Rarely, a tumor such as a hemangiopericytoma can present at birth and mimic such a congenital midline nasal mass.[143]

When they occur in the oral cavity, dermoid cysts most commonly involve the floor of the mouth (sublingual, submental, or submandibular regions), although other sites have been reported including the lips, tongue, and buccal mucosa.[141, 144–149] Extracapsular excision of cysts in the floor of the mouth is performed by either an intraoral or an external approach, depending on the relationship of the cyst to the mylohyoid muscle.[150] For those cysts that lie above the mylohyoid muscle (sublingual), an intraoral approach is preferable because it avoids a conspicuous scar, it preserves the mylohyoid muscle, and it is associated with a shorter recovery time. Those lesions that lie inferior to the mylohyoid muscle (submental and submandibular cysts) must usually be removed via an external approach. Therefore, the imaging identification of the cyst in relationship to the mylohyoid muscle is extremely helpful in surgical planning. Axial and especially coronal imaging are useful in this regard.[150]

Clinically, these lesions are rubbery or doughy and exhibit pitting after palpation due to their ''cheesy'' content. They are also usually nontender, nonpainful, slow-growing masses. Rapid growth may occur during pregnancy.

On CT, dermoid cysts typically appear as low-density, well-circumscribed, unilocular masses, less dense than muscle, that may or may not contain fat (Figs. 35-41 and 35-42). The wall of the cyst usually enhances following contrast administration. In the absence of fat globules, epidermoid and dermoid cysts are indistinguishable. On MR imaging, epidermoid cysts are of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images, reflecting their fluid content. Dermoid lesions present a more variable appearance, depending upon their fat content, being either hypointense or hyperintense to muscle on T1-weighted images and typically hyperintense on T2-weighted sequences. The use of contrast permits determination of the thickness of the cyst wall (2 to 6 mm) (Fig. 35-43).[150]

Most of the dermoids that occur in the nasopharynx are present at birth and develop in the nasopharyngeal midline or the lateral wall. The patient is usually first diagnosed early in the third decade of life, and females are affected six times more often than males.[139]

The teratomatous lesions that occur in the nasopharynx and paranasal sinuses are usually composed of well-differentiated tissues, and neuroectodermal and neural tissues predominate. The rare malignant teratoma has a low level of differentiation and may be a teratosarcoma or present with metastases.[151] Cervical teratomas are rare, and are found in newborn full-term infants and in premature or stillborn infants. The infant usually has severe respiratory distress and dysphagia. There is no increased incidence of coexistent congenital anomalies, and maternal hydramnios is present in 19.6% of the cases.[139] The thyroid gland is involved in most of these cases and the lesions are large, usually between 5 and 12 cm.[152]

RARE CYSTS AND LESIONS

The term *choristoma* refers to a nidus of tissue that is histologically normal but is not normally present in the organ or structure in which it is located. Only a few cases have been described in the head and neck. In one case, there was a mediastinal choristoma that contained thymic, parathyroid, and salivary tissue. Another case was a mediastinal parathyroid adenoma that contained thymic tissue. In both of these instances the lesions were cystic, which may have led to their being confused with other low neck parenchymal cysts such as a large thyroid cyst, a parathyroid cyst, or a cervical thymic cyst.[27, 153] There have been reports of brain tissue in the back, the parapharyngeal space, the pterygopalatine fossa, and the lateral face.[154] There have also been reports of salivary tissue in the middle ear, a branchial cleft fistula in the neck, and respiratory epithelium in the tongue.[155–161] In addition, there has been a report of an adenocarcinoma developing in salivary tissue in the neck.[162]

Enterocystomas are rare lesions that are choristomas composed of gastric and/or intestinal mucosa. They usually occur in the floor of the mouth and tongue, and most have been reported in infants.[163–166]

A tracheoesophageal cyst has been reported in the neck of an infant. The mass was 12 cm in diameter and contained elements of both respiratory and upper esophageal wall origin. It was believed to have developed from a spurious sequestrum of the foregut that became separated before the development of the tracheoesophageal partition.[167]

Cervical bronchogenic cysts are derived from small buds that separate from the foregut during the formation of the tracheobronchial tree. As such, they occur primarily in the lung or mediastinum, but they have also been reported in the neck, presumably after erratic migration of primordial cells. They are more common in males (3:1) and range in size from 1 to 6 cm.[27, 168]

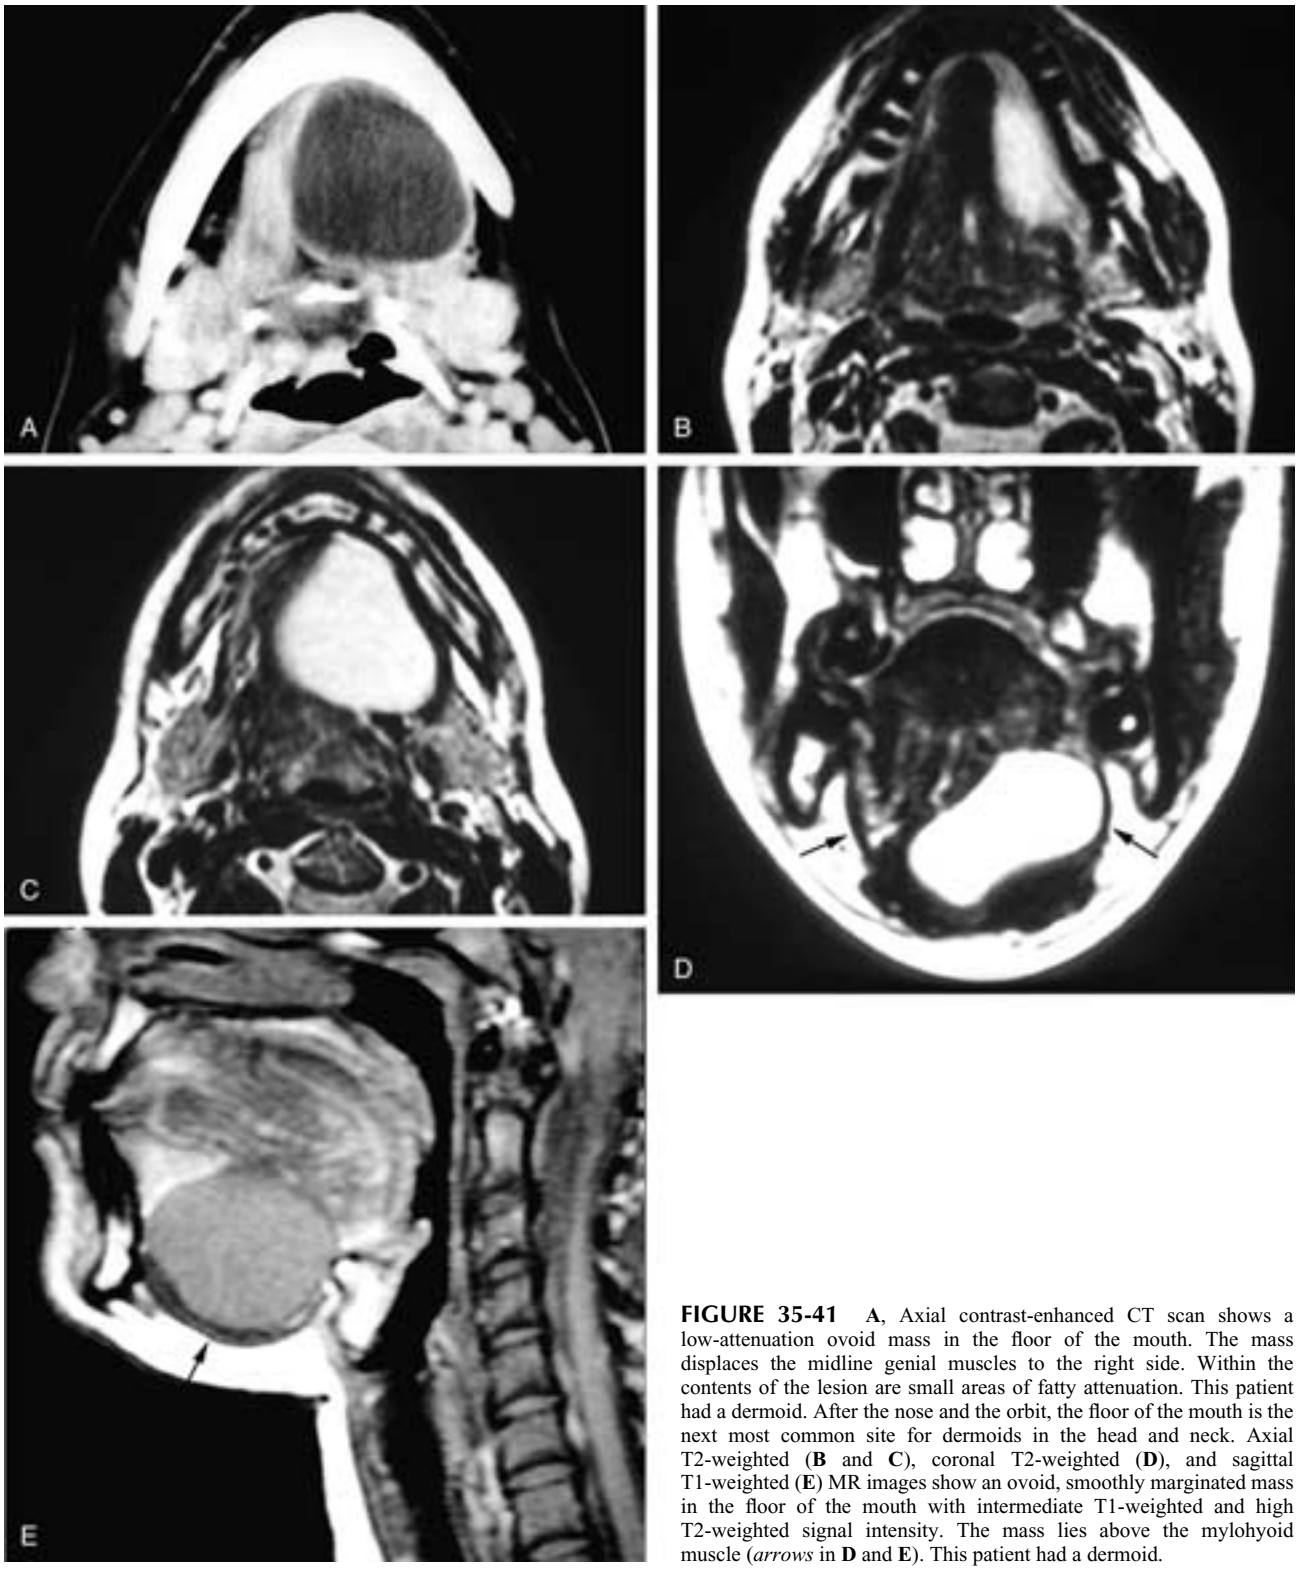

FIGURE 35-41 **A**, Axial contrast-enhanced CT scan shows a low-attenuation ovoid mass in the floor of the mouth. The mass displaces the midline genial muscles to the right side. Within the contents of the lesion are small areas of fatty attenuation. This patient had a dermoid. After the nose and the orbit, the floor of the mouth is the next most common site for dermoids in the head and neck. Axial T2-weighted (**B** and **C**), coronal T2-weighted (**D**), and sagittal T1-weighted (**E**) MR images show an ovoid, smoothly marginated mass in the floor of the mouth with intermediate T1-weighted and high T2-weighted signal intensity. The mass lies above the mylohyoid muscle (*arrows* in **D** and **E**). This patient had a dermoid.

INTRODUCTION

Most often, imaging of the cervical lymph nodes is performed incidental to mapping a potential primary tumor or a source of infection. When lymph nodes are assessed by imaging, the examination can confirm the clinical suspicion of an inflamed or metastatic node, further characterize a suspicious palpable lesion as being an enlarged lymph node, or identify occult lymphadenopathy. In addition, the therapeutic response can be monitored accurately with imaging. Regardless of the reason, imaging usually contributes new information to the overall evaluation of these patients, and it should be considered a basic adjunctive study to clinical evaluation.[1–15]

THE LYMPHATIC SYSTEM

The lymphatic system consists of a number of lymph nodes, mucosa-associated lymphoid tissue (Waldeyer's ring in the head and neck), the spleen, and the thymus. The lymph navigates via an extensive lymphatic capillary network that begins as blind channels that collect the lymph from the intercellular fluid. These channels then develop into afferent lymphatic vessels that carry lymph to the lymph nodes. Efferent lymphatic vessels carry lymph from peripheral lymph nodes to other lymph nodes and eventually, via the thoracic duct on the left side and the right lymphatic duct, to the blood through the great veins in the root of the neck. The embryology of the lymphatic system is discussed in Chapter 33.

LYMPH AND LYMPHATIC FLOW

The direction of the flow of fluid within the vascular and lymphatic capillary beds differs on the arterial and venous sides of these beds. On the arterial side, the blood pressure exceeds the osmotic pressure of the adjacent tissue spaces driving fluid from the capillaries into the interstitial spaces. On the venous side of the capillary bed, the blood pressure drops and the interstitial osmotic pressure rises sufficiently to drive fluid into the postcapillary venules. About 90% of the interstitial fluid is returned to the blood, while the remaining nearly 10% enters the lymph. Virtually any liquid or mobile solid material, including tumor cells, can also enter the lymph.

Lymph is a transparent, colorless, or slightly yellow, watery fluid with a specific gravity of 1.015. It closely resembles blood plasma but is more dilute. The term *peripheral lymph* refers to lymph that is formed in the peripheral tissues and that has not passed through a lymph node. This peripheral lymph is paucicellular. Lymph nodes are referred to as either peripheral or intermediate. Peripheral lymph nodes receive only peripheral lymph. After passing through a peripheral lymph node, the lymph becomes enriched with lymphocytes and is referred to as intermediate lymph.

The efferent lymphatic vessels of these peripheral lymph nodes function as the afferent vessels of the next lymph nodes in a nodal chain. These nodes are referred to as intermediate lymph nodes, and they have two types of afferent lymph supply: (1) the peripheral lymph from the immediate regions and (2) the intermediate lymph from the efferent lymphatics of other peripheral lymph nodes. In turn, the lymph passes to deeper lymph nodes and ultimately to the main lymph trunks and thoracic duct. The lymph within these central trunks and ducts is referred to as central lymph, as it does not pass through additional lymph nodes before reaching the blood.[16]

The peripheral lymph contains between 200 to 1000 cells/mm^3, of which about 15% are cells of the macrophage-monocyte series and the remaining cells are recirculating lymphocytes extravasated from the blood. Most of these lymphocytes are T cells; only about 10% are B cells. The cellularity of intermediate and central lymph varies greatly, ranging from 5000 to 50,000 white cells/mm^3. Most of these cells are small lymphocytes that have migrated from the lymph node paracortices. About 25% are B cells, and the remainder are subsets of T cells. Few macrophage-like cells are present, having apparently been retained by the first lymph nodes they encountered.[16] The population of cells in the lymph alters with stimulation. Large numbers of lymphoid blast cells (immunoblasts) can be seen after antigenic stimulation, comprising nearly half of the cells of efferent lymph from stimulated nodes. This change indicates the vigor of the immune response.[16]

The lymphatic capillaries have no valves; however, the lymphatic vessels have valves that are more closely spaced together than those in comparably sized veins. Expanded pouch-like sinuses are present immediately above the point of attachment of each lymphatic valve, imparting a distended beaded appearance to the lymph vessel when it is fully filled. The lymph is propelled by contractions of the larger vessel walls.

LYMPH NODES: STRUCTURE AND FUNCTION

The lymph nodes are the raison d'être of the lymphatic system. They are situated in either groups or chains so that the afferent lymphatic vessels leading to these lymph nodes drain discrete anatomic regions. In addition to mechanical filtration of the lymph, the lymph nodes are involved with recognition and processing of antigens and lymphopoiesis. Lymph emerging from efferent channels is always enriched with more lymphocytes than the corresponding afferent lymph. Most lymph nodes have an oval or bean shape with a slight depression on the hilar side. The hilum contains arterioles, venules, and efferent lymphatic vessels. There are usually only 2 or 3 efferent vessels at the hilum, but between 6 and 25 afferent lymphatic vessels that enter the nodal periphery away from the hilum (Fig. 36-1).[16–19]

Lymph nodes have a complex architecture that arranges a variety of specific cell populations so that they interact in a favorable environment that allows the various cellular components to process antigens, interact, and generate the immune response. This nodal architecture varies with the anatomic region and with the response to antigen stimulation. Thus, the lymph nodes that drain areas of active antigen stimulation, such as the neck, have larger and more numerous germinal centers, or areas of active lymphoid cell production, than do mesenteric lymph nodes.[19]

The circulating lymph travels to each node through the afferent lymphatic vessels. The lymph then circulates within a system of sinuses, first entering the marginal or subcortical sinuses, then the cortical or intermedullary sinuses, and lastly the medullary sinuses. Finally, the lymph exits the lymph node via the efferent lymph vessels in the nodal hilum. As the lymph flows through the lymph node, it first contacts the cortex, then the paracortex, and then the medulla. Each of these areas has a distinct morphology and function. The lymph brings antigens to the node and carries out antibodies, T cells and macrophage components of cellular immunity, and activated B lymphocytes of humoral immunity. In addition, the phagocytic apparatus of the sinuses filters the lymph, retaining foreign antigens and substances. The passage of the lymph and cells from one chain of lymph nodes to the next is a means by which the immune response is conveyed from the peripheral to the more central lymph nodes.[16–19]

The majority of lymphocytes are brought to the lymph node by the blood supply rather than by the afferent lymphatic vessels. The blood enters the lymph node at the nodal hilum via one or more arterioles. The vessels then divide into branches in the medulla, ramify further into capillary networks in the cortex and paracortex, and then exit the node via a parallel venous system. The blood vessels within the lymph node are morphologically identical to those in other organs, except for the postcapillary venules of the paracortex. These vessels are lined by high endothelial venules (HEV) that are tightly bound together by close interdigitations. The HEV have specialized lymphocyte-homing receptors that are recognized by the circulating lymphocytes and that facilitate lymphocyte migration from the circulating blood into the lymphoid tissue. HEV are also

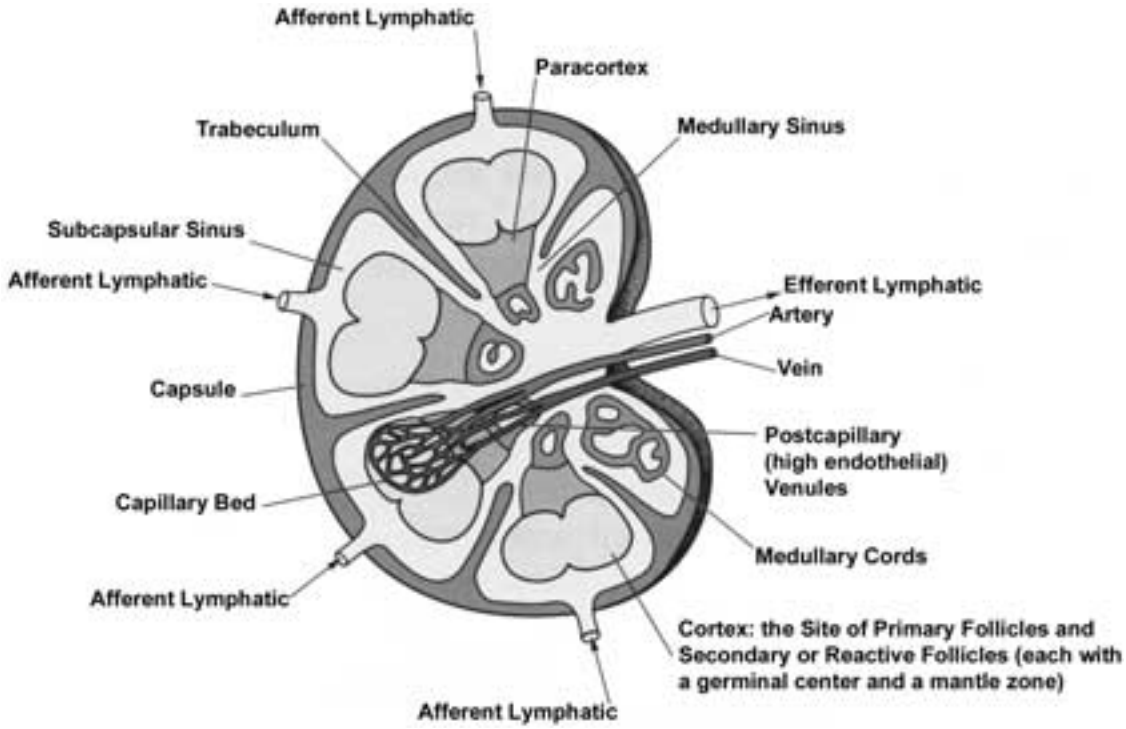

FIGURE 36-1 Diagram of a lymph node. The arrows indicate the direction of the flow of lymph. Afferent lymphatics bring the lymph to the node, and the lymph exits the node via the efferent vessels in the hilum. In the cortex of the node are the primary follicles and the secondary or reactive follicles, each with a germinal center and mantle. It is through the HEV in the paracortex that 10% to 20% of circulating lymphocytes enter the node. (Modified from Iochim H. Lymph Node Pathology. 2nd ed. Philadelphia: JB Lippincott, 1994;1.)

present in extranodal mucosa-associated lymphoid tissue (MALT) such as tonsillar tissue and the gastrointestinal tract. The blood vessels of the cortex and the medulla are not specialized and thus do not allow exit of lymphocytes.[16, 19]

More specifically, it is known that CD44, an 80- to 90-kDa hyaluronate-binding glycoprotein, is involved in binding cells to the HEV of the postcapillary venules, and LECAM-1, a 75- to 85-kDa glycoprotein with lectin activity, is also known to interact with human peripheral lymph node vascular addressin (PNAd) on the HEV. Both CD44 and LECAM-1 are expressed on B lymphocytes. L-Selectin is a cell adhesion molecule that mediates homing of lymphocytes to peripheral lymph nodes and is speculated to bind with the carbohydrate determinant specifically expressed by HEV in the peripheral lymph nodes. It is also probable that sialyl leX determinants, having complex carbohydrate structures, also serve as the ligand for L-selectin on HEV cells.[20–29]

The stroma or supporting framework of the node is formed by the lymph node capsule, trabeculae, and a network of reticular cells and fibers that form the main extracellular matrix of the lymph node and maintain the structure of the node by connections to the trabeculae. These fibers are reinforced by fine collagen fibers, and together this framework supports the lymphoid cells within the lymph node. The main components of the capsule and trabeculae are fibroblasts; however, there are also smooth muscle cells, nerves with Schwann cells, and blood vessels with pericytes.

The cortex, or superficial cortex, is the seat of humoral immunity, mediated by B-cell lymphocytes. Thus, the cortex consists mostly of B cells. The cortex contains lymphoid follicles (primary follicles) that, when stimulated, develop reactive germinal centers (secondary follicles). Reactive follicles are surrounded by a peripheral mantle zone composed of small, mature, circulating, nonactivated B-cell lymphocytes.[19] These lymphocytes enter the node via the postcapillary venules and, failing activation, return to the general circulation within a few hours through the efferent lymphatics. If the small B-cell lymphocytes in the peripheral mantle zone become stimulated by antigens, they undergo blastic transformation and migrate into the germinal zone as small cleaved cells (nondividing centocytes). These cells acquire a narrow rim of pyroninophilic cytoplasm as they reach the large cleave cell stage. The nuclear cleavage then disappears as the nuclei become round or oval, and mitosis of these cells results in small noncleaved (dividing centroblasts) cells that further mature into large noncleaved cells (immunoblasts) that typify germinal follicles. Stimulated immunoblasts then give rise to plasma cells. In the cortex, there are also dendritic reticulum cells that aid in antigen presentation to the lymphocytes. In addition, there are a few T-cell lymphocytes.[16, 19] Thus, when naive B cells are activated by antigen, they mature and produce an expanded population of identical dedicated cells that recognize the same antigen. Histologically, this is seen as an increase in the number and size of germinal centers, with the above-mentioned mantle zone and pale centers containing abundant immunoblasts, and ''tingible body'' macrophages with cytoplasmic nuclear debris.

The paracortical area, or deep cortex, is a densely cellular subcortical area extending between the lymphoid follicles and interdigitating to the corticomedullary junction. It contains postcapillary venules and lymphoid cells. The paracortex is the main site of cellular immunity.[19]

The T cells also enter the lymph node via the postcapillary HEV and, unless activated, leave the node within a few hours through efferent lymphatics. If activated, the T cells enlarge, proliferate, and produce a clone of cells that disseminate peripherally, where they are most active. The T cells are composed of two major subpopulations: T4 (helper cells, CD4 cells) and T8 (suppressor cells, CD8 cells).[19]

The medulla contains lymphocytes, plasmatoid lymphocytes, and mature plasma cells and is the main site of plasma cell proliferation and antibody production. Under intense antigenic stimulation, the medullary cords may extend deep into the cortex. The cords of plasma cells and precursors are separated by wide medullary sinuses containing lymphocytes, monocytes, plasma cells, and macrophages. The plasma cells are primarily responsible for the memory-recall type of antibody stimulation.[19] Additional accessory immunologic cells involved in antigen presentation and processing (monocytic/histiocytic cells) migrate from the peripheral tissues and the bone marrow to the lymph node.

Normally, the lymph node is estimated to recirculate its entire population of lymphocytes within about 12 days. This flow can double or treble when the node is antigenically challenged. In part, this reflects the normal rich lymph node blood flow of about 1 ml/minute/gram and the normal lymph flow of about 10 ml/minute/gram. These flows also increase with antigenic challenge. As the blood flows through the node, between 10% and 20% of the blood lymphocytes extravasate out. Within 5 hours, these lymphocytes migrate through the node and emerge in the efferent lymph.[16]

PATHWAYS OF LYMPH NODE METASTASIS

The ability of tumor to invade basement membrane and underlying connective tissue and gain access to vascular/lymphatic channels is dependent upon the elaboration of extracellular proteases such as matrix metalloproteinases (MMP) and plasminogen activators (see Chapter 44).[30, 31] Lymphatico-lymphatic spread is the dominant pathway by which invasive tumor cells enter the lymph capillaries and metastasize to the lymph nodes. That is, tumor cells enter the lymph and pass into a node via the afferent lymphatic vessels. However, there is also evidence for a hematogenous route, or veno-lymphatic pathway, that allows tumor cells to enter the lymph node via the blood circulation at the nodal hilum and then enter the central region of the lymph node via the HEV cells of the postcapillary paracortical venules following the pathway taken by lymphocytes.[32] This mechanism accounts for the occasional observation of isolated tumor metastasis in the paracortical zone, away from afferent lymphatics.

It has been established that tumor cells may recognize nodal homing sites on the HEV cells of the postcapillary venules.[33–38] There is also evidence that squamous cell carcinoma cells have specific surface markers that may influence their propensity to metastasize to lymph nodes.[20, 21, 23–29, 33–44]

CD44 is a membrane protein involved in cell adhesion, lymphocyte activation, and cellular homing. Numerous splice variants have been described, one of which (CD44v6)

has been found upregulated in metastatic adenocarcinoma.[45, 46] However, conflicting data exist regarding the relationship of CD44v6 and metastatic potential. Downregulation of CD44 has also been associated with metastatic potential, and it has been hypothesized that the lack of ''anchorage'' may enable a tumor to metastasize.[47]

CLINICAL SIGNIFICANCE OF METASTATIC NODAL CARCINOMA

The presence of cervical metastatic nodal disease is a major prognostic determinant for patients with head and neck cancer, significantly reducing patient survival.[48] Historically, surgeons believed that a cure could only be achieved if the primary tumor site was controlled. It is now known that patient mortality may result from recurrent cervical nodal disease and distant metastasis despite control of the primary tumor. In fact, the presence of positive lymph nodes at initial presentation is the strongest prognosticator for the recurrence of cervical nodal metastases and the eventual development of distant metastases.[1–15, 49–52] The presence of a solitary ipsilateral or contralateral positive lymph node, or extracapsular tumor spread, each reduces the expected survival by nearly 50% for all head and neck sites. Presumably due to a reseeding effect, it has also been observed that the persistence or recurrence of tumor at the primary site is associated with an increased incidence of both nodal and distant metastases.

As a result of better local and regional control, patients with head and neck cancers are surviving longer, allowing for the development of distant metastases. Usually the lungs, bones, and liver are involved as a reflection of the natural history of this disease.[8, 53] The potential for distant metastases provides the rationale for neoadjuvant chemotherapy, although this is not presently a universally accepted part of standard initial therapy.

An important issue for upper aerodigestive tract carcinoma is the treatment of the clinically and radiographically negative (N0) neck. When all upper aerodigestive tract sites are considered, about 15% of such N0 necks will eventually develop metastatic disease.[49] The resultant dilemma is how to predict which patients will fall into this 15% group and require treatment, thus avoiding overtreating 85% of these patients. Alternatively, there are the conflicting survival data regarding the approach of awaiting the clinical development of metastatic cervical nodal disease versus treating the neck prophylactically at initial presentation.[54]

One approach to identifying those N0 cases that may require treatment is to examine the risk factors at the primary tumor site. It has been advocated that either a selective neck dissection or radiotherapy should be offered to patients with N0 necks when the risk of occult metastasis exceeds 20%.[55, 56] In multivariate analysis of risk factors, the following are significant independent predictors of occult metastases: tumor site, T stage, tumor thickness, histologic grade, vascular embolization, and perineural infiltration.[55, 57] The number of microvessels in the primary tumor may also be closely associated with the tumor's potential to metastasize to regional lymph nodes.[58] Additionally, metastases with a desmoplastic pattern are associated with a sevenfold increase in the risk of subsequent recurrent neck disease.[59]

There is a wide range of metastatic rates (1% to 85%) for all upper aerodigestive tract sites. For T3/T4 carcinomas of the oral cavity, oropharynx, hypopharynx, and supraglottic larynx, the ipsilateral metastatic rate is greater than 50%.[55] The rate for bilateral metastases or isolated contralateral metastases ranges from 2% to 35%. Tables 36-1 to 36-3 summarize different experiences regarding the incidence of nodal metastasis associated with various head and neck primary tumors. These factors may be helpful in predicting which primary tumors within N0 necks require treatment.

THE CLINICAL IMPACT OF IMAGING METASTATIC LYMPH NODES

Once metastatic adenopathy is identified within the neck, the information derived about the number of nodes, the unilaterality or bilaterality of the disease, the location of the nodes, and the size of the nodes can be used in two different formats to aid prognostication and patient treatment. First, nodal classification incorporates the location of involved lymph nodes to allow selection of the proper type of neck dissection. Second, N status as part of the overall TNM staging system is a critical predictor of survival and dictates treatment philosophy. The ability of imaging to identify clinically silent adenopathy does not necessarily correlate

Table 36-1
INCIDENCE OF IPSILATERAL AND CONTRALATERAL METASTASIS ACCORDING TO STAGE

Tumor Site	% of Cases with Ipsilateral Metastasis				% of Cases with Contralateral Metastasis

Supraglottic larynx	II, III, IV	31–54	22.5

with ''upstaging'' for all patients, as, among other reasons, enlarged nodes may be hyperplastic rather than metastatic.

Various literature reports reveal that imaging can identify 7.5% to 19% of clinically silent metastatic nodes.[1, 3, 4, 6, 7, 60] However, the actual impact of these nodes on staging is not obvious, and several series reflect a wide variation in imaging upstaging. Mancuso et al. reported that 6% of necks were upstaged from N0 to N1.[2] Stevens et al. reported that 2.5% of 40 cases were upstaged from N0 to N1, 10% of cases were upstaged from N0 to N2, and 10% of cases were upstaged from N1 to N2 necks.[4] However, at the other extreme, Close et al. reported imaging upstaging in 67% of N0 necks, while van den Brekel et al. reported imaging upstaging in 71% of N0 necks.[6, 7] These latter two studies probably reflect a smaller number of patients. We believe that larger series would no doubt reflect a lower rate of N0 to N1 upstaging, probably closer to 5% of the time.

Pretreatment imaging may also identify lymph nodes outside of the typical treatment areas (e.g., retropharyngeal or high level II nodes, low level IV or V nodes, or nodes in levels VI and VII), thus expanding the typical treatment fields and potentially improving patient survival.

Postsurgical and/or postradiation surveillance imaging is a mainstay of patient follow-up. Such surveillance probably has very little impact on facilitating cures after local recurrence, but imaging surveillance certainly improves palliation and prolonged disease-free survival (see Chapter 43). Untreated local recurrences usually result in a rapid, uncomfortable death. The treatment of local recurrence thus can result in good palliation, often lasting for several years, which is of incalculable value to these patients and their families.

Table 36-3
PATTERNS OF NODAL METASTASES

	% of Nodal Metastases Based on Palpation					
Primary Tumor	IA	IB	II	III	IV	V
Palatine tonsil	0.6	9.2	59.5	14.4	8.1	8.1
Base of tongue	0.8	4.4	56.4	25.3	5.8	7.1

NODAL CLASSIFICATION

Initially, the aim of developing a classification for identifying the cervical lymph nodes was to achieve anatomic precision. Prior to the early 1900s, there was little established nodal classification, and there was a relative lack of understanding of the cervical lymphatic pathways and their respective drainage regions. The scope of the problem of developing an acceptable nodal nomenclature for the head and neck is exemplified by noting that of the estimated 800 lymph nodes in the body, about 300 are located in the head and neck.[61] Thus, approximately 40% of the lymph nodes in the body are located in about 20% of the body's volume. Further complicating nodal identification is the fact that all of these lymph nodes are situated in fat and, if not reactively or pathologically enlarged, they are almost impossible to identify at surgery or autopsy.

For nearly four decades, the most commonly used classification for the cervical lymph nodes was that developed by Rouviere in 1938.[61] His work followed an earlier classification by Trotter in 1930, which was based on earlier work by Poirer and Charpy in 1909.[62, 63] Many of the landmarks used in these classifications were based on the superficial triangles of the neck, areas that were easily accessible to palpation and referred to by familiar names (Fig. 36-2).

In 1981, Shah et al. suggested that the anatomically based terminology be replaced with a simpler level-based system. Since then, a number of clinically and radiologically based classifications have been proposed that employ such nonanatomic terminology.[2, 50, 64–72] The aim of these more recent classifications was more functional than anatomic. That is, their purpose was to aid the surgeon in selecting the most appropriate type of nodal dissection based on the nodal groups involved. This was accomplished by grouping the cervical nodes into *levels* that were based on pathophysiologic observation of cancer spread. Thus, the distinction between the upper internal jugular and spinal accessory nodes described by Rouviere was replaced by one group of level II nodes.

The landmarks used to separate the nodal levels in these various clinically based classifications vary from those determined by physical palpation to those identified at surgery. This has led to some confusion regarding nodal level boundaries. One of the most recent and most widely utilized classifications is the 1997 version of the American Joint Committee on Cancer (AJCC) (Table 36-4) (Fig. 36-3).[70] Although this work is the product of many years of modification, dis-

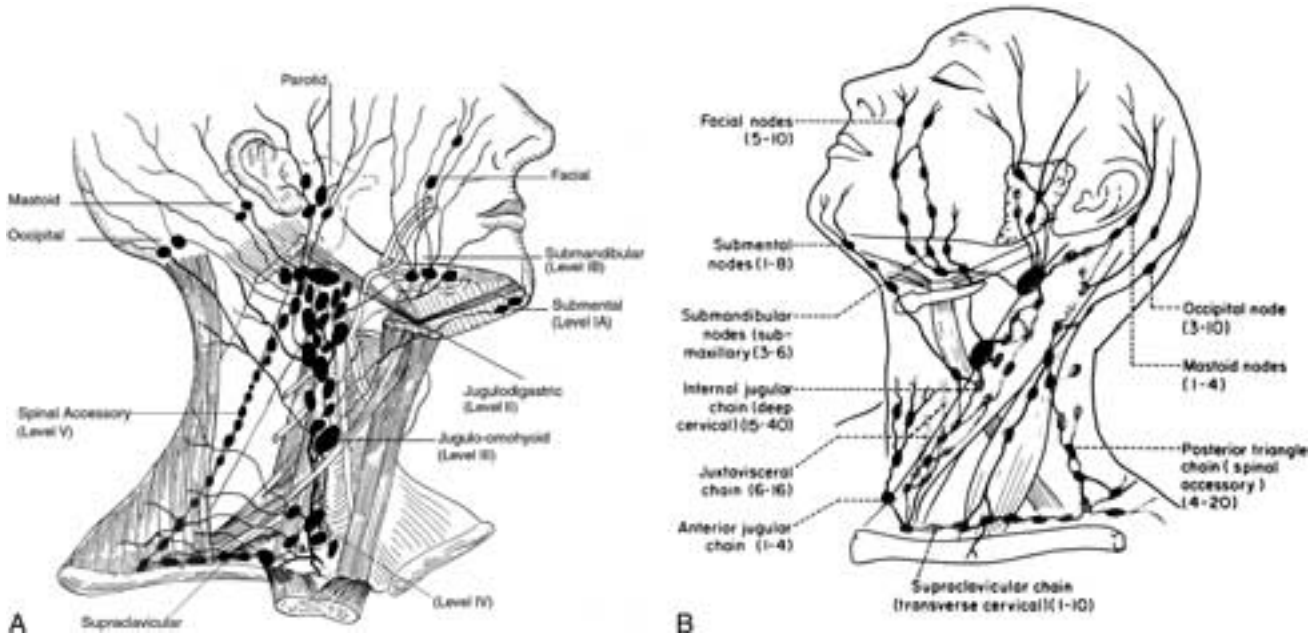

FIGURE 36-2 **A**, Drawing of the head and neck region as seen from the right side. The major nodal chains, as described by Rouviere, are identified, and their corresponding nodal levels are noted. Several of the important superficial nodal groups are also shown. **B**, Drawing of the head and neck region as seen from the left side also shows the important nodal groups described by Rouviere, and the approximate number of nodes usually seen within each nodal group is noted. The retropharyngeal nodes and other deep nodes are not shown.

Table 36-4
1997 AJCC NODAL CLASSIFICATION

Level I	Contains the submental and submandibular triangles bounded by the posterior belly of the digastric muscle, the hyoid bone inferiorly, and the body of the mandible superiorly.
Level II	Contains the upper jugular lymph nodes and extends from the level of the skull base superiorly to the hyoid bone inferiorly.
Level III	Contains the middle jugular lymph nodes from the hyoid bone superiorly to the cricothyroid membrane inferiorly.
Level IV	Contains the lower jugular lymph nodes from the cricothyroid membrane superiorly to the clavicle inferiorly.
Level V	Contains the lymph nodes in the posterior triangle bounded by the anterior border of the sternocleidomastoid muscle anteriorly and the clavicle inferiorly. For descriptive purposes, level V may be further subdivided into upper, middle, and lower levels corresponding to the superior and inferior planes that define levels II, III, and IV.
Level VI	Contains the lymph nodes of the anterior compartment from the hyoid bone superiorly to the suprasternal notch inferiorly. They lie between the medial borders of the carotid sheaths.
Level VII	Contains the lymph nodes inferior to the suprasternal notch in the upper mediastinum.

Note: Retropharyngeal, parotid, facial, occipital, and other nodes are referred to by these names.

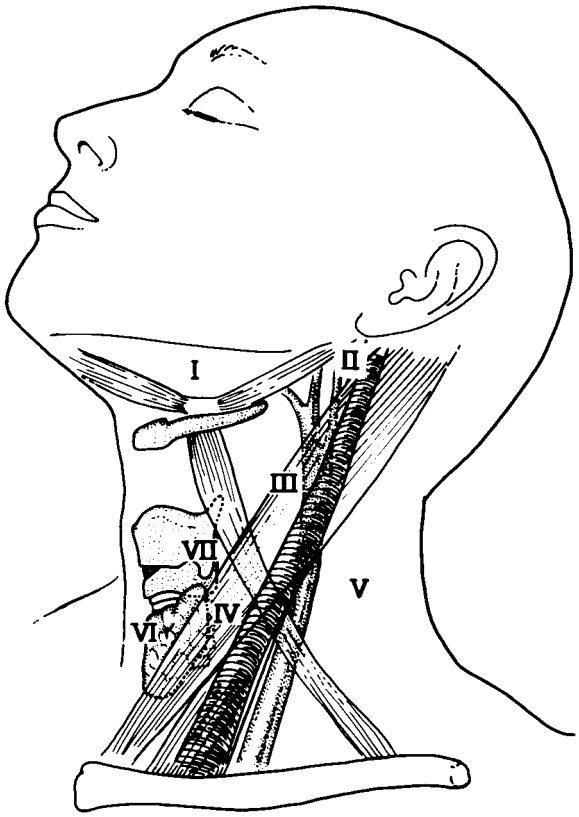

FIGURE 36-3 Drawing of the head and neck region as seen from the left side showing the AJCC nodal levels. Note that the internal jugular vein parallels the oblique orientation of the sternocleidomastoid muscle, and the vein is lateral to the internal carotid artery, which runs more vertically in the neck. Thus, the vein is dorsal to the artery at the skull base but ventral to the artery at the root of the neck. The digastric and omohyoid muscles are indicated for reference. Nodal levels I to VII of the AJCC classification are indicated.

cussion, and pathologic correlation, there are several areas that are somewhat broadly defined and may lack reproducibility. The American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) classification was modified by Robbins in 1998.[73] Differences between these two classifications include the separation of level II nodes into the internal jugular chain (IIA) and the spinal accessory chain (IIB), the separation of level IV nodes into those deep to the sternal head of the sternocleidomastoid muscle (IVA) and those that lie deep to the clavicular head (IVB) of this muscle, and the division of the level V nodes into upper (VA) and lower (VB) divisions rather than into the three divisions suggested in the AJCC classification. These alterations were suggested because (1) involvement of level IIB nodes most often is associated with tumors in the oropharynx and nasopharynx, (2) involvement of level IVA nodes has a high risk of nodal disease in level VI, (3) disease in level IVB is associated with nodal metastasis in level V, and (4) the observation that the upper level V nodes of the AJCC system actually contain few, if any, nodes. It was thus considered more reasonable to divide level V simply into an upper and a lower group based on the position of the inferior belly of the omohyoid muscle. Having noted these differences, it should be mentioned that there is no present consensus as to the need to split some of the nodal levels into separate subcategories.

To address specific issues raised in both the AJCC and the AAO-HNS classifications, and to bring the anatomic detail and reproducibility of imaging to nodal classification, an imaging classification was suggested in 1999.[74] This classification can be applied to either the clinical examination or imaging studies using landmarks readily identified with either. The system is not meant to replace the clinical assessment, but rather to allow clinicians and radiologists to use the same system. Imaging was chosen to be the basis of the modification for three reasons: (1) most patients with head and neck cancer today have an initial computed tomography (CT) or magnetic resonance (MR) imaging study to assess both the primary tumor and the extent of nodal disease; this is especially true for deeply situated tumors. It is estimated that over 80% of cancer patients obtain such imaging. (2) Imaging can identify clinically silent nodes (usually in areas inaccessible to palpation such as retropharyngeal nodes, nodes deep to the sternocleidomastoid muscle, and deep low visceral nodes).[1–8, 60] (3) Imaging has the potential to best reveal precise anatomic landmarks that lend themselves to a consistent definition of nodal groups or levels. This classification is presented in Table 36-5 and is summarized in Figures 36-4 and 36-5, and a comparison between the three clas-

Table 36-5
SUMMARY OF THE IMAGING-BASED LEVEL NODAL CLASSIFICATION

Level I	The submental and submandibular nodes. They lie above the hyoid bone, below the mylohyoid muscle and anterior to the back of the submandibular gland.
Level IA	The submental nodes. They lie between the medial margins of the anterior bellies of the digastric muscles.
Level IB	The submandibular nodes. On each side, they lie lateral to the level IA nodes and anterior to the back of each submandibular gland.
Level II	The upper internal jugular nodes. They extend from the skull base to the level of the bottom of the body of the hyoid bone. They are posterior to the back of the submandibular gland and anterior to the back of the sternocleidomastoid muscle.
Level IIA	A level II node that lies either anterior, medial, lateral, or posterior to the internal jugular vein. If posterior to the vein, the node is inseparable from the vein.
Level IIB	A level II node that lies posterior to the internal jugular vein and has a fat plane separating it from the vein.
Level III	The midjugular nodes. They extend from the level of the bottom of the body of the hyoid bone to the level of the bottom of the cricoid arch. They lie anterior to the back of the sternocleidomastoid muscle.
Level IV	The low jugular nodes. They extend from the level of the bottom of the cricoid arch to the level of the clavicle. They lie anterior to a line connecting the back of the sternocleidomastoid muscle and the posterior-lateral margin of the anterior scalene muscle. They are also lateral to the carotid arteries.
Level V	The nodes in the posterior triangle. They lie posterior to the back of the sternocleidomastoid muscle from the skull base to the level of the bottom of the cricoid arch and posterior to a line connecting the back of the sternocleidomastoid muscle and the posterior-lateral margin of the anterior scalene muscle from the level of the bottom of the cricoid arch to the level of the clavicle. They also lie anterior to the anterior edge of the trapezius muscle.
Level VA	Upper level V nodes. They extend from the skull base to the level of the bottom of the cricoid arch.
Level VB	Lower level V nodes. They extend from the level of the bottom of the cricoid arch to the level of the clavicle as seen on each axial scan.
Level VI	The upper visceral nodes. They lie between the carotid arteries from the level of the bottom of the body of the hyoid bone to the level of the top of the manubrium.
Level VII	The superior mediastinal nodes. They lie between the carotid arteries below the level of the top of the manubrium and above the level of the innominate vein.
Supraclavicular Nodes	They lie at or caudal to the level of the clavicle and lateral to the carotid artery on each side of the neck as seen on each axial scan.
Retropharyngeal Nodes	Within 2 cm of the skull base they lie medial to the internal carotid arteries.

Note: The parotid nodes and other superficial nodes are referred to by their anatomic names.

sifications is shown in Table 36-6. Nodal classifications are continuously evolving, with modifications constantly being proposed to better allow surgeons to plan the most appropriate surgery. Thus, these classifications are presented with the understanding that modifications can be anticipated. The enthusiastic clinical acceptance of the imaging-based classification hopefully has ushered in an era in which classification and staging of head and neck malignancies will require CT or MR imaging studies.

The Rouvière System

The predominant nodal classification used for nearly 40 years was that of the French anatomist Rouvière (Fig. 36-2).[61] He described a lymphoid ''collar'' of nodes encircling the top of the neck composed of the occipital, mastoid, parotid, facial, retropharyngeal, submaxillary, submental, and sublingual lymph nodes. Anterior and lateral cervical groups of lymph nodes, respectively, descended from the collar along the front and sides of the neck. Rouviere described the deep lateral cervical group as being composed of an internal jugular chain, a spinal accessory (posterior triangle) chain, and a transverse cervical (supraclavicular) chain. These three chains, joined at their edges, formed a lateral triangle of nodes in the neck. The deep cervical or internal jugular lymph node chain is the primary drainage pathway of the head and neck and ultimately receives lymph from all of the other nodal chains. Two nodes in this chain are of special importance. The first is the jugulodigastric (JD), or sentinel, node, which lies near the angle of the mandible and receives lymph from the tonsils, pharynx, mouth, and facial region. As a result of numerous infections in its drainage area, this node tends to be hyperplastic and larger than most other lymph nodes. The second node is the juguloomohyoid (JO) node, which lies near the point at which the omohyoid muscle crosses the internal jugular chain. The JO node receives all of the lymph from the tongue, and if enlarged, it may be the first physical finding to suggest an otherwise clinically silent tongue tumor.[61]

As summarized by Last, the lymphatics of the head and neck, with the exception of the tongue, are organized into two circles or cylinders: an outer one that contains the superficial nodes extending from the chin to the occiput (the submental, submandibular, buccal, mandibular, preauricular, and occipital nodes) and an inner one that lies within the outer one and surrounds the upper aerodigestive tract. Specifically, the nodal groups included in the inner circle are the retropharyngeal, pretracheal, and paratracheal nodes. Lying vertically between these two circles and accompanying the internal jugular veins are the deep cervical

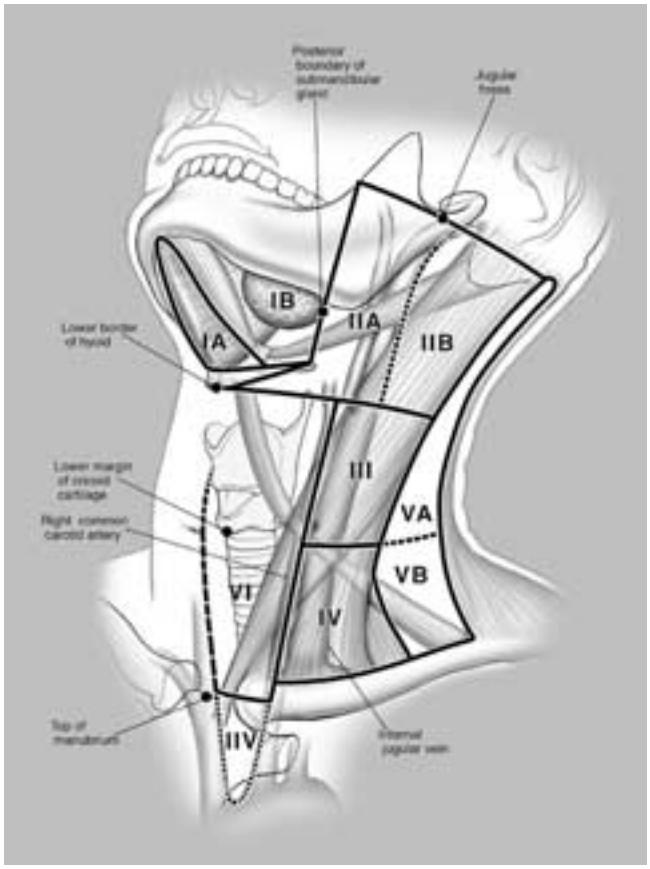

FIGURE 36-5 Diagram of the head and neck viewed from the left anterior oblique projection. The broad lines outline the boundaries of the nodal levels, and I to VII identify the specific nodal levels of the imagery-based nodal classification.

Table 36-6
COMPARISON OF AJCC, AAO-HNS, AND IMAGING NODAL CLASSIFICATIONS

	1997 AJCC	1998 Modification of the 1991 AAO-HNS	1999 Imaging
Level I	Contains the submental and submandibular triangles bounded by the posterior belly of the digastric muscle, the hyoid bone inferiorly and the body of the mandible superiorly.	Submental and submandibular nodes from the mandible to the hyoid and anterior to the posterior bellies of the digastric muscle.	The submental and submandibular nodes. They lie above the hyoid bone, below the mylohyoid muscle and anterior to the back of the submandibular gland.
Level IA		Submental nodes between the anterior bellies of the digastric muscles, above the hyoid bone and below the mandible.	The submental nodes. They lie between the medial margins of the anterior bellies of the digastric muscles.
Level IB		Submandibular nodes between the anterior and posterior bellies of the digastric muscle below the body of the mandible.	The submandibular nodes. On each side, they lie lateral to the level IA nodes and anterior to the back of each submandibular gland.
Level II	Contains the upper jugular lymph nodes and extends from the level of the skull base superiorly to the hyoid bone inferiorly.	Upper jugular nodes from the skull base to either the carotid bifurcation or the hyoid bone. Anterior to the posterior border of the sternocleidomastoid muscle and posterior to the lateral border of the stylohyoid muscle.	The upper internal jugular nodes. They extend from the skull base to the level of the bottom of the body of the hyoid bone. They are posterior to the back of the submandibular gland and anterior to the back of the sternocleidomastoid muscle.
Level IIA		Level II nodes anterior to the spinal accessory nerve.	A level II node that lies either anterior, medial, lateral, or posterior to the internal jugular vein. If posterior to the vein, the node is inseparable from the vein.
Level IIB		Level Il nodes posterior to the spinal accessory nerve.	A level II node that lies posterior to the internal jugular vein and has a fat plane separating it and the vein.
Level III	Contains the middle jugular lymph nodes from the hyoid bone superiorly to the cricothyroid membrane inferiorly.	Middle jugular nodes from the hyoid bone or carotid bifurcation to the cricothyroid membrane or where the omohyoid muscle crosses the internal jugular vein bone. They are anterior to the posterior border of the sternocleidomastoid muscle and posterior to the lateral border of the stylohyoid muscle.	The midjugular nodes. They extend from the level of the bottom of the body of the hyoid bone to the level of the bottom of the cricoid arch. They lie anterior to the back of the sternocleidomastoid muscle.
Level IV	Contains the lower jugular lymph nodes from the cricothyroid membrane superiorly to the clavicle inferiorly.	Lower jugular nodes from the level where the omohyoid muscle crosses the internal jugular vein to the level of the clavicle. Anterior to the posterior border of the sternocleidomastoid muscle and posterior to the lateral border of the sternohyoid muscle.	The low jugular nodes. They extend from the level of the bottom of the cricoid arch to the level of the clavicle. They lie anterior to a line connecting the back of the sternocleidomastoid muscle and the posterior-lateral margin of the anterior scalene muscle. They are also lateral to the carotid arteries.
Level IVA		Level IV nodes deep to the sternal head of the sternocleidomastoid muscle.	
Level IVB		Level IV nodes deep to the clavicular head of the sternocleidomastoid muscle.	
Level V	Contains the lymph nodes in the posterior triangle bounded by the anterior border of the sternocleidomastoid muscle anteriorly and the clavicle inferiorly. For descriptive purposes, level V may be further subdivided into upper, middle, and lower levels corresponding to the superior and inferior planes that define levels II, III, and IV.	Posterior triangle nodes lying between the posterior border of the sternocleidomastoid muscle, the anterior border of the trapezius muscle, and above the clavicle.	The nodes in the posterior triangle. They lie posterior to the back of the sternocleidomastoid muscle from the skull base to the level of the bottom of the cricoid arch and posterior to a line connecting the back of the sternocleidomastoid muscle and the posterior-lateral margin of the anterior scalene muscle from the level of the bottom of the cricoid arch to the level of the clavicle. The also lie anterior to the anterior edge of the trapezius muscle.
Level VA		Level V nodes lying above the level of the posterior belly of the omohyoid muscle.	Upper level V nodes extend from the skull base to the level of the bottom of the cricoid arch.

Table 36-6
COMPARISON OF AJCC, AAO-HNS, AND IMAGING NODAL CLASSIFICATIONS *Continued*

	1997 AJCC	1998 Modification of the 1991 AAO-HNS	1999 Imaging
Level VB		Level V nodes lying below the level of the posterior belly of the omohyoid muscle.	Lower level V nodes extend from the level of the bottom of the cricoid arch to the level of the clavicle as seen on each axial scan.
Level VI	Contains the lymph nodes of the anterior compartment from the hyoid bone superiorly to the suprasternal notch inferiorly. On each side, the lateral border is formed by the medial border of the carotid sheath.	Central compartment nodes extending from the hyoid bone to the suprasternal notch and lying between the medial border of each carotid sheath.	The upper visceral nodes. They lie between the carotid arteries from the level of the bottom of the body of the hyoid bone to the level of the top of the manubrium.
Level VII	Contains the lymph nodes inferior to the suprasternal notch in the upper mediastinum.		The superior mediastinal nodes. They lie between the carotid arteries below the level of the top of the manubrium and above the level of the innominate vein.
Supraclavicular Nodes	They lie below the level of Ho's triangle.		They lie at or caudal to the level of the clavicle and lateral to the carotid artery on each side of the neck, as seen on each axial scan.
Retropharyngeal Nodes			Within 2 cm of the skull base, they lie medial to the internal carotid arteries.

Note: Retropharyngeal, parotid, facial, occipital, and other nodes are referred to by these names for all classifications.

(jugular chain) nodes, into which virtually all of the lymph from both the inner and outer circles of nodes drains. Table 36-7 compares the Rouviere nomenclature with the level systems.[75]

The Level Systems

Since the introduction of the initial level nodal classification, there have been a number of classifications that define the nodal groups slightly differently.[2, 50, 64–72] Of these various proposals, the 1997 AJCC classification, the 1991 AAO-HNS classification and its 1998 modification, and the 1999 imaging modification[70, 73, 74] are the most widely used. They are summarized in Tables 36-4 to 36-7.

The Imaging-Based System

How to Scan the Neck

It is imperative that any nodal classification based on CT and MR imaging be reproducible no matter what scanner is utilized or where the imaging study is performed. In order to accomplish this, a consistent technique must be used. This is especially true for CT, where patient positioning and gantry angulation are variables. There is no one universal technique that is utilized to perform CT scans of the neck. However, the following technique is used by many head and neck radiologists, and slight variations from it do not effectively influence the nodal levels.

The axial plane referred to in this classification is obtained with the patient's head in a comfortable neutral position, with the hard palate perpendicular to the table top and the shoulders down as far as possible. The scanner gantry is aligned along the inferior orbital meatal (IOM) plane and, if possible, the examination should be performed with the administration of intravenous contrast to allow the best possible differentiation of nodes from vessels. The recommended field of view is 16 to 18 mm. With CT, the examination is performed as contiguous 3-mm scans from the skull base to the manubrium or as a spiral study reconstructed as contiguous 2-mm or 3-mm slices. With MR imaging, the scans should be no thicker than 5 mm (preferably 3 to 4 mm), with either no interslice gap or a 1-mm interslice gap. If there is a history of thyroid or cervical esophageal cancer, the caudal margin of the studies should be extended down to the level of the carina to ensure inclusion of the superior mediastinum.

When imaging a neck, the entire neck should be studied to evaluate both a potential primary tumor or infection site as well as any lymphadenopathy. Thus, the routine neck imaging examination should include the skull base and extend down to the manubrium. Using this imaging approach, the most likely potential primary sites along Waldeyer's ring, as well as all of the nodal chains, are visualized. This approach is especially pertinent when imaging the 3% to 9% of patients who present with metastatic adenopathy and no known primary tumor site. A discussion of ultrasound imaging of the neck appears in Chapter 37.

How to Use the Imaging-Based Classification

The classification was designed to be easily and readily usable. Each side of the neck should be evaluated separately. That is, the ''lines'' that are used to define the boundaries of the levels should be ''drawn'' separately for each side of the neck. The lines need not actually be drawn, as when one becomes familiar with the classification, they can be easily approximated visually or a straight-line guide or ruler can be placed on the film or monitor. Whenever a lymph node is transected by one of the lines that define the levels, the side

Copyright © 2003, Mosby, Inc. All rights reserved.

of the line on which the majority of the nodal cross-sectional area lies is the level in which the lymph node should be classified. The supraclavicular fossa is defined on each axial scan whenever any portion of the clavicle is identified on one side of the neck. That is, if the scan level is cranial to any portion of the clavicle, the nodes in the lower lateral neck should be classified as being in either level IV or level VB. Once any portion of the clavicle is seen on the scan, the level VB nodes are classified as supraclavicular nodes. If nodes are seen below the level of the clavicle and lateral to the ribs, they are axillary nodes. The clinically important internal jugular nodes described by Rouviere are now classified as level II, III, or IV nodes, depending on their location with reference to the axial scan levels of the bottom of the body of the hyoid bone and the bottom of the arch (anterior rim) of the cricoid cartilage (Figs. 36-4 and 36-5).

The Imaging-Based Classification

Level I includes all of the nodes above the bottom of the body of the hyoid bone, below the mylohyoid muscles, and anterior to a transverse line drawn on each axial image through the posterior edge of the submandibular gland (Figs. 36-6 to 36-8). Thus, level I nodes include the previously classified submental and submandibular nodes. Level I nodes can be subclassified into levels IA and IB.

Level IA represents the nodes that lie between the medial margins of the anterior bellies of the digastric muscles, above the bottom of the body of the hyoid bone and below the mylohyoid muscle (previously classified as submental nodes) (Figs. 36-7 and 36-9).

Level IB represents the nodes that lie below the mylohyoid muscle, above the bottom of the body of the hyoid bone, posterior and lateral to the medial edge of the anterior belly of the digastric muscle, and anterior to a transverse line drawn on each axial image tangent to the posterior surface of the submandibular gland on each side of the neck (previously classified as submandibular nodes) (Figs. 36-6 to 36-8).

Level II extends from the skull base, at the lower level of the bony margin of the jugular fossa, to the level of the lower body of the hyoid bone (Figs. 36-6 to 36-10). Level II nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle and lie posterior to a transverse line drawn on each axial scan through the posterior edge of the submandibular gland. If a node situated within 2 cm of the skull base lies anterior, lateral, or posterior to the carotid sheath, it is classified as a level II node. If the node lies medial to the internal carotid artery, it is classified as a *retropharyngeal node* (Figs. 36-9 and 36-11). Caudal to 2 cm below the skull base, level II nodes can lie anterior, lateral, medial, and posterior to the internal jugular vein. Level II nodes can be subclassified into levels IIA and IIB.

Level IIA nodes are level II nodes that lie posterior to the internal jugular vein and are inseparable from the vein, or they are nodes that lie anterior, lateral, or medial to the vein (previously classified as upper internal jugular nodes) (Figs. 36-6 to 36-10).

Level IIB nodes are level II nodes that lie posterior to the internal jugular vein and have a fat plane

Table 36-7
COMPARISON OF THE ROUVIERE AND LEVEL SYSTEMS OF NODAL CLASSIFICATION

Rouviere System	AJCC Level System	Imaging-Based Level System
Submental nodes	I	I (IA) (medial to the medial edge of the anterior belly of each digastric muscle)
Submandibular nodes	I	I (IB) (lateral to IA nodes and anterior to the back edge of the submandibular gland)
Internal jugular nodes	II (skull base to hyoid bone, anterior to back edge of sternocleidomastoid muscle)	II (skull base to bottom of body of hyoid bone, anterior to back edge of sternocleidomastoid muscle)
Retropharyngeal nodes		Retropharyngeal node medial to internal carotid artery within 2 cm of skull base
	III (hyoid to cricothyroid membrane, anterior to back edge of sternocleidomastoid muscle)	III (bottom of body of hyoid bone to bottom of cricoid arch, anterior to back edge of sternocleidomastoid muscle)
	IV (cricothyroid membrane to clavicle, anterior to back edge of sternocleidomastoid muscle)	IV (bottom of cricoid arch to top of manubrium, anterior to back edge of sternocleidomastoid muscle)
Spinal accessory nodes	V (posterior to sternocleidomastoid muscle, anterior to trapezius, above clavicle)	V (posterior to sternocleidomastoid muscle, anterior to trapezius, above clavicle) VA (level V nodes from skull base to the level of the bottom of the cricoid arch) VB (level V nodes from level of bottom of cricoid arch to level of clavicle)
Anterior compartment nodes	VI (below hyoid bone, above suprasternal notch, between carotid sheaths)	VI (below bottom of body of hyoid bone, above top of manubrium, medial to carotid arteries)
Upper mediastinal nodes	VII (below suprasternal notch)	VI (below top of manubrium and above innominate vein)

Note: Facial, parotid, retropharyngeal, occipital, and other nodes are referred to by these names for all classifications.

VIEW IMAGE

FIGURES 36-6 TO 36-19 Representative axial contrast-enhanced CT scans of the neck illustrating the use of the imaging-based nodal classification. In Figures 36-6 to 36-9, note that the dorsal edge of the submandibular gland (*S*) separates levels I and II. The medial edge of the anterior belly of the digastric muscle (*ad*) separates levels IA and IB. Also, note that level IIA nodes can be medial, anterior, or lateral to the internal jugular vein (*v*). They can also be posterior to the vein and touching it. Level IIB nodes are posterior to the vein and are not touching the vein. The back edge of the sternocleidomastoid muscle separates levels II, III, and IV from level V.

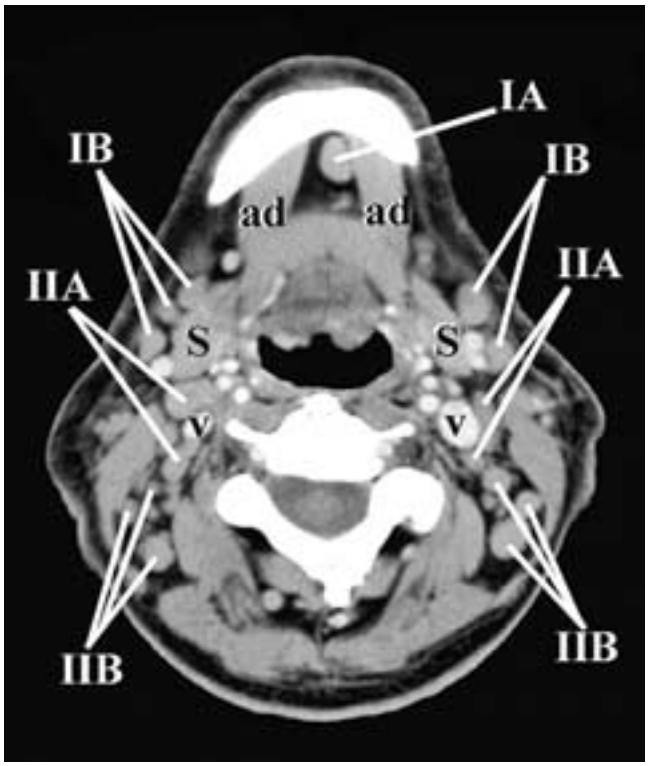
In Figures 36-10 and 36-11, note that the medial border of the internal carotid artery separates level II nodes from retropharyngeal nodes. Figures 36-12 and 36-13 are between the levels of the bottom of the body of the hyoid bone and the bottom of the cricoid cartilage. They define the level III nodes. In Figures 36-14 to 36-18, a line drawn from the back of the sternocleidomastoid muscle and the lateral edge of the anterior scalene muscle separates level IV from level V. Whenever a portion of the clavicle is seen on the image (Figs. 36-16 to 36-18), the level V nodes are referred to as *supraclavicular nodes.*

Below the bottom of the hyoid, the medial borders of the carotid arteries separate level IV nodes from level VI nodes. The upper border of the manubrium separates levels VI and VII (Fig. 36-19).

separating the nodes and the vein (previously classified as upper spinal accessary nodes) (Figs. 36-6 to 36-8).

Level III nodes lie between the level of the lower body of the hyoid bone and the level of the lower margin of the cricoid cartilage arch (Figs. 36-12 and 36-13). These nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle. Level III nodes also lie lateral to the medial margin of either the common carotid artery or the internal carotid artery. On each side of the neck, the medial margin of these arteries separates level III nodes (which are lateral) from level VI nodes (which are medial). Level III nodes were previously known as the midjugular nodes.

Level IV nodes lie between the level of the lower margin of the cricoid cartilage arch and the level of the clavicle on each side, as seen on each axial scan. These nodes lie anterior and medial to an oblique line



VIEW IMAGE

FIGURE 36-7 *Continued*

drawn through the posterior edge of the sternocleidomastoid muscle and the lateral posterior edge of the anterior scalene muscle (Figs. 36-14 to 36-18). The medial aspect of the common carotid artery is the landmark that separates level IV nodes (which are lateral) from level VI nodes (which are medial) to this artery (Figs. 36-14 and 36-18). Level IV nodes were previously known as the low jugular nodes (including the prescalene nodes).

Level V nodes extend from the skull base, at the posterior border of the attachment of the sternocleidomastoid muscle, to the level of the clavicle, as seen on each axial scan (Figs. 36-8, 36-10, and 36-12 to 36-16).

FIGURE 36-19 *Continued*

Level VA (*upper level V*) nodes lie between the skull base and the level of the lower margin of the cricoid cartilage arch. They are behind the posterior edge of the sternocleidomastoid muscle (Figs. 36-8, 36-10, 36-12, and 36-13).

Level VB (*lower level V*) nodes on each side lie between the level of the lower margin of the cricoid cartilage arch and the level of the clavicle, as seen on each axial scan. They are behind an oblique line through the posterior edge of the sternocleidomastoid muscle and the lateral posterior edge of the anterior scalene muscle (Figs. 36-14 to 36-16).

Level VI nodes lie inferior to the lower body of the hyoid bone, superior to the top of the manubrium, and between the medial margins of the left and right common carotid arteries or the internal carotid arteries. They are the visceral nodes (Figs. 36-14 and 36-18).

Level VII nodes lie caudal to the top of the manubrium in the superior mediastinum, between the medial margins of the left and right common carotid arteries (Fig. 36-19). These superior mediastinal nodes extend caudally to the level of the innominate vein.

To maintain consistency with the prior classifications, the following nodal groups continue to be referred by their anatomic names: supraclavicular, retropharyngeal, parotid, facial, occipital, postauricular, and the other superficial nodes.

It is also important to recognize that from both a clinical and an imaging perspective, once a metastatic lymph node is identified, knowledge of the lymphatic anatomy of the neck often allows the likely location of a primary tumor to be suggested. This is summarized in Tables 36-2, 36-3, 36-8, and 36-9).[70, 76]

As mentioned earlier, in the ever-changing world of nodal classification, there has been some clinical discussion about subdividing level IV nodes into IVA and IVB nodes. However, the imaging identification of the IVA nodes deep to the sternal head of the sternocleidomastoid muscle is inconsistent. It may be that these nodes, if they are added to the clinical nodal classification, along with the supraclavicular nodes, may be better and more consistently classified clinically.

NODAL STAGING

Nodal staging differs from nodal classification. Whereas nodal classification identifies the nodal groups involved and, hopefully, is useful in assisting the clinician in determining the type of surgery that is best for that specific nodal disease, nodal staging relates the overall number, size, and location of the affected nodes to the prognosis. That is, rather than being concerned with the precise location of any nodal disease, as with a classification, staging is concerned with the presence or absence of nodal disease, nodal size, and a limited assessment of nodal number. Initially, the assessment of cervical lymphadenopathy was based on clinical evaluation, and the criteria included nodal size, nodal mobility or fixation, the unilateral or bilateral location of the nodes, and whether the disease represented single or multiple nodal involvement.[48] The primary limitations to this clinical approach were the variations in the subjective evaluation of some of these criteria.

In 1987, the AJCC and the International Union Against Cancer (IUCC) developed a common staging system that eliminated the subjective criterion of nodal fixation, which varied with nodal location and with the skill of the clinician.[68] Table 36-10 shows the refinements in this system as of 1997.[70] It is a TNM-based system that assesses the size of the primary tumor (T), regional lymph node involvement (N), and distant metastasis (M). Although this single reporting system is now used worldwide, this categorization still does not address a number of pathophysiologic issues such as the significance of a node's location in relation to the primary tumor site, the specific nodal chain involved, the reactive lymphoid response, tumor histology, and the effect of the primary site on the prognosis.

The initial clinical pretreatment classification is referred to as the cTNM classification. Once the pathologic assessment of a resected specimen is made, pathologic staging (pTNM) can be performed. If a cancer recurs after therapy, it is restaged using the same criteria utilized in the initial staging; however, this restaging is referred to as rTNM staging. A final classification after autopsy, if available, is referred to as the aTNM classification. If imaging becomes recognized by the AJCC as a staging modality, its classification might be referred to as iTNM. Other descriptors can be used to assess multiple primary tumors (m), the effect of neoadjuvant therapy (y), histopathologic grade (G), lymphatic vessel invasion (L), venous invasion (V), and residual tumor after treatment (R). Unfortunately, as with all such staging systems, interobserver inconsistencies and errors in measurements and assessments remain potentially confounding factors.[70]

By definition, direct extension of the primary tumor into a lymph node is considered lymph node metastasis. Metastasis to any lymph node other than a regional node is considered distant metastasis. If a microscopic tumor nodule measuring up to 3 mm in greatest dimension is found, it is considered discontinuous tumor extension and it is classified in a T category. If the tumor nodule is greater than 3 mm and even if there is no evidence of residual lymph node tissue, it is

Table 36-8
PRIMARY TUMOR LOCATIONS AND THEIR LYMPH NODE DRAINAGE AREAS

Anatomic Area	Anatomic Subdivision(s)	Primary Nodal Drainage Group(s)
Scalp	Frontal region	Preauricular, parotid
	Temporoparietal region	Parotid, retroauricular
	Occipital region	Occipital, III, IV
Pinna and external auditory canal	Anterior portion	Preauricular, parotid
	Posterior portion	Retroauricular, II, III
	Inferior portion	Superficial, II, III
Face	Eyelids and conjunctiva	IB (submandibular), parotid
	Posterior cheek	Parotid
	Anterior cheek, side of nose, upper lip, and lateral lower lip	IB (submandibular)
	Deep portion of temporal and infratemporal fossae	Deep facial, II, III
	Buccal cheek and lips	IB (submandibular)
	Central lower lip and chin	IA (submental)
Nasal cavities	Anterior nose	IB (submandibular)
	Posterior two-thirds of nasal cavities and paranasal sinuses	Retropharyngeal, II, III
		IB (submandibular)
Mouth	Lower gums	IB (submandibular)
	Upper gums and hard palate	II, III
	Soft palate	Retropharyngeal, parotid, II, III
	Anterior floor of mouth	IA (submental), II, III
	Rest of floor of mouth	II, III, IB (submandibular)
Pharynx	Nasopharynx, oropharynx	Retropharyngeal, II, III, V
	Hypopharynx	II, III, V, retropharyngeal
	Postcricoid	II, IV, VI
Palatine tonsil	Palatine tonsil	II, III, IV, V
Tongue	Tip	IA (submental)
	Sides of anterior two-thirds and floor of mouth	IB (submandibular), II, III
	Posterior third	Bilateral II, III, (jugulo-omohyoid), IV, V
Larynx	Supraglottic	II, III
	Glottic	
	Subglottic	VI, IV, III
Esophagus	Cervical esophagus	VI, VII, IV, III
Thyroid and parathyroid	Thyroid, parathyroid	VI, III, IV, I, V, VII
Salivary glands	Parotid	II, III, V, superficial
	Submandibular	IB (submandibular)
	Sublingual	IA, IB (submental and submandibular)
Orbit	Eye	Preauricular, parotid, II
	Lacrimal gland	

Table 36-9
NAMED LYMPH NODE GROUPS: THEIR PRIMARY DRAINAGE AREAS AND WHERE THEY DRAIN

Nodes	Drainage Regions	Drain To
Occipital	Occipital region of scalp	II (superior deep cervical nodes)
Retroauricular (mastoid)	Posterior temporoparietal region Upper pinna, dorsal external auditory meatus	II
Preauricular	Lateral pinna, skin of frontal and temporal regions	II
Parotid	Root of the nose, eyelids, frontotemporal region, external acoustic meatus, tympanic cavity posterior palate	II, III
Subparotid	Posterior nasal cavity, nasopharynx	II, III
Facial (infraorbital or maxillary, buccinator, supramandibular)	Eyelids, conjunctiva, skin and mucous membrane of nose and cheek	IB (submandibular)
Deep facial	Temporal and infratemporal fossae, nasopharynx	II, III
Retropharyngeal	Nasal cavities, nasopharynx, eustachian tubes, oropharynx, palate, hypopharynx	II, III
Submandibular	Medial palpebral commissure, cheek, side of nose, upper lip, lateral lower lip, gums, anterior lateral tongue	II, III
Submental	Central lower lip and floor of mouth, tip of tongue	IB (submandibular), II, III
Superficial cervical	Superficial to sternocleidomastoid muscle, lower pinna, parotid	II, III
Anterior cervical	Superficial, prelaryngeal, pretracheal larynx, thyroid, upper trachea	IV
Spinal accessory	Pharynx, tonsil, base of tongue	IV, supraclavicular (transverse cervical)

Table 36-10
1997 AJCC NODAL (N) STAGING SYSTEM FOR CERVICAL LYMPH NODES

NX	The regional lymph nodes cannot be assessed (clinically)
N0	There are no regional metastatic lymph nodes present
N1	There is metastasis to a single ipsilateral lymph node that is 3 cm or less in greatest dimension
N2	There is metastasis in a single ipsilateral lymph node that is between 3 and 6 cm in greatest dimension; there are multiple ipsilateral lymph nodes, none of which are greater than 6 cm in greatest dimension; or there are bilateral or contralateral lymph nodes, none of which are greater than 6 cm in greatest dimension
N2a	There is metastasis in a single ipsilateral lymph node that is between 3 and 6 cm in greatest dimension
N2b	There are multiple ipsilateral lymph nodes, none of which are greater than 6 cm in greatest dimension
N2c	There are bilateral or contralateral lymph nodes, none of which are greater than 6 cm in greatest dimension
N3	There is metastasis in lymph nodes that are more than 6 cm in greatest dimension

classified as a regional lymph node metastasis. A final comment on nodal assessment relates to the observation that generally most nodal masses greater than 3 cm in diameter are not single nodes, but are either confluent nodes or tumor in the soft tissues of the neck.[70]

There are two primary head and neck tumors whose distribution of nodal metastases and the prognosis associated with such regional metastases are sufficiently different from those of the other head and neck cancers that they have been recognized by the AJCC as requiring separate nodal (N) classifications. These tumors are nasopharyngeal carcinoma and thyroid carcinoma.

Nasopharyngeal Carcinoma Nodal Staging

The AJCC staging utilizes Ho's triangle, which is a surface triangle formed by the upper medial and lateral ends of the clavicle and the point dorsally where the neck meets the shoulder. This triangle defines the supraclavicular fossa, and the AJCC classification is given in Table 36-11.[70]

Thyroid Carcinoma Nodal Staging

Regional lymph node spread for thyroid cancer is common, but is of less prognostic significance in the generally well-differentiated tumors (papillary, follicular) than in the medullary cancers. The first echelon of nodal metastasis is the paralaryngeal, paratracheal, and prelaryngeal (Delphian) nodes adjacent to the thyroid (level VI), but involvement of these nodal stations has no prognostic value and therefore is not part of the staging system. Metastases secondarily involve the middle and lower jugular (level III and IV) nodes, supraclavicular nodes, and, much less commonly, the submental (level IA), submandibular (level IB), and spinal accessory nodes (level V). Upper mediastinal nodal spread

Table 36-11
NODAL CLASSIFICATION FOR NASOPHARYNGEAL CARCINOMAS

NX	Regional lymph nodes cannot be assessed (clinically)
N0	No regional metastatic lymph nodes are present
N1	Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa
N2	Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa
N3	Metastasis in lymph node(s)
N3a	More than 6 cm in greatest dimension
N3b	Extension to the supraclavicular fossa

Note: The supraclavicular fossa is defined by Ho's triangle, a plane defined by the upper sternal and lateral ends of the clavicle and the point posteriorly where the neck meets the shoulder.

occurs frequently, both anteriorly (level VII) and posteriorly. Retropharyngeal nodal metastases may be seen, usually in the presence of extensive cervical metastases. Bilateral metastases are common. Metastases from medullary thyroid carcinoma follow a similar pattern of spread but are associated with a poorer prognosis. The AJCC classification schema for thyroid neoplasia is given in Table 36-12.[70]

PATHOLOGY

The detection of metastatic disease can be a multidisciplinary diagnostic problem. That is, the surgeon identifies palpable disease, the radiologist detects nonpalpable disease, and the pathologist may discover microscopic disease. When one considers that an estimated 1 billion malignant cells are required to create a mass of only 1 mm^3, the limitations of even pathologic detection become clear. Only careful pathologic analysis of the nodes can be considered the ''gold standard,'' and as mentioned, even histologic examination of the lymph nodes is not free of potential error. It has been found that up to 30% of lymph node metastases may be missed if the lymph node is simply bisected sagitally. In addition, micrometastases in supraomohyoid neck dissection specimens were not initially diagnosed in 7.6% of cases.[55] These types of sampling errors may explain why 4% to 8% of patients with pathologically N0 necks develop recurrences in the neck.[48] Between 20% and 40% of clinically N0 necks are pathologically staged as N1 (reported range, 4% to

Table 36-12
NODAL CLASSIFICATION FOR THYROID CARCINOMAS

NX	Regional lymph nodes cannot be assessed (clinically)
N0	No regional metastatic lymph nodes are present
N1	There is regional lymph node metastasis
N1a	Metastasis in ipsilateral cervical lymph node(s)
N2b	Metastasis in bilateral, midline, or contralateral cervical or mediastinal lymph node(s)

Note: Regional lymph nodes are the cervical and upper mediastinal lymph nodes.

60% of cases). Interestingly, a clinically N0 neck is just as likely to contain multiple positive nodes (13%) as it is to have a solitary positive node (16%).[48, 77, 78] Van den Brekel and colleagues examined the value of additional pathologic sectioning (step sectioning or ''leveling'' the paraffin tissue block) and of adding cytokeratin immunohistochemistry in detecting micrometastases. They performed step sections on 600 lymph nodes from 64 patients originally classified histopathologically as negative. Five further patients (7.8%) were found to have positive lymph nodes. Antikeratin staining revealed four micrometastases in 739 originally histopathologically negative lymph nodes. However, as no adjuvant therapy was offered to these ''new N1'' patients, and as the prognostic significance of this group is still unknown, these authors concluded that the massive additional work of immunostaining and deeper sectioning was not yet warranted for routine use in clinical practice.[79] Thus, the ultimate use of pathology as the gold standard may some day require the caveat that multiple slices of the nodes and immunostaining be obtained. Table 6-1 describes the immunohistochemical testing of tumors.

THE NONDIAGNOSTIC NODAL BIOPSY

A definitive diagnosis can be made in more than half of the enlarged lymph nodes that are biopsied.[19] Of the remainder, most are diagnosed as nonspecific reactive lymphoid hyperplasia. Longitudinal follow-up on 100 children with nondiagnostic biopsies revealed that 37 were finally diagnosed with reactive hyperplasia, and 74% of these children were alive and well at 20 years. In adults, there is a greater likelihood of eventually establishing a diagnosis of malignancy. Half of the adults followed remained without a specific diagnosis, and 25% to 53% of these patients eventually received a specific diagnosis 8 months to 1 year after initial biopsy. Twenty percent of the adults were ultimately diagnosed with malignant lymphoma. When only cases of atypical lymph node hyperplasia were considered for the adults, 37% of patients ultimately were diagnosed with lymphoma.[80] Thus, only between 25% and 47% of patients with either Hodgkin's lymphoma or large cell lymphoma received a specific diagnosis on submission of the initial specimen.[19] Diagnostic problems were due either to sampling errors (surgeons should biopsy the largest lymph node in a group, not just the most surgically accessible node) or to improper specimen processing (poor fixation, inadequate sectioning, or poor staining).

CONSIDERATION OF THE PRIMARY TUMOR SITE

When evaluating a patient with cervical nodal metastasis, the mapping of the primary upper aerodigestive tract (UADT) tumor site is critical to the imaging study. In fact, the relationship between various primary sites and the location and frequency of cervical metastasis has been well studied (Tables 36-1 to 36-3).[7, 48, 81] In general, for carcinomas of the oral cavity, soft palate, true vocal cord, paranasal sinuses, and nasal cavity, there is a direct relationship between the size of the primary tumor and the risk of metastatic neck disease. However, this relationship is not direct for other UADT carcinomas such as nasopharyngeal carcinomas. Nonetheless, of special note is the observation that tumors arising in Waldeyer's ring are the ones most likely to present with metastatic adenopathy. They are also the tumors most likely to present with bilateral neck disease and posterior triangle (level V) adenopathy. In patients who present with nodal disease and no known primary tumor site, knowledge of the nodal drainage areas may help direct attention to the most likely primary areas (Tables 36-8 and 36-9).

LIMITATIONS IN IMAGING CERVICAL LYMPH NODES

Despite the normal imaging appearance of a hyperplastic or reactive cervical node, a variety of diseases may still have affected the node. In most of these cases, the precise pathology may not be predicted on imaging and, in the final analysis, it is the pathologist who determines the diagnosis. Although elective fine needle aspiration (FNA) biopsies have their limitations, FNA cytology is a reasonable next diagnostic step.[54] A definite positive diagnosis can triage the patient and set the therapeutic wheels in motion, and a negative FNA diagnosis should not be taken as the absence of pathology.

Newer approaches such as MR spectroscopy (MRS), PET, and Thallium-201 SPECT may become alternative, noninvasive techniques to quickly identify the presence of nodal metastasis. These topics are discussed in Chapter 45. Even if microscopic tumor cannot be identified, it is possible that in the near future the current capabilities of both clinical and imaging evaluations can be advanced to a new, more refined level.

Most of the research addressing the assessment of size criteria and nodal architecture has been done to evaluate squamous cell carcinoma metastasis. In summary, classically such a metastatic node will be enlarged, have central tumor and necrosis, and have extracapsular tumor spread (Fig. 36-20). However, even when all of these imaging criteria are present, the histology may still reveal some form of lymphoma or infectious process. As already mentioned, it must always be remembered that in a patient with a head and neck tumor, hyperplastic-appearing lymph nodes may still harbor microscopic metastases, highlighting a persistent limitation of clinical and radiographic evaluation.

THE NECESSITY OF CLINICOPATHOLOGIC CORRELATION

Imaging analysis is limited by the lack of specificity in the CT and MR imaging appearances of many different diseases. Correlation with the clinical history, physical findings, and laboratory test results allows the radiologist and clinician to hone the differential diagnosis to a pertinent few possibilities rather than suggesting a long list of potential diagnoses. Thus, a tender, painful, firm node usually signifies an acute inflammation. Conversely, a hard,

VIEW IMAGE

FIGURE 36-20 There are ribbons of viable tumor (*T*) within this metastatic lymph node, with shedding of necrotic cells (*N*). This is seen as central necrosis on CT and MR imaging.

fixed, nontender, painless node is the classic nodal metastasis. However, even clinical findings can be misleading in rare cases, and uncommonly, metastatic nodes, if acutely enlarged, may be painful and tender. A soft, nontender, painless node could be either hyperplastic, lymphoma, or even an infection. Nonetheless, correlation with clinical information usually limits the vast majority of the imaging differential diagnoses and makes the imaging contribution to the case more pertinent.

The number and the specific chains of lymph nodes involved may also suggest a diagnosis. Diffuse nodal disease (especially if suboccipital nodes are involved) suggests a systemic process such as infectious mononucleosis, acquired immune deficiency syndrome, sarcoidosis, or lymphoma. Unilateral involvement of lymph nodes is less specific and can be found in many diseases including metastatic carcinoma, lymphoma, tuberculosis, and a variety of local infections. Nodes in the infraomohyoid neck (levels IV and VB, including Virchow's node), without supraomohyoid nodes (levels II and III) suggest that the source of the nodes lies in the thyroid, in the cervical esophagus, or in a primary tumor caudal to the clavicles, most often in the lung or breast (Fig. 36-21).

Obviously, a history of a previous primary tumor or a recent infection may strongly suggest the etiology of cervical adenopathy. However, occasionally even such a history may be misleading, as new or multiple pathologic processes can occur.

Whenever possible, imaging should be performed prior to any biopsy procedures so that the images reflect the disease process and not obfuscating iatrogenic effects. Whatever the limitations of establishing an imaging-based diagnosis, clearly in most cases the contribution of imaging is more focused if the history and clinical information is available at the time of the examination.

SPECIFIC NODAL PATHOLOGIES

With regard to the clinical and imaging evaluation of the cervical lymph nodes, although the primary concern is usually with metastatic squamous cell carcinoma, there are a number of other diseases that require consideration. In most of these instances, the imaging characteristics are nonspecific and the diagnosis is based on a combination of the history, clinical findings, imaging, and laboratory data. The role of imaging in these cases is to map the disease, namely, to identify the number and location of lymph nodes, potentially

FIGURE 36-22 Cranial (**A**) and caudal (**B**) axial contrast-enhanced CT scans show multiple enlarged, enhancing, fairly homogeneous, well-delineated nodes in the left neck. Nodes are seen in levels II, III, and V. This patient had EBV infection.

determine the site of primary pathology, and evaluate any associated findings such as soft-tissue infiltration, necrosis and/or abscess formation, bone involvement, and so on. The following are capsule reviews of the diseases, other than squamous cell carcinoma, that can affect the cervical nodes. For each of the pathologic sections described, a brief summary of the imaging findings for affected lymph nodes in that group of diseases is included.

Viral Lymphadenitides

There are a number of viruses that may cause acute or chronic lymphadenitis. In some cases, the viruses can be demonstrated within the lymph node; in other cases, the presence of virus can only be suspected. Some of the nonspecific reactive lymphadenitides may be in this latter group.[19]

On imaging, these lymphadenitides can have a variable appearance. There usually is diffuse nodal involvement, with most nodes being either normal in size or mildly enlarged. As a rule, there is little, if any, adjacent inflammation. The nodes are usually homogeneous, often with an attenuation slightly less than that of muscle, with mild enhancement on CT and MR imaging (Figs. 36-22 to 36-24). They most often have low to intermediate T1-weighted and high T2-weighted signal intensities.[82] It is in this group of diseases that the occipital nodes are most often affected.

Infectious Mononucleosis

The Epstein-Barr virus (EBV) is a Herpesvirus with 173-kb double-stranded linear DNA, which is strongly trophic for B lymphocytes, epithelium, and T lymphocytes by binding complement receptor type 2 (CR2) via a viral envelope glycoprotein (gp350/220). Infection with EBV usually occurs in early life with worldwide ubiquity. Nearly 100% of children have positive serology by the age of 3 years, and in the Western world, only about 50% of those exposed to EBV actually become infected. Acute EBV infection is infectious mononucleosis (IM), which is a self-limited disease that primarily affects adolescents and young adults. In the United States the incidence is 50 per 100,000, or about 100,000 cases per year. Patients with acute IM present with cervical adenopathy, pharyngitis, abdominal pain, and fever after a nonspecific prodromal period of 3 to 5 days. The pharyngitis and tonsillitis may be ulcerative and exudative. In extreme cases, the tonsillitis may cause upper airway obstruction. There is generalized adenopathy (including the posterior cervical chain) and hepatosplenomegaly. Multiple cranial nerve palsies may rarely occur, possibly secondary to brainstem encephalitis.[83]

The diagnostic feature of IM is the peripheral lymphocytosis with significantly elevated (10% to 20%) atypical lymphocytes (Downey cells) of T-cell origin (Fig. 36-25). IgM antibodies to viral capsid antigen (VCA) rise at first and disappear within a week, replaced by rising IgG titers to VCA, which persist for life. Elevated VCA titers indicate reactivation of latent infection. Early antigen-diffuse type and Epstein Barr nuclear antigen (EBNA) antibodies also rise early in the course of the acute illness. Antibodies to EBNA-1 rise after the first month and remain elevated throughout life. Antibodies to EBNA-2 peak during the acute phase of IM and then drop off. Failure to generate

VIEW IMAGE

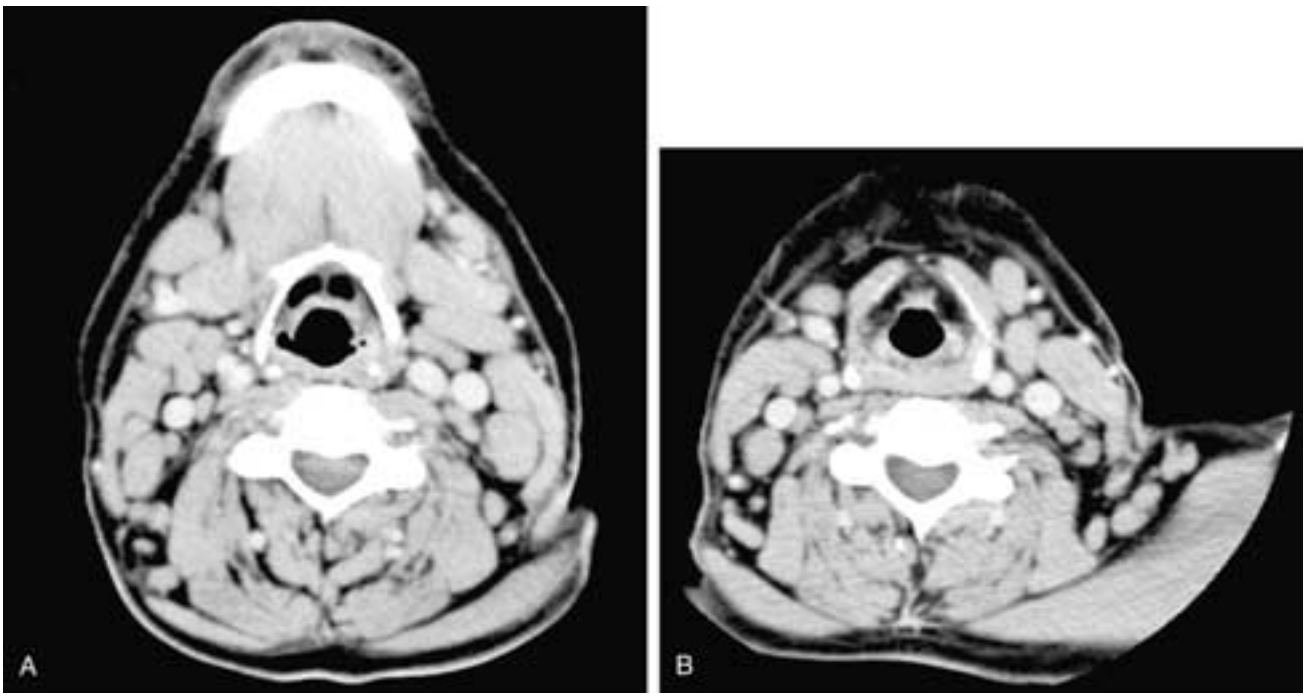
EBNA antibodies indicates a failure in immune surveillance. Low titers to EBNA in the face of recent EBV infection have been seen in chronic EBV infections and in X-linked lymphoproliferative disorder.[84]

Uncomplicated IM can resolve within 3 to 4 weeks, but occasional patients remain symptomatic for months. Progressive fatal cases may occur in patients with inherited immunodeficiences (see below) or in rare patients with ''normal'' immunity. The T cells of these latter patients develop exuberant graft-versus-host responses that may result in myocarditis, hepatitis, nephritis, and encephalitis. Rather than being immunosuppressed, Purillo et al. point out, they are ''immune dysregulated'' in the vigorous self-directed immune reaction in response to EBV infection.[85]

Children with IM tend to be less symptomatic and have



VIEW IMAGE

shorter illnesses than young adults or, as mentioned, have subclinical illnesses. The infecting viral dose and the maturity of the host's immune system are thought to explain the differences between the pediatric and adolescent disease courses. Resolution of acute IM occurs as killer T lymphocytes eliminate the infected B lymphocytes. A small residual pool of infected lymphoblastoid cells always remain, kept in check by sensitized cytotoxic T cells. Reactivation of latent infection will not occur unless this balance is disturbed by various possible mechanisms.[85–87]

Cytomegalovirus

Cytomegalovirus (CMV) is a double-stranded DNA Herpesvirus (180 nm in diameter) trophic for endothelial cells, B and T lymphocytes, mononuclear cells, and salivary gland epithelium. CMV has a high prevalence worldwide. It is ubiquitous in AIDS patients, nearly all of whom have serum antibodies to primary or reactivated CMV infection. CMV reactivation is caused potentially by viral/viral interactions with HIV. CMV directly impairs cell-mediated immunity through a variety of mechanisms: infected monocytes have inhibited antigen-presenting functions and downregulation of interleukin-1 production.[88] The marked decrease in interleukin-1 may contribute to the depressed lymphocyte responses. Fresh clinical isolates from various strains of CMV can also directly suppress null killer cell function and inhibit mitogen-induced T-cell proliferation.[89]

In general, viral/viral interactions play a crucial role in the clinical downward spiral of immune function. CMV interacts with HIV and EBV to potentiate immunosuppression. A general mechanism of viral/viral interaction is the cross-reactivity of viral activating factors. CMV (as well as EBV and HIV) produce transactivating proteins that activate the flanking long terminal repeat (LTR) regions of HIV, thereby upregulating viral transcription and promoting active HIV replication. Specifically, CMV protein transcripts of the immediate-early region-2 can transactivate HIV LTR.[90] In turn, HIV infection potentiates CMV and is responsible for reactivation of latent CMV infection. H9 lymphoblastoid cell lines coinfected with HIV-1 and CMV demonstrate enhanced transcription CMV late region antigens, as well as enhanced HIV replication.[91]

The clinical course of most CMV infections is basically asymptomatic, subclinical, or may cause mononucleosis-like illnesses in immunocompetant individuals. After primary infection, CMV may be shed in saliva, urine, semen, and cervical secretion for extended periods of time.[92] The virus then remains latent in the host, to be potentially reactivated at any time, producing chronic persistent infection.

Serious disseminated CMV infections are seen as a result of some congenital infections and immunosuppression (e.g., posttransplant and AIDS). An autopsy study of 164 AIDS patients revealed that almost half had evidence of active CMV infection; adrenalitis, pneumonia, gastrointestinal ulceration, central nervous system infection, and retinitis were the most common findings.[93]

Involvement of the upper respiratory tract was seen in only 4% of these cases. CMV infection may result in large oropharyngeal and nasopharyngeal ulcerations in patients with active AIDS, causing odynaphagia and dysphagia.[94, 95] The ulcers have a ''well-punched-out'' appearance without induration of the periphery or the base.[96] These lesions are self-limiting, and most resolve with gancyclovir (Fig. 36-26). CMV parotitis has been reported; FNA revealed the characteristic and diagnostic cytomegalic cells.[97]

The larynx and trachea may be sites for ulcerative CMV infections in the absence of CMV pneumonitis.[98, 99] Vocal cord paralysis (without mucosal ulceration) due to laryngeal neuritis has been seen: CMV inclusions have been demonstrated at autopsy within the recurrent laryngeal nerve.[100] Concomitant supraglottic diffuse large cell lymphoma and CMV epiglottitis have been reported. Although CMV is not firmly established as having oncogenic potential, it may reactivate latent EBV infection, which, of course, is associated with B-lymphocyte neoplasia.[101]

Herpes Simplex Virus

Herpes simplex virus (HSV) is a double-stranded DNA (150 kb pairs) Herpesvirus that is trophic for epithelium and nerve ganglia. HSV causes oropharyngeal and genital infections, recurrent episodic infections, and a serious disseminated infection in neonates and immunosuppressed individuals.

The pathobiology of HSV infection is similar to that of other Herpesviruses. HSV may produce either an active replicating lytic infection or a latent quiescent infection that can be reactivated under certain conditions. HSV binds to target cells by attaching to heparin sulfate proteoglycan molecular receptors.[102] HSV enters by envelope fusion with cell membranes rather than by phagocytosis. HSV DNA is then extruded from the capsid via nuclear pores into the host nucleus, where it becomes circularized. The ability of HSV to effect productive infection depends on several viral talents. HSV subterfuges host RNA polymerase II for viral transcription.[103] HSV also causes a decline in most cellular synthetic processes.[104] This is efficiently accomplished early on by integument proteins present between the viral envelope and capsid.[102] It is also postulated that functional redundancy in the estimated 70 HSV encoded proteins allows successful viral adaptation to various cellular environments.[102]

After primary infection, HSV travels retrograde via axons to nerve ganglia, where it remains in a latent state; thus, reactivated infection will occur along neural dermatomes.[105] Ex-

perimental explantation of ganglia months after primary experimental infection results in viral reactivation.

Cell-mediated and humoral immunity play crucial roles in protecting against primary infection and controlling against reactivation of latent infection. The topic of cell-mediated immunity and HSV infection has been extensively reviewed.[106] Natural killer (NK) effector lymphocytes normally lyse HSV-infected cells, even in the absence of anti-HSV antibodies. This may be seen in patients with antibody deficiencies who retain NK activity against HSV-infected cells.[107] The very stress of prolonged physical restraint in animals has been shown to result in decreased NK activity, with attendant reactivation of HSV infection.[108] A longitudinal study revealed that interleukin-2, alpha-interferon, and cell-mediated cytotoxicity decreased 3 to 7 days prior to the development of recurrent herpes labialis.[109]

Clinically, HSV I is a ubiquitous virus contracted through routine household contact. HSV I may commonly infect normal hosts ''above the waist'' and is responsible for oral and labial disease (cold sores), cutaneous disease (''herpetic whitlow''), and herpetic conjunctivitis. HSV II is less common than HSV I and usually hits ''below the belt,'' is transmitted through sexual contact, and causes genital infections.

Primary HSV I infection occurs during childhood in the majority of cases and may be subclinical. Adult-onset herpetic gingivostomatitis is much more severe than the pediatric form. Acute primary herpetic gingivostomatitis presents after a nonspecific prodrome of fever, headache, and myalgias. The gums are red, swollen, and friable. Painful vesicles erupt on the labial, anterior gingival, and intraoral mucosa. Tiny vesicles may also appear around the nose. The lesions heal within 2 weeks. Both acute gingivostomatitis and subclinical infection result in latent infection of sensory ganglion nuclei. An infrequent sequela of primary gingivostomatitis is herpetic encephalitis, which is commonly fatal; survivors are left with severe morbidities.

Reactivation of latent infection may occur in up to half of infected individuals. It can be stimulated by emotional factors, hormonal changes, excessive sunlight, and fever. Reactivation, heralded by tingling and pain, results in clusters of coalescing vesicles. It has been noted that immunocompetent individuals tend to have labial lesions (herpes labialis), not intraoral lesions, while AIDS patients tend to have recurrences widely distributed throughout the oral cavity, which persist longer.[110–112] In fact, mucocutaneous HSV lasting for more than 1 month was one of the original criteria for defining AIDS prior to the advent of serologic testing, and it remains a diagnostic criterion.

Herpetic whitlow, consisting of painful digital pustules and vesicles, occurs after autoinoculation through skin abrasions from oral or genital lesions. It is an occupational hazard of hospital personnel and dentists. Herpetic paronychia is the result of deep vesicles under the nail bed.

HSV II is the cause of genital herpes. Primary infection is associated with fever, malaise, and lymphadenopathy. Men develop painful penile vesicles and ulcerations with dysuria and a penile discharge. Women develop vulvar and cervical lesions with vulvar pain and burning dysuria. Recurrent episodes are not uncommon and are associated with milder symptoms. Intrauterine transmission of HSV II occurs uncommonly and results in ''TORCH'' infection sequelae: mental retardation, microencephaly, microphthalmia, and blindness. Active genital herpes at the time of delivery results in neonatal infection with serious sequelae such as encephalitis, keratoconjunctivitis, and hepatitis, with high morbidity and mortality.

Disseminated HSV infection with visceral involvement occurs in immunosuppressed and cancer patients. Localized HSV lymphadenitis, and also tonsillitis, in the absence of disseminated disease has been rarely reported.[112–115] Some (but not all) of these patients had underlying hematopoietic diseases. In immunosuppressed patients, herpetic esophagitis and infection of the lower respiratory tract may lead to a chronic and severe disease. It is in this latter group of patients that herpes simplex lymphadenitis primarily occurs, and it is the regional lymph nodes that tend to be affected.[116, 117]

Varicella

Varicella zoster virus (VZV) is a Herpesvirus that causes varicella (chicken pox) and herpes zoster (shingles). Primary exposure to the highly contagious VZV results in malaise, anorexia, and mild fever, followed by vesicles and maculopapular eruptions within 24 to 48 hours. The dermal eruptions begin centrally on the trunk and progress distally to the limbs and head. Childhood infections are self-limiting, but primary VZV in adults may lead to more serious manifestations such as pneumonia. Herpes zoster infection represents an adult reactivation of VZV, which may occur in the setting of chronic illness, neoplasm, and so on. The cutaneous lesions of herpes zoster resemble those of varicella but usually are limited to one or several sensory dermatomes. Generalized lymphadenitis can occur in the setting of both VZV and herpes zoster.[118]

Vaccinia

Vaccinia is a DNA poxvirus that causes vesicular skin eruptions less serious than those of smallpox. Vaccinia is antigenically similar to the smallpox virus and has been employed as a vaccination against smallpox. Parenthetically, it has been theorized that the spread of HIV in Central Africa is in no way coincidental with the massive vaccination campaign against smallpox in Africa in the late 1960s and 1970s.[119] Cervical or axillary lymphadenopathy may develop 1 to 3 weeks after vaccination. The morphologic changes are similar to those of other virus infections such as Herpesvirus, measles, and other unidentified viral agents.

Measles

Measles, or rubeola, is a highly contagious acute exanthematous childhood illness caused by an RNA paramyxovirus. Measles is uncommon in the United States due to use of the live measles virus (MV) vaccine, but it may still occur among nonimmunized children. In Third World countries where nutrition and immunity are poor, measles may be a routinely fatal disease. Measles is transmitted by oral/respiratory secretions. The incubation period averages 10 to 12 days, after which the child develops a prodrome of high fever, conjunctivitis, photophobia, lymphadenopathy, and intraoral small, erythematous vesicles and ulcers (Koplick's spots), usually on the lower buccal mucosa. A generalized skin rash develops, beginning on the face and spreading downward to involve the trunk and extremities; this pattern of spread distinguishes measles from chicken pox. The rash

Copyright © 2003, Mosby, Inc. All rights reserved.

usually resolves within 10 days. Pneumonia (interstitial giant cell pneumonia) and acute encephalitis are serious immediate complications of measles; they occur, albeit rarely, in normal patients.[120, 121] Subacute sclerosing panencephalitis (SSPE) is a rare, progressive, fatal, late sequela of measles characterized by mental deterioration and motor abnormalities. SSPE is detectable 5 to 10 years after primary measles and is the result of defective, nonreplicative MV persistence in the brain. Patients with AIDS, malignancies, or immunosuppression due to other causes are quite likely to develop serious sequelae. They may also fail to develop the characteristic rash, or develop an atypical rash that takes longer to resolve, thus obscuring the clinical diagnosis. Fatal disseminated cases may also rarely occur after vaccination with attenuated virus in immunosuppressed children.[122] Vaccines are prepared from live, attenuated strains of measles virus, and regional lymphadenitis, most often cervical, axillary, and inguinal, may develop within a few days to 2 weeks after vaccination.

Histologically, Warthin-Finkeldey (WF) cells were first observed in tonsillectomy specimens from children who subsequently developed measles; they are characteristic of this infection. Immunohistochemical studies reveal them to be of T-cell origin. The nuclei of these syncytial giant cells are numerous and crowded; up to 100 nuclei may be present, with a ''bunch of grapes'' appearance. Eosinophilic inclusions are present in both the nuclei and the cytoplasm. WF cells can be seen in the stratum corneum and tonsils, as well as in other organs, most notably the lungs, in disseminated cases.

Rubella (German Measles)

Rubella, or German measles, is a childhood disease characterized by mild constitutional symptoms, a rash similar to that of mild rubeola or scarlet fever, and enlarged, tender, postoccipital, retroauricular, and posterior cervical lymphadenopathy. The lymphadenopathy precedes the rash by at least 24 hours; the latter may last for about 1 week. In older patients rubella can be more severe, with arthralgias and purpura. Prior to the development of the vaccine, rubella was quite common; now it is rarely encountered. Maternal rubella in early pregnancy will cause severe congenital anomalies in the newborn infant, first noted in 1941.[118]

Human Immunodeficiency Virus

Human immunodeficiency virus type 1 (HIV-1) is a member of the lentiviruses, a subfamily of retroviruses, with a strong tropism for components of the mononuclear phagocyte system (MPS), namely, CD4+ T lymphocytes, monocytes, macrophages, and dendritic cells.[123] The HIV viremia follows infection, peaking at about 6 weeks and becoming undetectable after about 8 weeks. Antibody seroconversion is detectable after 6 weeks and peaks at approximately 8 to 10 weeks. After seroconversion, proviral host integration is established and a latency/quiescent period of variable duration follows, with normal T4 counts and immune function. HIV may not be detectable at all in circulating lymphocytes. A vigorous cytotoxic T-lymphocyte response immediately follows HIV infection, specifically targeted against envelope proteins and internal proteins such as Gag and Nef. This cytotoxic immune response selects against active viral replication early in the disease, and the selection pressure is toward early viral integration. The pressure toward integration and latency allows HIV to effectively elude the host immune system while it is still intact. Specific cytotoxic immunity is also apparently eluded and exhausted as AIDS becomes manifest. The switch from a quiescent/latent state to actively productive infection is not completely understood, but may represent a progressive move from imperceptible infection to immune deterioration, exhaustion, and a fatal downward spiral. This course may play out over a decade or longer. Although little or no HIV may be detected in circulating T cells during latency, HIV is actively replicating in tissue lymphocytes.[124]

Primary HIV infection may be entirely asymptomatic, with seroconversion as the only clue to infection. More than half of patients infected with HIV may present with a range of symptoms: fever, malaise, myalgias, diarrhea, pharyngitis, macular erythematous rash, lymphadenopathy, splenomegaly, and weight loss, akin to the presenting symptoms of infectious mononucleosis. The acute illness occurs 3 to 6 weeks after exposure and may last for up to 2 weeks, though milder symptoms may persist for months. Mucosal ulcerations accompanying acute HIV seroconversion, thought to be a direct result of HIV infection (the ''chancre of HIV''), has been reported. Multiple, painful, small (0.3 to 1.5 cm) discrete ulcers have been reported on the palate, esophagus, anus, and penis of patients during acute seroconversion that relate to sexual activity.

A large percentage of AIDS cases initially come to medical attention because of complaints related to the head and neck, especially oral complaints. The three most common general complaints are skin lesions such as Kaposi's sarcoma (KS), oropharyngeal symptoms such as candida oropharyngitis or HSV infections, and cervical lymphadenopathy. Among 375 homosexual males (AIDS and non-AIDS patients) presenting to an oral medicine clinic, candidiasis was diagnosed in 66%, KS in 53%, and hairy leukoplakia in 28%.[125] Persistent generalized adenopathy (PGA) is a common presenting symptom of AIDS. Early in the course of HIV, lymph node infection reveals reactive follicular hyperplasia and follicular lysis: an influx of mantle cells and polymorphonuclear cells into germinal centers, with their architectural disruption.[126] Multinucleated giant cells and monocytoid B cells can be seen in sinusoids. As the reactive hyperplasia regresses, follicles become fewer, with a ''washed-out'' paucicellularity. Terminal lymph nodes may have virtually no lymphocytes; one sees only macrophages, fibroblasts, and granulocytes. On imaging, when there is a diffuse lymphadenitis (lymphadenopathy) and multiple benign-appearing parotid cysts (lymphoepithelial cysts; see Chapter 39), the diagnosis of AIDS can be established. In approximately one third of these patients, there also is considerable enlargement of the adenoids.[116]

Bacterial Lymphadenitides

Bacteria cause localized direct cell injury by secretion of exotoxins or release of endotoxins with bacteriolysis. Lymph nodes draining infected tissues may reveal acute suppuration with abscess formation and necrosis, reactive germinal centers, and scar formation. On imaging, bacterial lymphadenitides may appear similar to viral lymphadeni-

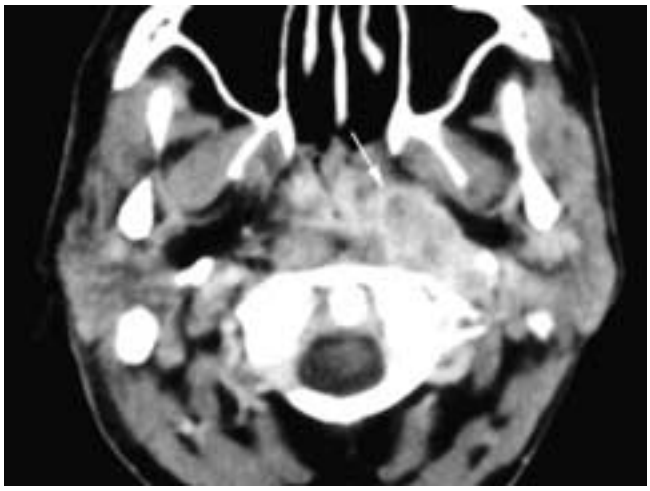

FIGURE 36-27 Axial contrast-enhanced CT scan shows an abscessed left retropharyngeal node (*arrow*) with an enhancing nodal capsule in a patient with an acute bacterial pharyngitis. Note that only the node and not the entire retropharyngeal space is enhancing, a differentiating point from a retropharyngeal abscess.

tides in that there are nonnecrotic enhancing nodes. However, often the nodes are more enlarged. There is a tendency toward central nodal necrosis with a thick, irregular, enhancing nodal wall and adjacent cellulitis. If one does not consider the clinical presentation, the imaging appearance may mimic that of metastatic carcinoma (Figs. 36-27 to 36-32).

FIGURE 36-28 Axial contrast-enhanced CT scan shows multiple variably enhancing left level II and level V lymph nodes with some effacement of the immediate nodal fat planes in this patient with tuberculosis.

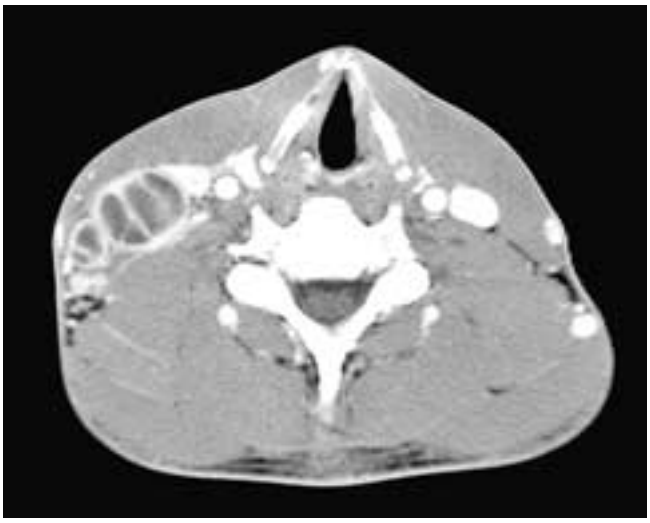

FIGURE 36-29 Axial contrast-enhanced CT scan shows several right partially necrotic, partially enhancing level III nodes. There is little effacement of adjacent fat planes in this patient with tuberculosis.

Routine Bacterial Lymphadenitis

Acute, suppurative lymphadenitis is most often caused by staphylococci. Abscess and or sinus formation may completely obliterate lymph node architecture. Acute lymphadenitis may also be caused by yersiniosis, listeriosis, fungal infections, and cat-scratch disease. Rarely, gonorrhea may cause acute suppurative lymphadenitis. Because of the widespread availability of antibiotics, suppurative lymphadenitis

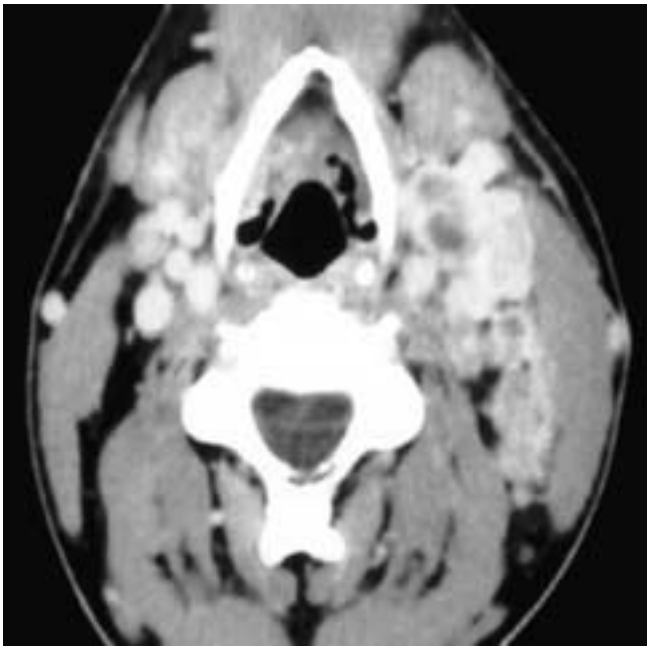

FIGURE 36-30 Axial contrast-enhanced CT scan shows multiple left level II nodes and one right level II node. These nodes have a variable imaging appearance with some nodes enhancing, some with an attenuation close to that of muscle, and some that are necrotic. Despite the number of affected nodes, there is virtually no infiltration of the adjacent fat planes. Although this imaging appearance could be that of lymphoma, this patient had tuberculosis.

is rarely encountered. The involved nodes are enlarged, tender, and soft, and there are secondary changes of inflammation in the adjacent soft tissues.[127, 128]

Lemierre's Syndrome

Lemierre's syndrome represents an uncommon complication of an acute pharyngotonsillitis in which an anaerobic oropharyngitis results in septic thrombophlebitis of the ispsilateral internal jugular vein, with subsequent septicemia and septic emboli, most often to the lungs and large joints.[129] There usually is an associated regional reactive lymphadenitis (see Chapter 41).

Cat-Scratch Lymphadenitis

Cat-scratch disease (CSD) has an associated necrotizing granulomatous regional lymphadenitis that is caused by *Rochalimaea henselae*, a member of the Rickettsiaceae. Most often, the bacteria are introduced at a skin site by either a scratch, splinter, or thorn. Children and young adults are most often affected.[128] An erythematous lesion develops at the site, and the lesion resolves spontaneously within 1 to 3 weeks. CSD then comes to medical attention when regional lymph nodes become painfully enlarged within weeks of the

primary lesion. Lymphadenopathy may be accompanied by fever, headache, and myalgias. An erythema nodosum–type rash may follow but may also be manifest as erythema annulare, erythema multiforme, or thrombocytopenic purpura. This illness runs a self-limiting course within 2 to 4 months.

Occasionally, though, 1% to 2% of patients with CSD may progress to severe systemic infections such as encephalitis, osteomyelitis, hepatitis, and pleuritis. Histologically, early CSD lymphadenitis may reveal only nonspecific reactive changes. The finding of coalescent epithelioid granulomata forming stellate necrotizing microabscesses suggests the diagnosis of CSD, but bacilli are rarely present within the granulomata. The bacilli stain with Warthin-Starry silver stain, stain weakly with Brown and Hopp stain, and have been noted in capillaries and within macrophages. In practice, histologically they may be very difficult to distinguish from background.

Bacillary Angiomatosis

Bacillary angiomatosis (BA) is a *Rochalimaea* infection occurring in patients with AIDS that is related to CSD.[130] Patients with BA as well as those with CSD share a history of exposure to cats. BA presents clinically as solitary or multiple tender (or nontender) red or violaceous, friable, cutaneous papules or nodules 0.5 to 4.0 cm in size, which may crust over. These papules occur on the face, extremities, and scrotum. Deeper subcutaneous nodules, resembling cellulitis, may also develop and erode underlying bone. Lesions involving regional lymph nodes and internal organs such as bone, spleen, liver, and brain may also develop in AIDS victims. Clinically, the cutaneous lesions of BA may resemble KS, and have also been noted to bear a resemblance to verruga peruana, the chronic cutaneous manifestation of infection with *Bartonella bacilliformis* (the agent of Carrion's disease, or Oroyo fever). BA is responsive to antibiotics; erythromycin-type drugs are the drugs of choice.[127]

Histologically, BA reveals nodular proliferations of small vessels lined by enlarged cuboidal endothelial cells, which may be markedly atypical, mimicking malignancy. On the other hand, there is a resemblance to pyogenic granulomata, as these lesions are polypoid, with a collarette of epidermis. An acute inflammatory infiltrate and debris are seen. Clusters of slender rods may be observed on Warthin-Starry stain, and variably observed on Steiner treponeme silver stain and Brown and Brenn stain, similar to the bacilli seen in CSD.

Syphilitic Lymphadenitis

Syphilitic lymphadenitis is caused by the sexually transmitted bacterium *Treponema pallidum* (*treponema*—Greek: ''turning thread''; *palidum*—Latin: ''pale''), a long, slender spirochete that rotates along its long axis in fluid and may creep and crawl along solid surfaces. Syphilis may be divided clinically into three distinct phases: primary, secondary, and tertiary. Primary acquired syphilis develops 1 week to 3 months following initial exposure and is characterized by chancre formation at the site of infection. Only the regional lymph nodes are involved at this stage. Typically, cutaneous chancres are painless, hard, raised lesions that develop shallow ulcerations with sharp, raised borders. On mucosal surfaces, primary chancres may appear as silvery gray erosions, granulation tissue, or nonspecific ulcers or may even mimic carcinoma. Chancres are self-healing, with minimal scarring (''cigarette paper thin'' and semitranslucent), so individuals may not be prodded into seeking medical attention. Secondary syphilis occurs weeks to months after the primary chancre and is the result of systemic generalization of the infection. Individuals develop fever, pharyngitis, and a generalized macular/papular rash. The rash can affect the hair follicles of the scalp, eyebrows, and beard, causing a patchy, ''moth-eaten'' alopecia (alopecia syphilitica). These macular/papular lesions coalesce in warm, moist areas such as the anogenital and intertriginous areas to form hyperplastic lesions: condyloma lata or flat condylomata. As condyloma lata arise from the systemic spread of *T. pallidum*, they are not dependent on the initial site of inoculation. Like chancres, they are also infectious. Rarely, ulcerative lesions also occur in secondary syphilis: lues malignum. Generalized lymphadenopathy occurs during the secondary stage, with a predisposition for periarticular lymph nodes, such as those in the epitrochlear and inguinal areas. Secondary syphilis will lapse into a latent state, but patients may experience recurrent mucocutaneous symptoms of secondary syphilis.

Symptomatic tertiary syphilis is a late manifestation seen years to decades after primary infection; a minority of untreated patients (as shown by the infamous Tuskeegee study) progress to the tertiary form.[131] Tertiary syphilis most commonly affects the cardiovascular system and the central nervous system. Cardiovascular syphilis results in a coronary artery vasculitis and aortitis that may progress to aneurysmal dilatation. The aortic intima becomes contracted and scarred, resulting in a characteristic ''pebbled'' or ''tree bark'' appearance. Neurosyphilis results in a chronic syphilitic meningitis with a lymphoplasmacytic endarteritis. The brain and nerves may be directly infiltrated by *Treponema*, causing neural loss and resulting in psychiatric disorders, progressive dementia, cranial nerve deficits (e.g., eighth nerve deafness, vestibular symptoms), and sensory/motor losses (tabes dorsalis, taboparesis). Large necrotic lesions or gummas can occur. They are seen most commonly in the liver but may occur anywhere. Lymphadenopathy may also be associated with latent or early tertiary syphilis.

Lyme Lymphadenitis

Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is at present the most common arthropod-borne infectious disease in Europe and the United States. It is transmitted primarily by *Ixodes dammini* ticks, or deer ticks, in the Northeast and Upper Midwest, by *Ixodes pacificus* in Western states, and by *Ixodes ricinus* in Europe. The disease is transmitted to humans primarily in the spring, summer, and early fall. Lyme disease can affect the skin, nervous system, heart, eyes, and joints and is diagnosed in patients with these characteristic clinical features: exposure to an endemic area and usually a positive serologic test for *B. burgdorferi* 6 or more weeks after infection. Lymphadenopathy usually occurs in regional draining nodes. Full recovery is possible with early diagnosis and treatment.[132] However, if Lyme disease is not treated with antibiotics in the early stages, neurologic complications can occur.[133]

FIGURE 36-33 Numerous magenta mycobacterial bacilli seen on Ziehl Neelson stain.

Mycobacterial Lymphadenitides

Mycobacteria are aerobic, non-spore-forming, nonmotile bacteria with a thick, multilayered cell of complex lipids and waxes, which accounts for their staining and immunogenic properties. Once stained, they are resistant to decolorization by acid alcohol and hence are acid-fast (Fig. 36-33). Generally, the imaging findings of the mycobacterial lymphadenitides, particularly those of tuberculosis, are variable and include multiple hyperplastic nodes, a localized abscessed node (cold abscess), and on CT multiple nodes, some of which enhance, some of which are necrotic, and some of which have an attenuation similar to that of muscle. There usually is little infiltration of the adjacent fat planes, and there may be nodal calcification. Level V nodes tend to be involved, usually unilaterally, although diffuse adenopathy can occur. Overall, the imaging findings may be indistinguishable from those of lymphoma or even squamous cell carcinoma, and the clinical presentations may be identical. However, unlike these tumors, with tuberculosis there is often imaging evidence of prior pulmonary disease.[134, 135]

Mycobacterium Tuberculosis

A definite resurgence of tuberculosis has been reported in the United States, as a result of (1) immigration from endemic countries, (2) reactivation of disease in the elderly population, and (3) the AIDS pandemic. Primary *Mycobacterium tuberculosis* (MTB) infection is usually subclinical, occurring in the upper lobes, where the oxygen tension is highest (Simon's focus). The pulmonary infection and draining lymph nodes (Ghon complex) heal as calcified granulomata, which are usually negative for acid-fast bacilli. Latent bacilli are still present in these foci and are capable of reactivation. Primary infections become inactivated, but patients are at lifelong risk for developing active disease. Less commonly, primary infections progress to symptomatic pulmonary disease (progressive primary infection); children and young adults are most susceptible.

The more common scenario is that reactivation occurs years after latent primary infection, referred to as progressive secondary infection or endogenous reinfection tuberculosis. Patients present with fever, weight loss, and pulmonary symptoms such as bloody sputum. Cavitary tuberculosis develops, which can seed systemically (miliary spread), favoring the kidneys, adrenals, bone marrow, spleen, ovaries, testes, meninges, and bones. However, extrapulmonary tuberculosis is actually an uncommon event following secondary infection. Head and neck involvement in tuberculosis is rare, thought to be the result of direct infection from expectorated sputum and also hematogenous/lymphatic spread. A total of 136 cases of extrapulmonary tuberculosis were collected: 16 (12%) patients had head and neck involvement; 13 patients had tuberculosis lymphadenitis of cervical, supraclavicular, or submental nodes (scrofula); and there was 1 case each of gingivitis, otitis, and laryngitis.[136] Nasopharyngeal/sinonasal tuberculosis can occur more commonly secondary to pulmonary tuberculosis or uncommonly as a primary upper airway infection of Waldeyer's ring.[137] Primary nasopharyngeal infection presumably is the direct result of inhalation, and clinically and histologically it may mimic Wegener's granulomatosis. Nasopharyngeal tuberculosis can also be accompanied by lymphadenopathy. Clinically, this may mimic nasopharyngeal carcinoma, especially in the Asian population at risk for this neoplasm.

Lupus vulgaris (LV) consists of ragged, ulcerated mucocutaneous lesions, usually facial, that occur in secondary tuberculosis usually as a result of hematogenous or lymphatic spread. There is a significant association between LV (40% of cases) with cervical lymphadenitis or upper airway mucosal lesions.[138] Mucosal LV may occur in the nasal cavity, causing cartilaginous destruction of the palate, pharynx, or gingiva. LV is usually seen in patients with strong immune responses (strong reactors to purified protein derivative), so hypersensitivity to acid-fast bacilli is thought to be responsible for the destructiveness of these lesions. These lesions heal with dense scarring that may deform the underlying tissues. This may be a point of distinction between LV and syphilitic chancres. Laryngeal tuberculosis (''laryngeal phthisis''; *phthisis*: ''to dry up'') was one of the most common laryngeal diseases in the preantibiotic era.[134, 135]

Atypical Mycobacteria

Atypical mycobacteria (also referred to as *mycobacteria other than tuberculosis* [MOTT]) represents a large group of acid-fast bacilli other than *Mycobacterium tuberculosis*, only some of which are human pathogens. MOTT are present in water, milk (especially unpasteurized milk), dust, soil, and birds (*M. avium*). Human-to-human transmission of MOTT is not thought to occur. There are four common presentations of disease caused by MOTT: (1) pulmonary infection in those with underlying pulmonary diseases such as emphysema (e.g., *M. kansasii*), (2) ulcerative skin disease (*M. ulcerans, M. marinium*), (3) serious pneumonias and generalized infections in AIDS patients (e.g., *M. avium-intracellulare*), and (4) cervical lymphadenitis (e.g., *M. scrofulaeum, M. kansasii*). Cervical lymphadenitis (scrofula, scrofulous gumma, scrofuloderma gummosa, tuberculosis colliquativa) is a common presentation of MOTT in nonimmunocompromised patients. Patients are generally afebrile, with enlarged, erythematous lymph nodes mostly in the upper cervical region. Involvement of submental, preauricular, middle, or lower cervical nodes is much less common than upper cervical involvement.[139] Lymph nodes may spontaneously fisualize to the skin of the neck or upward to

Copyright © 2003, Mosby, Inc. All rights reserved.

the face. Primary cervical atypical MTB lymphadenitis is thought to gain entrance to the lymphatics possibly through a mucosal break on the tonsils. The most common MOTT cultured from these lesions are *M. scrofulaceum, M. kansasii*, and *M. avium-intracellulare*. The treatment of choice for MOTT cervical lymphadenitis is surgical excision, not incision and drainage.[140] MOTT are not susceptible to standard anti-MTB therapeutic agents (isoniazid, streptomycin, rifampin), so antibiotic therapy is not indicated. However, scrofula may also be caused by *M. tuberculosis* and *M. bovis*. The distinction between MOTT and MTB relies on cultures or special hybridization techniques, which has important epidemiologic and treatment repercussions. One third to one half of patients with mycobacterial lymphadenitis have radiographic evidence of pulmonary disease, indicating that mycobacterial cervical lymphadenitis can be the presenting symptom of pulmonary MTB disease. These patients then require the recommended full anti-MTB therapy (isoniazide and rifampin for 9 months) to eradicate the pulmonary focus. In the latter instance, it has been postulated that the primary pulmonary infection gives rise to cervical infection via drainage to mediastinal lymph nodes, and subsequently inferior deep cervical lymph nodes, or from the pleura to axillary lymph nodes to inferior deep cervical lymph nodes.

Mycobacterium leprae

Mycobacterium leprae, the causative agent of leprosy, is seen mostly in tropical climates. Leprosy affects more than 11 million people worldwide, mostly in rural areas of Latin America, South and Southeast Asia, Saharan Africa, the Mediterranean basin, and Northern Europe.[141] Endemic U.S. states include Florida, Louisiana, Texas, California, and Hawaii. The number of indigenous U.S. cases of leprosy has remained stable (10 to 29 per year) over the last two decades. On the other hand, the number of imported cases reported in the United States (which fluctuated between 100 and 150 reported cases per year) dramatically increased (up to 300 cases per year) starting in the late 1970s. Forty-five percent of these excess cases involved Vietnamese, Cambodian, and Laotian refugees; 21% were from the Philippines. Leprosy is a disease of low infectivity transmitted through prolonged exposure through either nasal secretions or injured skin. Nasal secretions contain concentrated amounts of infectious bacilli, while the amount of bacilli in skin lesions is variable. Other modes of transmission may include breast milk, mosquitos, and bed bugs. The rate of infection is higher for those with known household contacts than for those without known contacts; the risk of contact with lepromatous leprosy (LL) patients is much higher than that of contact with tuberculoid leprosy (TL) patients, indicating the importance of the exposure dose. The exact interval from exposure to clinical onset of disease is difficult to determine, as one is never certain of the time of initial exposure in endemic areas. However, the median incubation period for war veterans serving in endemic areas has been estimated to be 2 to 5 years for the development of TL and 8 to 12 years for the development of LL.[142]

Immunologically, leprosy can be graded by the host's histopathologic response as TL, BL (borderline leprosy), or LL. BL can be further subdivided into borderline tuberculoid (BT), borderline (BB), and borderline lepromatous (BL).[143] A clinically significant feature of this grading system is that the polar groups (TL and LL) are relatively stable and their immunologic responses do not shift, whereas in patients with BL, the immunologic response may be either upgraded or downgraded. TL is characterized by a robust immunologic response with few bacilli, with the possibility for spontaneous cures. LL is characterized by anergy to the lepromin test (purified suspension of killed *M. leprae*) and abundant bacilli.

Leprosy has a predisposition to affect cooler peripheral areas such as the digits, ears, and nose. It presents as cutaneous hypopigmented or hyperpigmented, hypesthetic, isolated macular lesions. Early lesions may also be tender, erythematous, and indurated (erythema nodosum leprosum) and can ulcerate. Neural involvement is common to all types of leprosy and results in severe pain and muscular atrophy. Sensory loss ultimately leads to repeated mechanical trauma and secondary infections. The classic signs of leprous nerve involvement include claw hand, foot drop, lagophthalmos (failure of the upper eyelid to move down), and anesthesias.[142] Clinically, LL presents with a widespread symmetric facial distribution of lesions leading to coarsening of features (leonine facies). The earlobes and nose are especially enlarged and infiltrated. Intranasal and paranasal sinus involvement is common and occurs after cutaneous nasal involvement. Sinus involvement may present with mucopurulent rhinitis, producing mucus with copious mycobacteria. Early mucosal lesions are plaque-like. Late sinonasal lesions are nodular and ulcerative and may ultimately lead to nasal collapse. LL is also associated with mycobacillemia and involvement of the liver, spleen, and bone marrow. Retrograde laryngeal involvement usually follows nasal disease. In a study of 973 untreated leprous patients, laryngeal involvement was common in LL (65%), with the strongest association seen in the most advanced cases. The epiglottis was most often involved, appearing thickened and irregular. This mirrors *M. leprae's* predisposition for cooler sites.[144, 145]

Fungal Lymphadenitides

Generally, mycotic infections tend to be superficial, limited to the mucocutaneous tissues; however, fungi can cause pulmonary infection, and also disseminated infections in the immunocompromised patient. Only those fungi that may have an associated lymphadenitis are discussed below. In general, the nonspecific imaging findings are similar to those of the bacterial lymphadenitides; often the nodes are enlarged and hyperplastic.[146]

Cryptococcosis

Cryptococcus neoformans is a ubiquitous yeast of worldwide distribution. Cryptococcosis (torulosis) is the result of inhalation of aerosolized bird droppings. It may cause asymptomatic, localized pulmonary granulomas; cryptococcal pneumonia or disseminated disease can develop in the immunosuppressed. It is reported to occur in about 7% of AIDS patients, and the lymph nodes involved may be in association with either an occult focus or part of the disseminated form of the disease. The meningeal infection seen in the AIDS population is thought to follow respiratory infection.

while mucicarmine and digested periodic acid–Schiff stain will accentuate the polysaccharide capsule. Uncollapsed round yeasts are the size of erythrocytes (6–7 μm), but may be as large as 20 μm (Fig. 36-34). Collapsed, deformed yeasts take on a "boat-like" or sickle-type shape similar to that of *Pneumocystis*. Single budding yeasts with narrow necks may be seen.

Histoplasmosis

Histoplasmosis (Darling's disease) was described early in the twentieth century by Samuel Darling.[147] The organisms he found were intracellular, within histiocytes; therefore, he coined the term *Histoplasma*. *Capsulatum* was further derived from the ''refractile rim'' observed around the organisms.

The introduction of a major vector of histoplasmosis, the European starling (*Sturnus vulgaris linnaeus*), lies in New York City and is an example of life imitating art. One of the features of Central Park, which was designed in the late nineteenth century, was the importation of pairs of all the birds mentioned in the writings of Shakespeare, including the starling. A murmuration of 60 starlings were released in Central Park in 1890. In 1895, Frank M. Chapman, an ornithologist, noted: ''They seemed to have left the park and have established themselves in various favorable places in the upper part of the city. They have bred for three successive years in the roof of the Museum of Natural History and at other points in the vicinity as they have already endured our most severe winters, we may doubtless regard the species as thoroughly naturalized.''[148, 149] Since this initial introduction, the starlings multiplied successfully and rapidly, to become one of the most numerous birds in North America. This tremendous ecological success has been attributed to the adaptation of a south-west migratory pattern and to the ability of starlings to oust other birds from their roosts—thus the lines ''I'll have a starling shall be taught to speak, Nothing but 'Mortimer,' and give it to him.''[150] Starlings were indirectly responsible for countless cases of histoplasmosis, as well as ruined crops and downed airplanes in the United States.

In the United States, histoplasmosis is endemic in the Midwest and Central states and in the Southeast. A dimorphic fungus, its hyphal form, *Emmonsiella capsulatum*, can be isolated from starling roosts, bat caves, pigeons' excrement, and chicken coops. Exposure occurs via aerosolized bird or bat droppings and contaminated soil and fertilizers. Starling congregations are especially risky, as these gregarious birds amass by the thousands in a ''Hitchcock-like'' fashion, and their accumulated droppings are especially dense, necessitating public health measures to decontaminate heavily infected soil.[151] Point source epidemics have been associated with construction and renovation sites, either through turning contaminated soil or by working on sites where birds had been roosting.[152]

As with most inhaled mycotic pathogens, the most common manifestation of histoplasmosis is a subclinical pulmonary infection, usually because of a small exposure source and normal patient immunity. Patients may develop acute pneumonia after massive inhalation. Chronic cavitating and fibrosing pulmonary infection, sclerosing mediastinitis, and disseminated infection with involvement of bone marrow and adrenals (resulting in Addison's disease) are more serious sequelae of histoplasmosis. Prior to the AIDS epidemic, disseminated histoplasmosis was seen very rarely, usually in elderly patients or in those immunosuppressed by chemotherapy or hematologic malignancy. Disseminated and extrapulmonary histoplasmosis in the face of HIV seropositivity has been included in the criteria for AIDS. Disseminated histoplasmosis presents with fever, septicemia, pneumonia, hepatic or renal failure, central nervous system infection, or skin lesions. It is thought to be due to reinfection or, less frequently, to reactivation of latent disease.[153] Cervical adenopathy, pharyngitis, tonsillitis, and ulcerating oral lesions may occur in AIDS patients.[154, 155]

Histologically, *Histoplasma* is seen as tiny intracellular and extracellular hematoxylinophilic bodies, each surrounded by a small halo (Fig. 36-35). A granulomatous reaction may be present. The overlying mucosa can be hyperplastic. The aforementioned ''halo'' or ''capsule'' does not stain and in actuality is an artifact of tissue embedding. Solitary and multiple thin-necked budding may be seen.

Coccidioidomycosis

Coccidioides immitis is endemic in the southern United States (southern Texas, New Mexico, Arizona, and Califor-

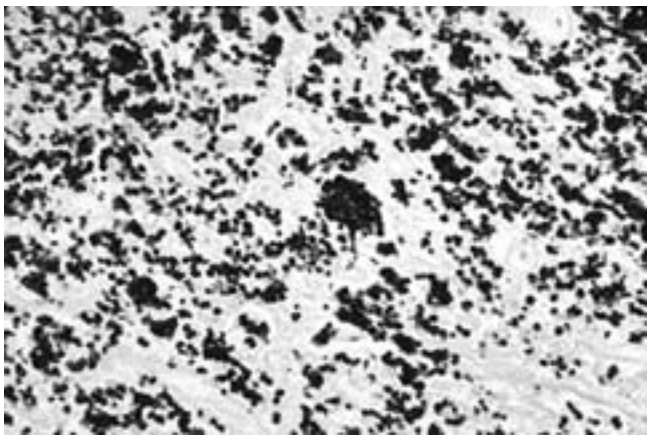

FIGURE 36-35 These small intracellular *Histoplasma* organisms stain with Gomori methamine.

VIEW IMAGE

nia) and in northern Mexico, as well as in Central America and South America. Coccidioidomycosis (San Joaquin Valley fever, desert rheumatism, the bumps) affects immunocompetent patients. It has also been estimated that 20% of the cases reported yearly are diagnosed outside the endemic areas, thus widening the relevance of the causative organism.[156] The endospores of *Coccidioides* are released and germinate to form hyphae and highly infectious arthrospores. There is seasonal variation in the rate of skin-test conversion: the higher rate of infection is seen at the end of summer during dry, dusty periods. Any profession that involves the movement of soil (e.g., construction, archaeology) places individuals in endemic areas at risk of infection. Point source epidemics have been related to archaeological digs, such as those at Indian sites, with an especially high rate of symptomatic pulmonary infection and an erythema multiforme hypersensitivity rash among individuals visiting from nonendemic areas.[157] *Coccidioides* is extraordinarily infectious; just 10 arthroconidia will cause infection in animals.[158] Handling petri dishes of laboratory cultures has caused disease, as has handling and washing infected glassware. Direct human-to-human transmission does not occur, as the tissue endospores are not infectious; they must first go through germination to yield the infectious arthrospores. Several hospital staff developed infections after removing a plaster cast from a patient with an osteomyelitis caused by *Coccidioides*.[159] It was postulated that the dressing under the cast had supported the growth of the mycelial phase, which gave rise to the infectious arthrospores.

Illnesses range from subclinical infections to disseminated and often lethal infections, depending on the patient's immune status, infectious dose, nationality, and other factors such as pregnancy. Pulmonary infection occurs through inhalation of arthrospores, and commonly causes self-limiting pulmonary and mediastinal disease. In an outbreak involving military personnel, third-trimester pregnant women are more likely to develop disseminated and fatal infections than are first-trimester pregnant women.[160]

Laryngotracheal coccidiomycoses may be seen, with or without concurrent pulmonary disease.[161] Patients with upper airway involvement present with hoarseness and stridor, which may progress to complete upper airway obstruction. The larynx and trachea have edematous, erythematous, polypoid-type tissue. Other sites of involvement of the head and neck include skin and scalp nodules, cervical soft tissue and lymph nodes, and peritonsillar and retropharyngeal tissues.[162]

AIDS patients living in or visiting regions endemic for *Coccidioidomyces* may present clinically with pulmonary infiltrates or erythematous skin lesions indistinguishable from the infections manifested in the nonimmunocompromised population. On the other hand, AIDS patients with disseminated coccidioidomycosis may have atypical presentations such as lymph node, hepatic, or cerebral involvement or pustular skin lesions.[163] Histologically, *Coccidioidomyces* evokes a granulomatous reactions with foreign body–type giant cells. The fungal spherules are large, measuring 30 to 80 μm, with thick spherule capsules that have a "double-walled" appearance (Fig. 36-36). Serum acute antibodies and a newly converted skin reaction to coccidioidin antigen may be helpful clinical diagnostic adjuncts; these tests may be falsely negative early in the course of infection. Additionally, patients with disseminated disease are likely to become anergic.

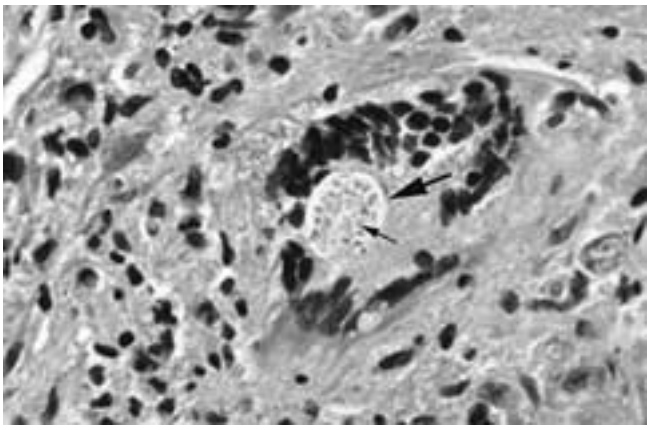

FIGURE 36-36 A multinucleated giant cell (center) containing a spherule (*large arrow*) filled with coccidioidomycosis organisms (*small arrow*).

VIEW IMAGE

Pneumocystosis

Pneumocystis carinii, the agent of pneumocystosis, is ubiquitous in nature, and exposure occurs in early childhood. The nature of *Pneumocystis* was generally unknown but had been assumed to be protozoal. Studies comparing the 16S-like ribosomal RNA of *Pneumocystis* with that of fungi and protozoa revealed that it is more closely related to fungi.[164] *P. carinii* is the most common opportunistic infection associated with AIDS and occurs in more than 60% of these patients, often leading to death. Lymph nodes may be involved in cases of bilateral pneumonia or in the rare disseminated form. Extrapulmonary pneumocystosis may be seen in AIDS patients, often in the absence of *Pneumocystis* pneumonia. These infections have occurred in patients maintained on aerosolized pentamidine, since it offers only pulmonary prophylaxis and is not systemically absorbed.

Extrapulmonary pneumocystosis of the head and neck appears to have a predisposition for the ear. Otitis externa forming external canal polyps and subcutaneous nodules and/or middle ear infections have been reported.[165–168] A suggested explanation is that *Pneumocystis* may colonize the nasopharynx and ascend the eustachian tube. Pneumocystosis appears as a foamy, frothy, granular exudate without much inflammatory response. Only the faint basophilic nuclei may be seen on hematoxylin and eosin stain. The Gomori methenamine silver stain can reveal the cystic formation of organisms that are partially collapsed, ''cup-shaped'' or ''boat-shaped,'' generally the size of erythrocytes.

Protozoal Lymphadenitis

Only *Toxoplasma* will be discussed, as this is the only protozoan that causes lymphadenopathy.

Toxoplasmosis

Toxoplasma was first isolated at the turn of the twentieth century in gondis, which are rodents in Tunis.[169] Domestic

Copyright © 2003, Mosby, Inc. All rights reserved.

cats and small rodents are major natural reservoirs for these protozoa. Feline coinfections with *T. gondii* and *Toxocara cati* had led to the initial conclusion that *T. gondii* was transmitted within *T. cati* larvae. This issue was resolved when it was shown that *Toxocara*-free cats could transmit infectious *T. gondii* oocysts.[170] The oocysts, 10 to 12 μm in size, are formed in the cat intestinal epithelium. Stray and household cats involved in catching mice or birds can pass tremendous numbers of infectious oocysts in their feces. For instance, 45% of stray cats in Kansas City have been exposed to *Toxoplasma*.[171] Cats usually develop immunity after primary infection. The excreted oocystes are unsporulated when first passed and thus are noninfectious. They require oxygen for sporulation, which can occur up to 5 days later. By contrast, feces remain infectious for up to 1 year.[172] Oocysts are resistant to drying, freezing, and disinfectants but not to boiling water. They may also become aerosolized or dispersed by houseflies or roaches.

Toxoplasmosis may be transmitted by direct inhalation of oocytes, or by ingestion of meat from secondary hosts. It may also be present in soil or sand. Oocytes in the soil also infect grazing herbivore hosts, such as cows, lambs, and pigs, and cause toxoplasmosis via ingestion of raw or rarely cooked meat. France has a higher rate of infection by *Toxoplasma* than other European countries, which is directly related to its culinary habits. For example, barely seared meat was customarily served at a tuberculosis sanitarium in France in the 1960s. The rate of *Toxoplasma* seropositivity in children increased from 0% to 18% after entrance to the sanitarium and increased further when the ration of undercooked meat was raised.[173]

Inhaled sporulated oocytes result in the release of tachyzoites (trophozoites) that invade and infect cells. The tachyzoites divide to form cysts (10 to 100 μm) filled with thousands of organisms, which can then remain latent in host tissue and serve as potential reservoirs for reactivation or chronic infection. Normal hosts commonly have asymptomatic infection. Cervical lymphadenopathy as well as fever, myalgias, anorexia, headache, sore throat, and rash are uncommon symptoms. Rarely, patients may develop necrotizing systemic infections such as retinitis, encephalitis, myocarditis, hepatitis, and pneumonitis. Chronic or recurrent infection is the result of persistence of tissue cysts.

Transplacental *T. gondii* infection may be entirely asymptomatic or result in fetal loss. The risk of fetal loss is greatest in first-trimester infections, while the risk of delivering a baby with evidence of severe congenital infection is greatest with third-trimester infections. The overall risk of fetal infection was 7.4% in a cohort of 339 pregnant women from France who contracted toxoplasmosis during pregnancy.[174] Transplacental transmission may result in severe intracranial infections causing microcephaly, hydrocephaly, cerebral calcifications, chorioretinitis, mental retardation, blindness, and seizure disorders. Immunosuppressed patients or those with AIDS are much more likely to develop severe and fatal infections such as encephalitis, myocarditis, pneumonitis, and hepatitis. *Toxoplasma* encephalitis is the most frequent cause of intracerebral mass lesions in AIDS.

Histologically, the tachyzoites, especially in an extracellular location, are hardly perceptible on hematoxylin and eosin stain but might be observed with a tissue Giemsa stain. They are banana-shaped or crescent-shaped, with a nucleus. The encysted forms of *T. gondii* are more easily visualized: they can be seen on hematoxylin and eosin stain but are rarely present in lymph nodes. Disseminated infections reveal areas of necrosis, intracellular and extracellular tachyzoites, and encysted tachyzoites adjacent to necrosis.

Reactive Lymphadenopathies

Reactive lymphoid hyperplasia may have many causes: bacterial or viral infection, exposure to chemicals, environmental pollutants, drugs, or foreign antigens. The reaction may be an acute inflammatory one or a chronic immune response. Histologically, the response may be focused within the germinal centers, there may be a sinusoidal pattern with antigen-processing cells filling the sinuses, or the pattern may be mixed. The imaging findings are nonspecific and usually consist of homogeneous, normal or slightly enlarged, variably enhancing, well-delineated nodes, similar to the findings of the viral lymphadenitides (see 'Normal' Reactive Nodes in the section on Imaging Criteria of Pathologic Adenopathy).

Atypical Lymphoid Hyperplasia

Atypical lymphoid hyperplasia is seen as activated germinal centers with peculiar dumbbell or serpentine shapes. The germinal centers may be distorted by an influx of small lymphocytes (follicular lysis). The crowded appearance of the follicles may bring to mind follicular lymphoma. Most commonly, atypical lymphoid hyperplasia may be seen in the early phase of AIDS.

Lymphadenopathies Associated with Clinical Syndromes

The following entities involve lymphadenopathies that may be localized to cervical lymph nodes or may have additional generalized manifestations. Two different imaging patterns can be seen. With Kimura's disease and Kikuchi-Fujimoto disease, usually only regional lymph nodes are involved. The nodes are enlarged and necrotic and enhance on imaging, and there is soft-tissue infiltration, often involving the parotid and/or submandibular glands. With other entities such as sinus histiocytosis with massive lymphadenopathy, sarcoidosis, dermatopathic lymphadenopathy, angiofollicular lymph node hyperplasia, angioimmunoblastic lymphadenopathy, and tumor-reactive lymphadenopathy, the lymph nodes are either hyperplastic or considerably enlarged, homogeneous, and often similar in imaging appearance to lymphomatous nodes (Figs. 36-37 to 36-42).[175–178]

Kimura's Disease

This disease, described by Kimura et al. in 1948, is endemic to Asia. The disease involves lymph nodes and deep subcutaneous tissues. By comparison, angiolymphoid hyperplasia with eosinophilia, once considered synonymous with Kimura's disease, is primarily restricted to the dermis. Kimura's disease occurs mainly in young adults age 27 to 40

VIEW IMAGE

FIGURE 36-37 Axial T1-weighted MR images from cranial (**A**) to caudal (**B**) on a patient with sarcoidosis. There are multiple homogeneously enlarged lymph nodes in the parotid gland and in the occipital region. There are also nodes in levels I, II, and V. There was no infiltration of the adjacent fat planes. Although this imaging appearance can be seen in lymphoma, the presence of the suboccipital nodes makes a viral adenopathy or sarcoidosis more likely.

years, and there is a male-female ratio of 3:1. The onset is insidious, with nodular masses enlarging mainly in the head and neck. Often the parotid and periauricular regions are involved, although the oral cavity, axilla, groin, and limbs can also be affected. Peripheral blood eosinophilia of 10% to 15% and elevated serum immunoglobulin E (IgE) levels are common. Histologically, Kimura's disease is characterized by intense infiltrates of eosinophils and vascular proliferation with plump reactive endothelium (Fig. 36-43). While the disease process is usually localized, systemic symptoms (allergic asthma, myocarditis, and focal segmental glomerulosclerosis) may occur as a result of the peripheral eosinophilia.[179, 180]

Surgery is the treatment of choice, and the disease usually has a benign course.[175]

Sinus Histiocytosis with Massive Lymphadenopathy

Sinus histiocytosis with massive lymphadenopathy (SHML) has also been referred to as Rosai-Dorfman disease, lymphadenitis with massive hemophagocytic sinus histiocytosis of Lennert, and histiocytose lipdique ganglionnaire pseudotumorale of Destombes.[181] There is a wide age range (newborn to age 74 years), although most cases involve children and teenagers. The male-female ratio is 6:4, and there is a worldwide distribution with no racial predisposition. SHML can affect lymph nodes and cause soft-tissue infiltrates of the ear, upper respiratory and gastrointestinal tracts, meninges, and other extranodal sites. Painless, enlarged lymph nodes may persist for several years, but the disease is self-limited. Lymph nodes reveal a proliferation of histiocytes within distended sinuses. These histiocytes contain ingested lymphocytes (emperipolesis). Soft-tissue infiltrates of SHML likewise reveal a lympho/histiocytic infiltrate with emperipolesis. Rarely, there is more aggressive involvement of underlying bone or vital organs, with resultant morbidity and mortality. There is no effective treatment.[176]

Kikuchi-Fujimoto Disease

Kikuchi-Fujimoto lymphadenopathy (KFL) has also been referred to as Kikuchi's disease, necrotizing lymphadenitis of Kikuchi and Fujimoto, and histiocytic necrotizing lymphadenitis without granulocytic infiltration. KFL commonly affects Japanese and is sporadic in Western countries. The majority of patients are female (80%), with a mean age younger than 30 years. The cervical nodes are involved, commonly unilaterally but occasionally bilaterally, and may be tender. There are occasional systemic symptoms such as fever, chills, myalgia, sore throat, skin rash, localized pain, leukopenia, or leukocytosis. Less often, patients complain of weight loss, nausea, vomiting, night sweats, arthralgias, and hepatosplenomegaly. Rarely, skin and bone marrow have also been involved.

KFL follows a self-limiting course, usually resolving spontaneously within a few weeks to months. The lymph nodes show a necrotizing process, with patchy or confluent areas of necrosis associated with karyorrhexis and absence or paucity of granulocytes. A proliferating component of large blastic cells, T lymphocytes, and histiocytes, mimicking lymphoma can be seen.[178, 182] The etiology of KFL is unknown, but an autoimmune process has been suggested based on the histologic resemblance to systemic lupus erythematosus.

Sarcoidosis

Sarcoidosis is a self-limiting systemic granulomatous disease that affects lymph nodes, upper aerodigestive tract mucosa, parotid gland, lungs, liver, skin, and spleen and is presumably the result of infection by a mycobacterial agent.

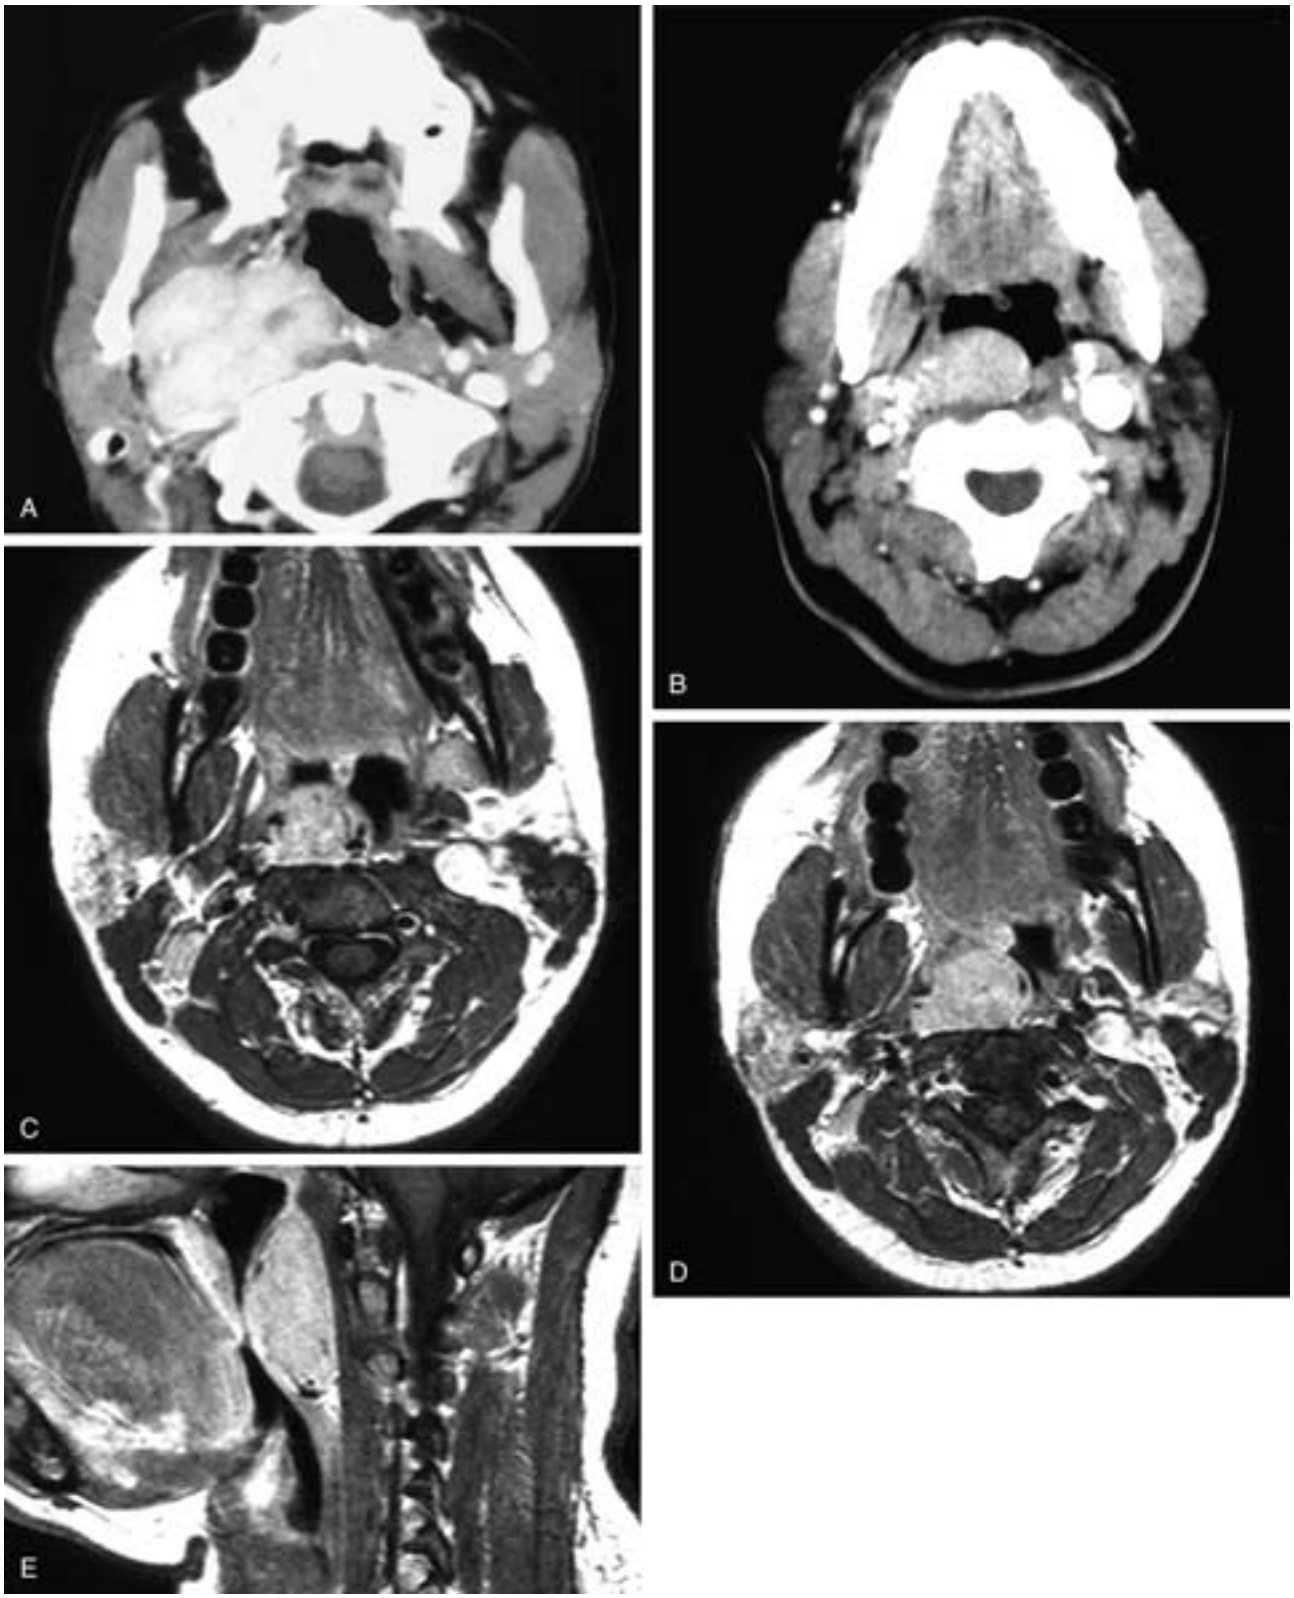

FIGURE 36-41 Axial contrast-enhanced CT scan (**A**) shows a large, enhancing mass in the right parapharyngeal space/carotid sheath region obliterating the silhouette of the internal carotid and internal jugular vein. The mass pushes the right pharyngeal wall forward and medially. At surgery, this was found to be Castleman's disease in a retropharyngeal node. Axial contrast-enhanced CT scan (**B**) on another patient shows findings similar to those in **A**; however, the enhancing mass is seen to be along the medial border of the carotid sheath, in the region of a retropharyngeal node. Axial T1-weighted images (**C**, **D**) show the mass to have an intermediate signal intensity with vascular flow voids. Sagittal T1-weighted, contrast-enhanced image (**E**) shows enhancement of the mass with vascular flow voids at its margins. At surgery, this was found to be Castleman's disease in a retropharyngeal node.

VIEW IMAGE

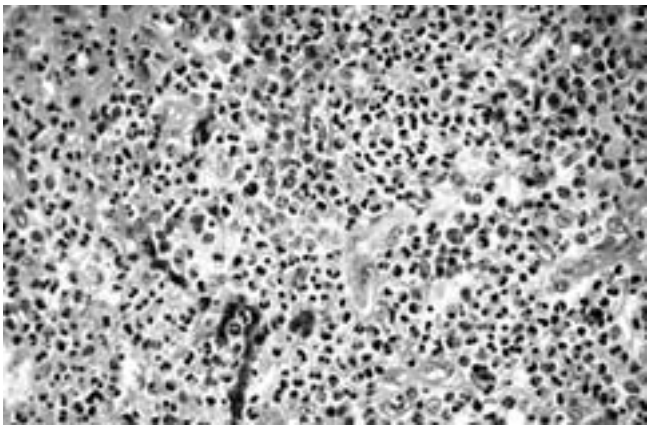
FIGURE 36-42 Axial CT scans from cranial (**A**) to caudal (**B**) show enlarged, enhancing, fairly homogeneous right level I and II nodes and a smaller left level II node. There is also thickening and enhancement of the adjacent skin in the right neck, and there is involvement of the right parotid gland in this Asian patient with Kimura's disease.

Sarcoidosis is most often diagnosed between the second and fourth decades of life. Worldwide, the highest incidence of sarcoidosis has been seen in Sweden, Norway, the Netherlands, and England. In the United States, it is 10 times more common among African Americans than among Caucasians. Sarcoid is most prevalent in the southeastern United States, and there is also an increased incidence in persons who have migrated from the South. Generally, there is an inverse relationship between susceptibility to MTB and sarcoid. Sarcoid is virtually nonexistent among ethnic populations with a high susceptibility to MTB, such as the Inuit, Native Americans, and Chinese.

Patients may present with nonspecific symptoms such as fever, malaise, weight loss, and erythema nodosum, or they may present with lymphadenopathy, and hepatosplenomegaly, as well as pulmonary, arthritic, and ocular symptoms.



VIEW IMAGE

FIGURE 36-43 Plump vessels and a lymphocytic infiltrate with prominent eosinophilia (note the binucleated cells) are seen within the periparotid soft tissue. The eosinophilia was also present in adjacent lymph nodes in this patient with Kimura'a disease.

Other individuals are totally asymptomatic; an incidental chest x-ray will reveal enlarged hilar lymph nodes and a diffuse pulmonary reticular pattern. A pulmonary screening program for sarcoid in Denmark in the early 1960s estimated that asymptomatic sarcoid was four times more prevalent than symptomatic cases. A Swedish autopsy study revealed the incidence of subclinical sarcoidosis to be even greater.[183] The majority of clinically symptomatic individuals follow a self-limiting course in which the disease ''burns out,'' usually within 2 years. Fewer individuals progress to severe pulmonary fibrosis and renal involvement. Death is only uncommonly attributed to sarcoidosis.[184]

In the head and neck, sarcoid may involve the anterior or posterior cervical lymph node chains. Extranodal head and neck manifestations can be seen in 38% of sarcoid patients. In one report, 20% of patients had ophthalmic involvement, 7% had parotid gland involvement, 6% had lacrimal gland involvement, and 3% had upper respiratory tract submucosal involvement.[184] Heerfordt's syndrome (uveoparotid fever) is an acute, febrile, self-limiting involvement of the parotid and lacrimal glands and the retina. Involvement of the temporal bone and of nerves VII and VIII results in neurosensory hearing loss, vertigo, and facial paralysis.

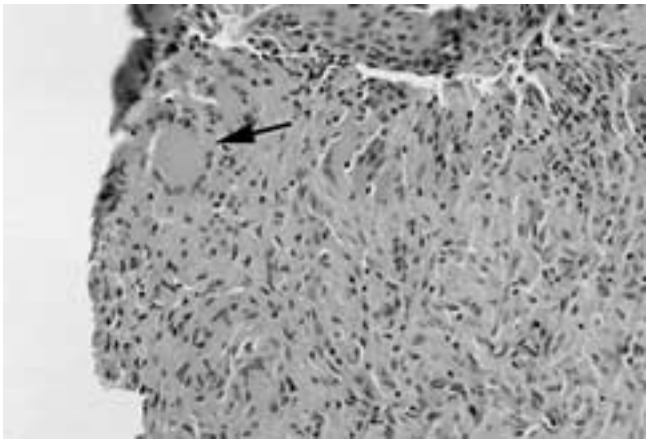
The relationship between sarcoidosis and a specific infectious agent has not yet been firmly established. Tissue homogenates from sarcoid patients injected into mice result in sarcoid-like granulomas with a distribution similar to that seen in humans (lungs, lymph nodes, liver, spleen).[185] However, direct inoculation of sarcoid tissue into athymic mice failed to lead to isolation of an infectious agent.[186]

Mycobacteria other than *M. tuberculosis* (MOTT) have been implicated in the etiology of sarcoid. Acid-fast bacilli are observed on rare occasion within granulomata of tuberculin-negative sarcoid patients after considerable inspection.[187] Moscovic studied cases in great detail by histochemistry and electron microscopy and described pleomorphic spindled, almond-shaped and round bodies

Copyright © 2003, Mosby, Inc. All rights reserved.

with electron-dense cores (nucleoids) and without cell walls. He concluded that they were consistent with L-forms of mycobacteria, the result of viral bacteriophage infection.[188] Bacteriophages cause mutated bacterial forms with loss of cell walls (L-forms, Much's granules, lysogenic forms). Bacteriophages have been isolated from the stools of 36% of tuberculosis patients and 6% of control patients. Interestingly, 94% of patients with pathologically proven sarcoidosis have been shown to harbor bacteriophages. On the other hand, serum antibodies to bacteriophages were present in tuberculosis patients but were absent in sarcoid patients. These antibodies could, in vitro, prevent the formation of L-forms.[189, 190] The presence of bacteriophages and the absence of neutralizing antibodies in sarcoid patients is consistent with the interpretation that sarcoidosis is the result of infection with mutated or lysogenic mycobacterial strains. Possibly, certain populations are genetically predisposed to a lack of immunity to certain bacteriophages (as well as the ''sarcoid mycobacterium''). This would explain the elevated incidence of sarcoid in particular populations. The majority of patients with sarcoid have been found to contain antibodies against an unclassified mycobacterium.[191] Sera from 23 sarcoid patients had elevated antibodies to *M. paratuberculosis* compared to a control group.[192] These antibodies, though, are not species specific and may cross-react with other MOTT. Application of more specific and highly sensitive techniques, such as in situ polymerase chain reaction, will probably illuminate the issue of mycobacterial and bacteriophage interaction in the development of sarcoid.

The granulomas seen in sarcoid are sufficiently characteristic to allow immediate recognition (Fig. 36-44). They are usually small, nonconfluent, nonnecrotic, and densely hyalinized. On rare occasions, patients with clinically confirmed sarcoidosis may have necrotizing granulomas. The pathologist must then make certain that these granulomas are not the result of MTB or fungal infection. Pathognomonic features of sarcoid include asteroid bodies (star-like crystalline inclusions within multinucleated giant cells), Schaumann bodies (calcified, laminated concretions within multinucleated giant cells), and Hamasaki-Wesenberg inclusions (coccoid, oval, or rod-shaped golden brown inclusions measuring 3 to 15 μm).



VIEW IMAGE

FIGURE 36-44 Sarcoid granulomas are characterized by epithelioid histiocytes and multinucleated giant cells (*arrow*). Necrosis is usually not present.

The Kveim test relies on the specific hypersensitivity that sarcoid patients have to the ''sarcoid antigen.'' It involves subcutaneous injection of heat-sterilized tissue homogenates from tissue (spleen or liver) involved by sarcoid. The injection site is biopsied 4 to 6 weeks later. A positive Kveim test reveals sarcoid granulomas at the injection site. The sensitivity of this test varies with disease activity: up to almost 90% of patients recently diagnosed with subacute cases may have a positive Kviem test, while patients with chronic or inactive sarcoid may have low or nonexistent rates of reactivity to this test. On the other hand, false positivity with the Kviem test is rare.[184]

Angiotensin converting enzyme (ACE) is responsible for the conversion of angiotensin I to angiotensin II. Its main tissue sources are foamy histiocytes and epithelioid histiocytes. Elevated serum ACE can be seen in sarcoidosis, especially in patients with active pulmonary disease, and may be helpful in clinically establishing the diagnosis. ACE is not elevated in inactive sarcoidosis, pulmonary tuberculosis, or berylliosis. Other conditions in which serum ACE may be elevated include liver disease, leprosy, silicosis, and asbestosis.[193]

On imaging, sarcoidosis usually has multiple reactive-appearing lymph nodes or enlarged ''foamy-type'' nodes similar to those of lymphoma. There is rarely any imaging evidence of extracapsular disease. When there is cervical adenopathy and multiple parotid lymph nodes, the most likely diagnosis is either sarcoidosis or lymphoma.

Dermatopathic Lymphadenopathy

Dermatopathic lymphadenopathy (DPL) is a reactive lymph node hyperplasia associated with chronic inflammatory skin disease. Axillary, inguinal, and regional nodes are most commonly involved, and there is an associated peripheral eosinophilia in 35% of patients.[194] Cervical or facial lymph nodes may be involved with facial dermal conditions.[195] Pruritis is a common finding. In 22.5% of cases, there is associated mycosis fungoides. Histologically, DPL is characterized by a paracortical proliferation of histiocytes and melanin deposition. Interdigitating reticulum cells (IDCs), which are antigen-presenting cells with broad cytoplasm, innumerable cytoplasmic interdigitation, and bizarre-shaped nuclei, are the most striking cell type in DPL.

Angiofollicular Lymph Node Hyperplasia

Angiofollicular lymph node hyperplasia (AFLNH) is also referrred to as Castleman's disease, giant lymph node hyperplasia, and angiomatous lymphoid hamartoma. This disease may be either unicentric, presenting as a solitary mass, or multicentric and systemic, presenting with widespread lymphadenopathy. There are two histologic subtypes: hyaline vascular and plasma cell types. The hyaline vascular type, which constitutes 91% of the cases of AFLNH, affects patients with a wide age range, without gender predominance. Most patients are young and present with single, asymptomatic masses of either cervical or mediastinal lymph nodes. Periparotid/intraparotid lymph nodes may be involved, as well as extranodal soft tissue.[196] Histologically, one sees lymphoid follicles with central hyalinized blood vessels surrounded by an ''onion skin'' arrangement of lymphocytes. Surgery is curative.

Copyright © 2003, Mosby, Inc. All rights reserved.

The plasma cell type is not restricted to the mediastinum and often has systemic manifestations including the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin abnormalities). These patients tend to be older. There can also be associated anemia, hypoferremia, antierythropoietin factor, and polyclonal hypergammaglobulinemia. Histologically, one sees germinal center hyperplasia with interfollicular sheets of plasma cells. The plasma cell type of AFLNH may pursue a different course from the hyaline vascular type in that it may persist, relapse, or progress to malignant lymphoma.[197]

Angioimmunoblastic Lymphadenopathy

Synonyms include *angioimmunoblastic lymphadenopathy with dysproteinemia* and *immunoblastic lymphadenopathy with dysproteinemia*. Patients are usually middle-aged and present with generalized lympadenopathy, skin rash, fever, and hyperglobulinemia. Immunologic and molecular studies have demonstrated that the majority of cases are T-cell clonal disorders; most cases show rearrangements of the T-receptor genes. Histologically, one sees effaced lymph nodes with a polymorphous cellular infiltrate including immunoblasts. Prominent proliferating postcapillary venules can be seen, along with proteinaceous deposition. Eighty percent of the cases follow an aggressive course with short median survival, especially if a complete response with chemotherapy is not achieved. There may be progression to immunoblastic lymphoma of either the T-cell or B-cell type, and the 5-year survival is only 20%.[177, 198]

Kawasaki's Syndrome

Kawasaki's syndrome, also known as mucocutaneous lymph node syndrome, is a systemic disorder of unknown etiology that manifests during infancy or early childhood. Children present with fever, skin rash, aseptic meningitis, conjunctivitis, uveitis, hyperemic tympanic membranes, fissured lips, injected pharynx, strawberry tongue, and diffuse lymphadenopathy. Neurologic complications are reported in 1% of patients and include facial nerve palsy, seizures, ataxia, encephalopathy, hemiplegia, and cerebral infarction.[199] An acute necrotizing coronary arteritis is common, leading to aneurysm, which may be fatal. When gamma globulin is administered in combination with oral aspirin within the first 10 days of the illness, there may be a reduced incidence of coronary artery abnormalities.[200–202]

Posttransplantation Lymphoproliferative Disorders

The posttransplantation lymphoproliferative disorders (PTLD) are a group of disorders ranging from lymphoid hyperplasia to lymphoma that occur in patients who have had chronic immunosuppression after solid organ transplantation.[203] PTLD occurs with a reported frequency of 1% to 10%, depending on the organ transplanted and the type and duration of immunosuppression. PTLD is an uncontrolled B-cell proliferation that can range from a polymorphic cellular process of large and small lymphocytes to large cell non-Hodgkin's lymphoma. Epstein-Barr virus has been shown to play a role in the pathogenesis of PTLD. In one study, the interval between transplantation and the onset of symptoms varied from 3½ to 108 months.[203] On imaging, reported abnormalities include enlargement of the adenoids and/or palatine tonsils and/or lingual tonsils, as well as adenopathy that can vary from a grossly enlarged lymph node to multiple reactive-appearing nodes. It is suggested that when these findings are seen in a transplanted patient, PTLD should be suspected.

Tumor-Reactive Lymphadenopathy

Frequently, lymph nodes adjacent to a neoplasm may be enlarged yet may not contain metastatic disease. Histologically, one sees typical reactive hyperplasia. On occasion, sarcoid-type granulomas may also be seen in lymph nodes draining from tumors.

Vascular Lymphadenopathies

These vascular-related lymphadenopathies can be the result of obstruction of nodal blood flow secondary to compression by tumor, vascular embolization and thrombosis, surgery, or, rarely, needle biopsy. Such changes can also be found with the nonneoplastic angiomatoses like angioimmunoblastic lymphadenopathy, AFLNH, Kimura's disease, HIV lymphadenitis type C, and vascular transformation of sinuses. The importance of these vascular lymphadenopathies lies in their potential confusion with vascular neoplasms in lymph nodes. In most recorded cases, the nonspecific imaging findings are those of reactive lymph nodes.[134, 200, 204–206] Lymph node infarction is rare due to abundant normal lymph node vascularity. The most common cause of massive lymph node infarction is nodal involvement by either lymphoma or metastatic carcinoma. Vascular transformation of sinuses is a benign vascular proliferation of lymph nodes with a characteristic sinus distribution. It is rare and in most cases is an incidental finding in lymph nodes excised at tumor surgery. It has also been associated with a distal lymphatic or venous obstruction.

Foreign Body Lymphadenopathies

Regional lymph nodes may drain endogenous or exogenous material which can cause reactive adenopathy. These substances may be endogenous, such as lipids (seen in elderly and obese patients or in those with diabetes mellitus or hyperlipidemia) and proteins (such as amyloid). Exogenous substances causing lymphadenopathy include agents used for lymphangiography, silicone (used for reconstructive or orthopedic surgery), Teflon (injected into a paralyzed vocal cord to improve vocal quality), and gold (previously used for the treatment of rheumatoid arthritis). Radiodense foreign material may be visualized as focal lymph node densities on CT; nonradiodense material manifests as nonspecifically enlarged lymph nodes.

Lymph Node Inclusions

Benign cellular inclusions within lymph nodes are important to recognize, as they may be confused with metastatic processes. These inclusions are usually microscopic, although on imaging they may be the cause of enlarged lymph

Copyright © 2003, Mosby, Inc. All rights reserved.

nodes. For instance, it is common to find salivary duct and acinar inclusions within parotid and periparotid lymph nodes. Nevus cell inclusions may be seen within peripheral lymph nodes, probably as a result of embryonal migration of neural crest cells. In the lower cervical lymph nodes, thyroid follicles may be found within the nodes (Fig. 36-45). This raises the obvious question of metastasis from an occult thyroid primary. Usually, metastatic papillary thyroid carcinoma contains some of the histologic hallmarks (papillae formation, overlapping oval nuclei), allowing for the correct diagnosis. Even if these findings are absent, it behooves the clinician, under these circumstances, to make sure that the thyroid gland is properly imaged. We have had occasion to examine thyroidectomies performed after the discovery of cervical lymph node thyroid ''inclusions.'' On one occasion, an exhaustive search failed to uncover any primary malignancy, confirming the possible existence of benign lymph node thyroid inclusions.

Lymphoproliferative Disorders

On imaging, lymphomas can appear as normal-sized to enlarged lymph nodes with variable enhancement. On CT, these nodes may be hyperdense, isodense, or hypodense relative to muscle. Central necrosis can be seen, although it is not as frequently observed as in comparably sized nodes containing metastatic squamous carcinoma. The fat planes adjacent to the nodes can be effaced, but there is usually little infiltration into the surrounding neck. Although there is no typical CT appearance for a lymphomatous node, the most common appearances are (1) slightly enlarged, homogeneous, reactive-appearing nodes; (2) enlarged, ''foamy''-appearing nodes; (3) an enlarged lymph node with a thin nodal capsule and a central homogeneous attenuation similar to that of water; or (4) a cluster of nodes with variable enhancement, some of which may have central necrosis. There usually is relatively little ''extracapsular'' infiltration of the adjacent fat planes compared to that of comparably sized nodes containing squamous carcinoma. Either a single lymph node or diffuse disease may be present. The adenopathy is usually nontender. The imaging appearance of lymph nodes in leukemia is similar to that of lymphoma. In addition, the imaging appearance of tuberculosis may be similar to that of lymphoma. If there is cervical adenopathy and multiple parotid lymph nodes, the most likely causes are lymphoma and sarcoidosis (Figs. 36-37 to 36-39 and 36-46 to 36-55).

Leukemia is a neoplastic proliferation of either myelocytic or lymphocytic precursor cells manifested within the circulating blood compartment; a tissue infiltrate may or may not be discernible. By comparison, lymphoma, by nature, usually arises within lymph nodes but may extend to the bone marrow compartment; it may also disseminate and produce a leukemic phase. Cytologically, leukemias and lymphomas can appear similar, as the same cell type gives

VIEW IMAGE

rise to both localized and systemic neoplastic proliferations.

The two most popular lymphoma classifications are the European Keil classification, by Lenner, and the Working Formulation, proposed by an international panel of American experts. A recently proposed Revised European-American Lymphoma (REAL) classification has been drafted by the International Lymphoma Study Group.[207, 208] This is a much broader, more complex schema than the Working Formulation, which includes Hodgkin's disease, non-Hodgkin's lymphomas, lymphoid leukemias, plasma cell neoplasms, extranodal lymphomas, and ''maltomas'' (mucosa-associated lymphoid tumors). It is based on both the morphologic and functional properties of the neoplastic cells (Fig. 36-56). The newly proposed REAL classification and the Working Formulation are compared in Table 36-13.

Proliferative Histiocytic Disorders

The advent of immunohistochemical cell typing has allowed characterization of disorders of true monocyte-macrophage cells. Prior to this, all large hematopoietic cells, including neoplastic T and B lymphocytes, were referred to as histiocytic proliferations. This group of disorders is still

broad, albeit better classified, and includes entities such as true histiocytic lymphoma, hemophagocytic syndromes (viral-associated hemophagocytic syndrome, familial erythrophagic lymphohistiocytosis, Rosai-Dorfman disease [covered above] and Langerhan's cell histiocytosis [granulomatosis] [LCG or histiocytosis X]). *LCG* is the term applied to a group of childhood disorders, including eosinophilic granuloma (EG), Hand-Schuller Christian (HSC) disease, and Letterer-Siwe (L-S) disease. EG is a localized form of LCG,

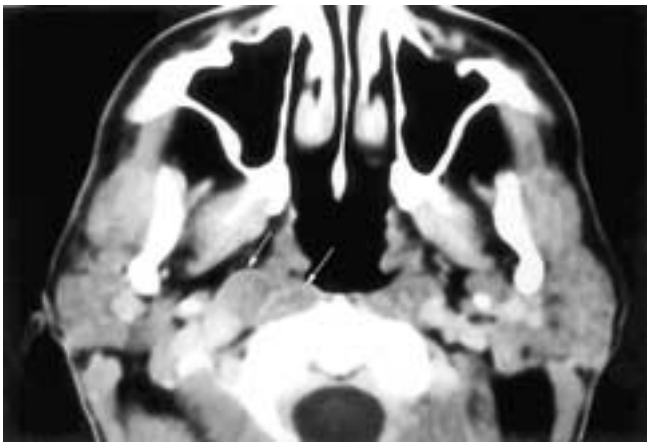

FIGURE 36-53 Axial contrast-enhanced CT scan shows enlarged medial and lateral right retropharyngeal lymph nodes with an attenuation slightly less than that of muscle (*arrows*). This patient had large cell lymphoma.

often manifesting as a solitary bone lesion, whereas the latter two syndromes have multifocal or disseminated disease, with involvement of lymph nodes, skin, liver, spleen, lung, head and neck, or the gastrointestinal tract. The etiology is unknown, however, a recent report suggests that all forms of LCG are clonal. Others, however, believe LCG to be a benign, possibly reactive process.

The head and neck are frequently involved in LCG. In a recent study, 82% of patients with LCG had head and neck disease, causing the presenting symptom in 40% of patients. Facial rash and cervical adenopathy are common. The skull is the most frequently involved flat bone; the mandible and temporal bone are also common sites. Otitis media and/or destructive lesions of the temporal bone may be the initial presentation in up to 60% of cases. Histologically, LCG is characterized by a polymorphous cellular infiltrate of mononuclear or multinucleated histiocytes (Langerhans

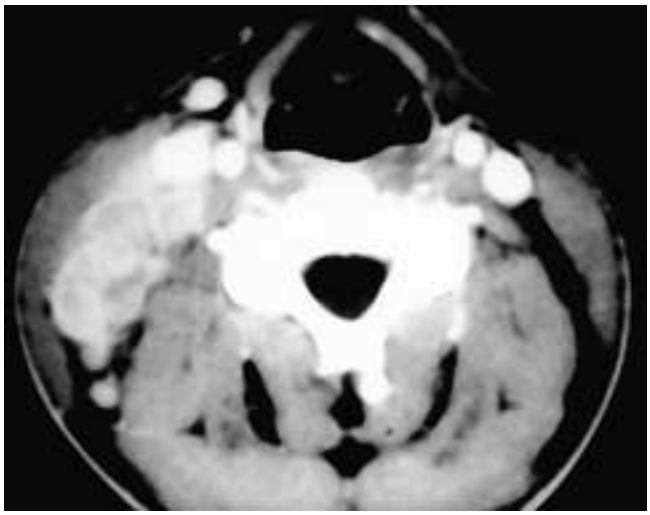

FIGURE 36-52 Axial contrast-enhanced CT scan shows multiple nonhomogeneously enlarged right level II nodes. Anteriorly, there is some involvement of the adjacent fat planes. The enhancing nodal capsules give an appearance suggesting numerous ''rings'' within the nodal mass, a sign highly suggestive of nodal disease. This patient had Hodgkin's disease.

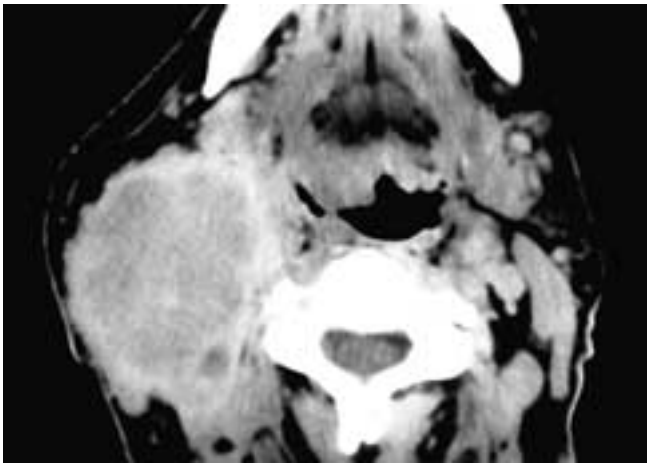

FIGURE 36-54 Axial contrast-enhanced CT scan shows a grossly enlarged right level II node with an enhancing rim and some involvement of the adjacent fat planes. The node is fairly homogeneous and has an attenuation less than that of muscle. Although metastatic squamous cell carcinoma nodes can have similar-appearing capsular enhancement with extracapsular disease, it would be unusual to find a node this large without central necrosis. This patient had large cell lymphoma.

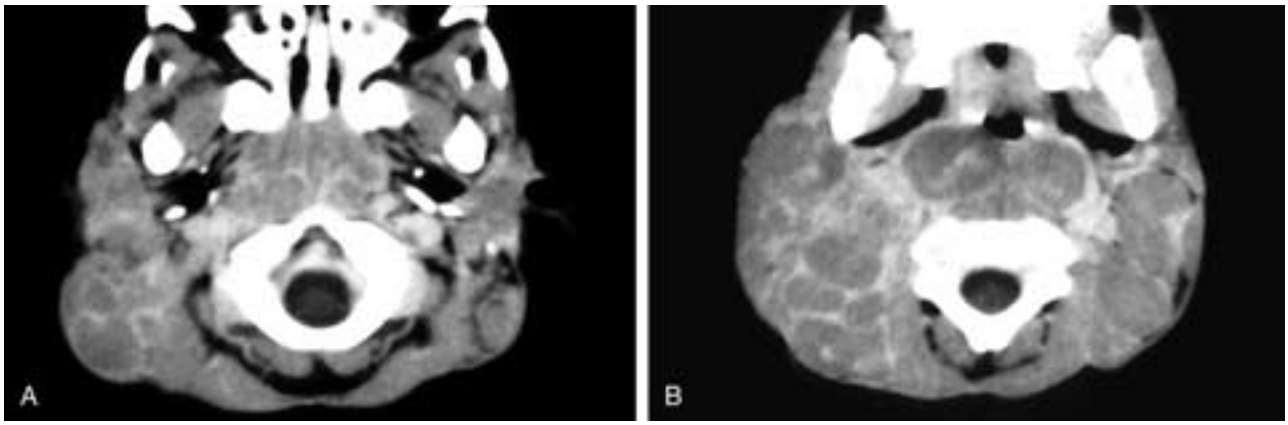
phage and is characterized by a syndrome of systemic symptoms, pancytopenia, adenopathy, hepatosplenomegaly, and wasting. The distinction between MH and THL is at times arbitrary, and overlap exists between these syndromes (Fig. 36-58).[209–217]

Spindle Cell Neoplasms of Lymph Nodes

A list of the various entities that can appear as spindle cell lesions within lymph nodes is given in Table 36-14. Intranodal myofibroblastoma is a rare primary spindle cell tumor that usually arises within inguinal lymph nodes. It is often a solitary mass but occasionally may be multicentric. The tumors consist of a fascicular proliferation of spindle cells with focal nuclear pallisading and acellular stellate-shaped, collagen-rich areas (so-called amianthoid fibers).[217] Intranodal myofibroblastoma is thought to arise from intranodal myofibroblasts. This lineage can be demonstrated by the immunohistochemical expression of muscle actin and the ultrastructural findings of intracytoplasmic microfilaments and rough endoplasmic reticulum. These tumors are generally cured by resection, although occasional recurrences have been documented.

Inflammatory pseudotumor of lymph nodes (IPT) can be considered to be vaguely related to intranodal myofibroblastoma in that myofibroblastic differentiation is also seen here; hence, *inflammatory myofibroblastic tumor* (IMFT) is the currently preferred term. IMFT is most likely a number of different entities with overlapping histologic features, the true nature of which is only beginning to be elucidated. The lung, liver, and gastrointestinal tract (omentum and mesentery) are the most common sites for IMFT. Lymph nodes at various sites (cervical, supraclavicular, inguinal, mesenteric, mediastinal, paraaortic) can be involved. In the head and neck, IMFT has been reported in the epiglottis, endolarynx, parapharyngeal space, maxillary sinus, submandibular region, and oral cavity. There is no pronounced gender predominance, and the tumor tends to occur in the first two decades of life. Occasionally, systemic symptoms such as fatigue, abdominal pain, weight loss, fever of unknown origin, pelvic inflammatory disease, nausea, or night sweats may occur.

Histologically, one sees a characteristic fibrosing/



VIEW IMAGE

FIGURE 36-58 Axial CT scans from cranial (**A**) to caudal (**B**) show considerable enlargement of virtually every node in this 1-month-old infant. Note that the retropharyngeal nodes are also involved, and all of the nodes have a fairly low attenuation. In an older patient, this imaging appearance would suggest a lymphoma. However, in a patient this young, histiocytosis must be considered. This patient had histiocytosis.

Table 36-14
THE DIFFERENTIAL DIAGNOSIS OF SPINDLE CELL LESIONS WITHIN LYMPH NODES

Metastatic
Sarcoma (smooth muscle, skeletal muscle, fibroblastic, etc.)
Carcinomas (spindle cell carcinoma [carcinosarcoma, pseudosarcoma], nasopharyngeal carcinoma)
Melanoma
Vascular (Kaposi's sarcoma, angiosarcoma, etc.)
Hematopoietic
Dendritic reticulum cell sarcoma
Interdigitating reticulum cell sarcoma
Nodular sclerosis variant of Hodgkin's disease
Benign
Intranodal palisaded myofibroblastoma (inflammatory/infectious)
Inflammatory pseudotumor (inflammatory myofibroblastic tumor) of lymph nodes
Spindled atypical mycobacterial infection

inflammatory process with a prominent inflammatory background. The myofibroblastic proliferation is variable. The polymorphous appearance of IMFT may reflect its variable etiology or its shifting histology during the disease course. Lymphocytes, plasma cells, histiocytes, fibroblasts, and myofibroblasts are the basic components of IMFT, with mutable proportions. Four basic histologic patterns have emerged: (1) a dominant lymphoplasmacytic infiltrate, (2) a dominant lymphohistiocytic infiltrate, (3) a predominantly ''young and active'' myofibroblastic process, and (4) a predominantly collagenized process with a lymphoplasmacytic infiltrate.

Many IMFT may resolve or regress with conservative excisional biopsy and/or steroid therapy. However, some cases may persist and worsen. Single or multiple recurrences developed in 25% of patients with IMFT at all body sites after excision. Histologic evidence of sarcomatous transformation can occur. Recurrence or transformation was more likely to occur with mesenteric or retroperitoneal multinodular tumors. These cases tend to remain localized.

Spindled atypical mycobacteriosis (SAM), or mycobacterial pseudotumors, is a mycobacterial infection, usually caused by an atypical mycobacterium, that produces an unusual myofibroblastic reaction. This lesion occurs in immunosuppressed patients, usually those with AIDS, hence the inability to mount a granulomatous or epithelioid histiocytic reaction. SAM may occur within lymph nodes, subcutaneous tissue, brain, bone marrow, spleen, lungs, and retroperitoneum. The spindled cells are actual myofibroblasts that act as facultative histiocytes, ingesting the mycobacteria.[219–224]

Vascular Neoplasms of Lymph Nodes

The primary disease in this category is Kaposi's sarcoma (KS). Imaging of lymph nodes affected by this disease usually shows nodes that are enhanced, enlarged, and often nonhomogeneous in appearance.

Prior to the AIDS epidemic, KS was rarely encountered in the head and neck. The classic form of KS is an indolent tumor seen most commonly as soft red nodules on the lower limbs and, less commonly, on the upper limbs. Lesions may be multicentric and coalescent but rarely exceed 2 cm. Patients with classic KS usually have long survivals and died ''with but not of KS.''

Gnepp et al. compiled a total of 83 cases of classic KS from the literature and from the files of the Armed Forces Institute of Pathology (AFIP) that affected the head and neck. Eight percent of all classic KS cases affected cutaneous sites on the head and neck, and only 2% affected the mucosal surfaces. Mucosal sites included conjunctiva, palate, tongue, gingiva, and tonsil; skin sites included eyelids, nose, ears, and face. By comparison, AIDS KS cases commonly affected skin of the head and neck (32%) and upper airway mucosal surfaces (19%). Common sites for AIDS KS cases in the head and neck include palate, gingiva, buccal mucosa, tongue, larynx, trachea, and sinuses. Patients with classic KS are usually over the age of 50 years at the time of tumor diagnosis, although 3% to 4% of cases with the classic form are diagnosed in those less than 15 years old. Patients with AIDS diagnosed with head and neck KS tend to be decades younger than those with classic KS (mean age, 38 years), although there is overlap in both age groups.

Histologically, KS appears as long, plump, spindle-shaped nuclei forming slit-like spaces. The description ''slit-like'' is emphasized to differentiate KS from high-grade angiosarcomas, which form incomplete, anastomosing channels, with protrusion of the malignant nuclei into the lumina. Mitotic figures are easily recognized. Erythrocytes are usually abundant within the slit-like spaces. Intracellular eosinophilic globules, or red bodies, are seen. They are usually smaller than erythrocytes, which have been mistaken for Russell bodies and even fungal conidia. These eosinophilic bodies have high sensitivity and specificity for KS. KS may frequently metastasize to lymph nodes, and early metastases may be confined to subcapsular sinusoids.

Original observations were derived from KS cell lines that revealed Herpesvirus type virions by ultrastructural examination.[225] Cytomegalovirus had long been suspected as a possible viral promoter. More recently, Human Herpes virus 8 has been implicated as promoting the KS lesion and precursor lesions.[226–229]

Metastatic Lymph Nodes

As mentioned in the section on Clinical Significance of Metastatic Nodal Carcinoma, metastases to lymph nodes carry a poor prognosis. Metastases can be found with high frequency in certain histologically well defined tumors (Fig. 36-59) (head and neck squamous cell carcinomas, breast carcinoma, and melanoma); with tumors that have poor cellular differentiation and a resemblance to lymphomas (neuroblastoma, Ewing's sarcoma, alveolar rhabdomyosarcoma, and small cell carcinoma of lung); with tumors that have characteristic histologic patterns such as clear cell tumors (renal cell carcinomas and seminoma) and mucinous carcinomas (adenocarcinomas primarily in the gastrointestinal tract, breast, ovary, and prostate); or with occult tumors (nasopharyngeal carcinomas, thyroid carcinomas, and melanomas). There are also hypervascular primaries that metastasize (hypernephroma and thyroid), as well as a variety of uncommon

FIGURE 36-59 **A**, Cystic degeneration (*C*) of metastatic carcinoma in a lymph node. **B**, Emboli (*arrow*) of squamous cell carcinoma within lymphatic channels.

primary tumors. For a discussion on the imaging of metastastic lymph nodes, see the section on Criteria for Assessing Metastatic Nodes.[19] Table 36-15 summarizes the diseases that are associated with specific tumor locations presenting with lymph nodes.

IMAGING CRITERIA OF PATHOLOGIC ADENOPATHY

"Normal" Reactive Nodes

Normal nonchallenged lymph nodes are small, on the order of a few millimeters in greatest diameter, and both on imaging and at surgery are very difficult to identify and separate from the normal fat of the neck in which they are situated. Once a lymph node is challenged by infection, it enlarges, reflecting the increase in the number and size of the germinal centers. Pathologically, this is referred to as reactive follicular hyperplasia. Lymph nodes that are so challenged over many years enlarge more than nodes that drain areas of less frequent infection. Thus, the jugulodigastric (level II) and submandibular (level I) nodes tend to be larger than other cervical nodes because they are the primary drainage nodes for, among other things, the inflammations associated with teething, tonsillitis, pharyngitis, sinusitis, and skin infections of the facial region.[1–8]

On imaging, these nodes are homogeneous, with smooth, noninfiltrating margins, and they enhance slightly (Fig. 36-60). On MR imaging, the nodes typically have homogeneously low to intermediate T1-weighted and fairly high T2-weighted signal intensities. On CT, such nodes usually have an attenuation similar to or slightly less than that of muscle.

Criteria for Assessing Metastatic Nodes

A number of CT criteria have been proposed to assess the presence of cervical nodal metastasis and to distinguish such nodes from reactive nodes.[2–7] More recently, there have been a variety of studies utilizing MR imaging and helical CT.[9–15, 78, 230–239] The two major imaging criteria used are nodal size and the presence of central nodal necrosis or nodal nonhomogeneity. If imaging shows a cervical lymph node to be highly suspicious for metastasis, clinicians will modify their treatment plan to include such a node.

Size Criteria

Surgeons have long recognized the ''normal'' size variation in hyperplastic lymph nodes, and over several decades they have developed clinical criteria for assessing cervical lymphadenopathy based on nodal size. In a patient suspected of having a head and neck carcinoma, when a lymph node was greater than 1.5 cm in maximum diameter, either in the jugulodigastric region (level II) or in the submandibular triangles (level I), or when a node was greater than 1 cm in maximum diameter elsewhere in the neck, it was considered likely to contain metastatic carcinoma. These size criteria alone are inaccurate in 20% to 28% of cases, either underestimating or overestimating the presence of tumor (Figs. 36-60 and 36-61). Subsequently, a

Table 36-15
AN APPROACH TO DIFFERENTIAL DIAGNOSIS WHEN THERE ARE CERVICAL LYMPH NODES AND AN IDENTIFIABLE MASS

Location of Mass with Nodes	Main Differential Diagnosis
Waldeyer's ring and nodes	Lymphoma, mononucleosis, HIV infection, squamous cell carcinoma
Skin lesion and lymph nodes	Basal cell carcinoma, squamous cell carcinoma, melanoma, lymphoma, Kaposi's sarcoma, Kikuchi-Fujimoto disease, actinomycosis, mycobacterial infection, cat-scratch fever
Parotid gland masses and/or cysts and lymph nodes	HIV infection, sarcoid, lymphoma, Kimura's disease, cat-scratch fever, and, rarely, Sjogren's syndrome

VIEW IMAGE

FIGURE 36-60 Axial CT scans from cranial (**A**) to caudal (**B**) show bilateral level I and level II lymph nodes that do not exceed the size criterion to suspect pathologic adenopathy. The nodes are sharply delineated, and there is some enhancement. These were reactive lymph nodes in this 22-year-old female who had a pharyngitis. Note the slight prominence of the right palatine tonsil.

number of imaging studies have reaffirmed these measurements and, in addition, have suggested using the minimum axial diameter of the node, with normal nodes not exceeding 11 mm in the jugulodigastric region and 10 mm elsewhere in the head and neck.[2–7] It has also been proposed that retropharyngeal nodes should not exceed 8 mm in maximum diameter or 5 mm in minimal transverse (short-axis) diameter.[2, 239] More recently, it has been suggested that the ratio of the maximum longitudinal nodal length to the maximum axial nodal length (L/T) should be greater than 2 for normal hyperplastic nodes, while a value of less than 2 strongly suggests that the node contains metastatic carcinoma.[1–8] This last approach is based on the concept that a normal lymph node tends to be oblong or lima bean–shaped, while a metastatic node often is spherical in shape. However, to some degree, the shape can vary with the location of the lymph node in the neck.

It has also been observed that a group of three or more lymph nodes with maximal diameters of 8 to 15 mm or minimum axial diameters of 9 to 10 mm in the jugulodigastric region and 8 to 9 mm in the remaining neck are suggestive of metastatic lymphadenopathy, provided that they are in the drainage area of the primary tumor site. All of these imaging criteria describe homogeneous, sharply outlined lymph nodes. Interestingly, regardless of which of these criteria are used, the overall error rates for both false-positive and false-negative diagnoses are between 15% and 20%, reflecting the limitations of imaging and the use of size criteria. Many im-

FIGURE 36-61 Axial contrast-enhanced CT scan shows two homogeneous left level I nodes. The more anterior node exceeds the normal size criterion; the posterior node does not. This appearance could be seen in a patient with lymphoma. However, these were reactive nodes that became smaller after a course of antibiotics in a patient who had an oral cavity infection.

Table 36-16
SIZE CRITERIA FOR HOMOGENEOUS CERVICAL LYMPH NODES ON CT AND MR IMAGING

Lymph nodes are considered pathologic if they exceed these measurements:
Maximal Longitudinal Diameter
Jugulodigastric and submandibular nodes >15 mm are abnormal
All other nodes except retropharyngeal nodes >10 mm are abnormal
Retropharyngeal nodes >8 mm are abnormal
Minimum Axial Diameter
Jugulodigastric nodes >11 mm are abnormal
All other nodes >10 mm are abnormal
L/T Ratio (Longitudinal Length/Transaxial Width)
<2 is suggestive of metastasis (round node vs. lima bean–shaped node)
For a group of three or more nodes in the drainage area of the tumor, suspect metastases if:
The maximal longitudinal diameter is greater than 8 to 15 mm
The minimum axial diameters are greater than 9 to 10 mm in level II or greater than 8 to 9 mm in the remaining neck

agers continue to use the greatest nodal diameter because it is that dimension that is used by the clinicians. However, at this time, there is no documented statistical advantage to any of these systems, so that radiologists can choose whichever one they are most comfortable with, provided that it is familiar to their clinicians. Stated differently, all of these methods are equally inadequate. Table 36-16 summarizes these size criteria.

In 1998, the Radiological Diagnostic Oncology Group compared CT and MR imaging in the staging of neck metastases and found that CT performed better for all interpretive criteria, especially if both nodal size and internal abnormalities were considered. However, a high negative predicative value (NPV = true negatives/true negatives + false negatives) was achieved only when small nodal size was considered, and this was associated with a low positive predicative value (PPV = true positive/true positives + false positives). Thus, in this study, if 10 mm was used as the upper size limit of a normal node, then the NPV was 84% and the PPV was 50%. That is, 16% of the patients with negative imaging would actually have metastases, while 50% of the patients with positive imaging would not have metastases.[72] In order to achieve a 90% NPV, this study found that it was necessary to go to a 5-mm or 6-mm node as the indicator of positivity, with a concomitantly unacceptably low PPV. The reason for seeking a 90% NPV was that a number of clinicians stated that if a population of patients could be defined by imaging in which a negative node had only a 10% chance of eventually harboring tumor, the clinicians would consider a ''wait and watch'' strategy.

Using sonography, van den Brekel et al. in 1998 found that smaller size criteria should be used for the evaluation of nodal metastases.[240] Their conclusion was that size criteria alone were in general not very accurate, especially in the clinically negative neck. They noted that although lymph nodes with minimum axial diameters of 10 mm in level I, 12 mm in level II, and 9 mm in level III were almost always metastatic, such large nodes without clinical evidence of metastasis (N0 neck) were rare. They suggested that a compromise between sensitivity and specificity could be achieved using a minimal axial diameter of 7 mm for level II and 6 mm for the rest of the neck in necks without palpable metastases. When considering all necks (with and without clinical disease), the minimal axial diameters should be 8 to 9 mm for level II and 7 to 8 mm for the rest of the neck. The authors also suggested the use of early sonographically guided aspiration cytology.[54]

Central Necrosis

Regardless of the route of metastatic spread to the nodal center, within this region there are tumor cells, residual lymph node tissues, and areas of necrosis. Despite this resulting complex cellular mixture, it has become common practice to simply refer to such lymph nodes as being *necrotic* or *having central necrosis*. In part, this may reflect the observation that on CT, such a node has a central region of ''water'' attenuation that represents all of these components. However, on MR, the necrosis (by its high T2-weighted signal intensity) can be distinguished from the other cellular components, more realistically representing the pathologic findings in these nodes.

When greater than 3 mm in size, nodes with central nodal necrosis have been observed by imaging in approximately one third of metastatic nodes.[71] On contrast-enhanced CT, such nodes have a central region of low ''water''attenuation (10 to 25 HU) and a variably thick and variably enhancing nodal rim (Figs. 36-62 to 36-67). On T2-weighted MR images, such nodes have areas of both high and intermediate

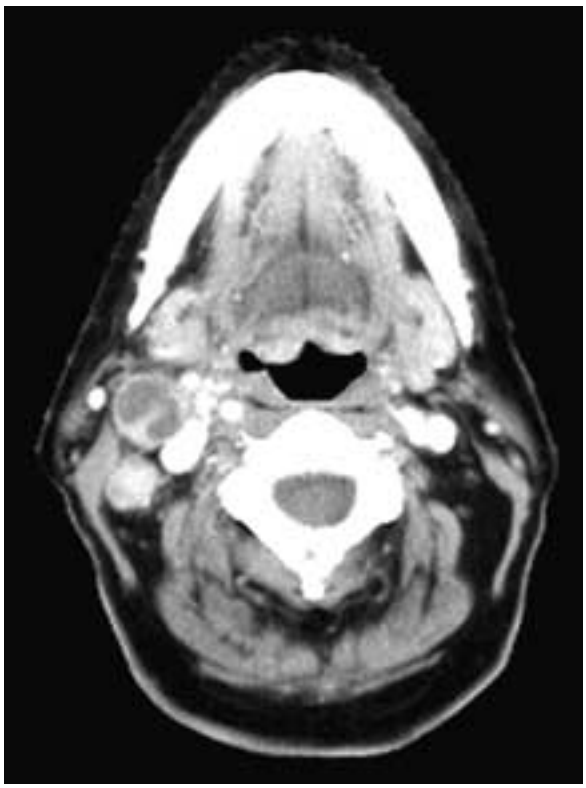

FIGURE 36-62 Axial contrast-enhanced CT scan shows two right level II lymph nodes. The more anterior node is enlarged and necrotic, with an irregular, enhancing rim. There is no gross extranodal tumor spread. The second node is enhancing, but normal by the size criterion. This patient had a right oropharyngeal carcinoma, and both of these nodes were metastatic.

VIEW IMAGE

FIGURE 36-63 Axial contrast-enhanced CT scan shows a large right level II node with a highly nodular enhancing rim and slight infiltration of the adjacent tissues. The nodularity of the wall differentiates this metastatic squamous cell carcinoma node from a cyst.

VIEW IMAGE

FIGURE 36-64 Axial contrast-enhanced CT scan shows two necrotic right level II nodes. Each enhancing nodal capsule is of uneven thickness, and there is extracapsular tumor spread, as noted by infiltration of the adjacent fat planes. Also note that the carotid artery is surrounded by tumor, making it likely that the arterial wall has been invaded by tumor.

VIEW IMAGE

FIGURE 36-65 Axial contrast-enhanced CT scan shows an enlarged, partially necrotic left level II node with some extracapsular tumor spread, as noted by minimal infiltration of the adjacent fat planes. In particular, the fat planes are obliterated along the lateral 180° of the left carotid artery. This suggests invasion of the arterial wall. The primary tumor is seen at the base of the tongue and in the hypopharynx.

signal intensity. The high signal intensity corresponds to the areas of necrosis, while the intermediate signal intensity corresponds to tumor cells and residual normal lymph node tissues. As such, the areas of high T2-weighted signal intensity are always smaller than the central region of low attenuation seen on CT (Figs. 36-68 to 36-70). Because fast spin-echo (FSE) T2-weighted images are comparable to conventional spin-echo (SE) T2-weighted images, either technique can be routinely used. However, since the FSE

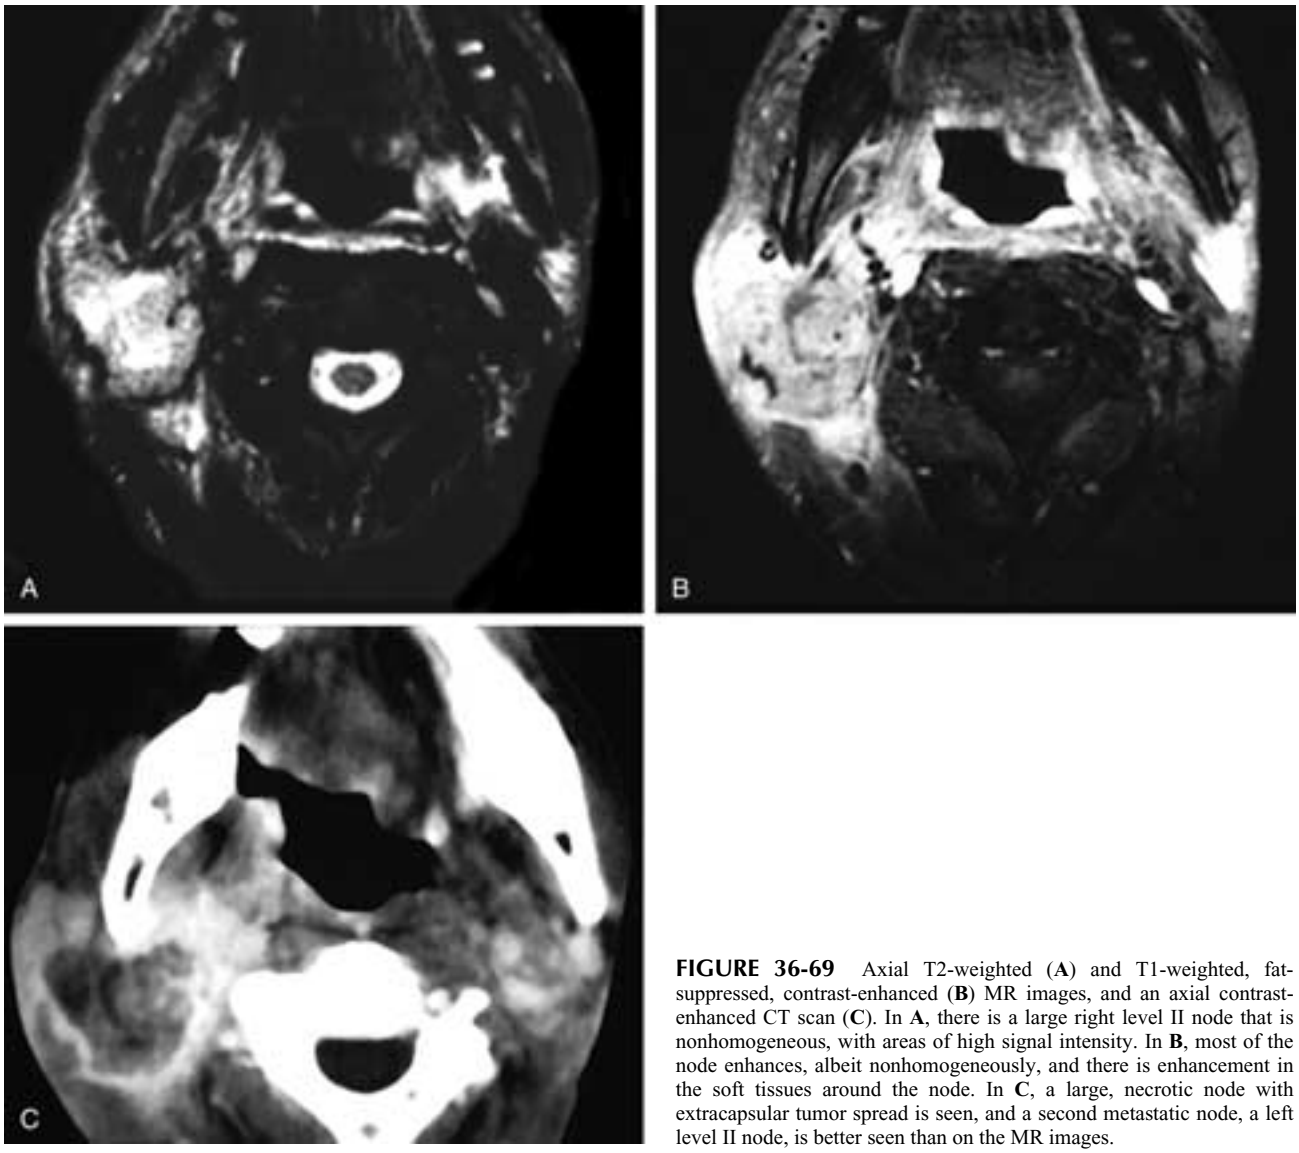

FIGURE 36-69 Axial T2-weighted (**A**) and T1-weighted, fat-suppressed, contrast-enhanced (**B**) MR images, and an axial contrast-enhanced CT scan (**C**). In **A**, there is a large right level II node that is nonhomogeneous, with areas of high signal intensity. In **B**, most of the node enhances, albeit nonhomogeneously, and there is enhancement in the soft tissues around the node. In **C**, a large, necrotic node with extracapsular tumor spread is seen, and a second metastatic node, a left level II node, is better seen than on the MR images.

VIEW IMAGE

images can be obtained with less scan time, this technique has become increasingly popular.[235]

Regardless of lymph node size, the most reliable imaging finding of metastatic disease is the presence of central nodal necrosis on contrast-enhanced CT and, as mentioned, when such areas are larger than 3 mm, they are routinely identified on CT.[7] On noncontrast MR, as described, the most reliable finding is variable T2-weighted signal intensity. A less reliable criterion is the presence on T1-weighted MR images of low signal intensity areas that do not enhance.[72] Although nodes with central nodal necrosis may be easily identified on contrast-enhanced CT scans, on routine SE noncontrast MR, such nodes may have homogeneously low to intermediate T1-weighted and high T2-weighted signal intensity. Unfortunately, this appearance is the same as that of a hyperplastic node, and it is only on a T1-weighted, contrast-enhanced, fat-suppressed MR image that a central nonenhancing region (akin to the central nodal necrosis appearance on CT) can be seen in these nodes (Fig. 36-71). Thus, a thorough MR examination should include noncontrast T1-weighted and T2-weighted (FSE) scans and a contrast-enhanced, T1-weighted, fat-suppressed sequence. Equivalent imaging sequences are also acceptable.

The primary imaging differential diagnosis of central tumor necrosis is fatty hilar metaplasia, which occurs almost exclusively at the periphery of the node, usually giving the node a pronounced lima bean configuration. Specifically, the central region of low attenuation can be seen to extend to the peripheral outer surface of the node. Such metaplasia is usually in response to chronic nodal infection and, if large enough, can be measured to have the attenuation of fat (Fig. 36-72). Rarely, metaplasia may occur centrally within a node. When this happens, the imaging distinction from a metastatic lymph node may be impossible.[7]

Subcapsular Nodal Tumor

Because the majority of the tumor load enters a lymph node via the afferent lymphatics, the tumor cells first start to proliferate within the node in the subcapsular regions. Occasionally on CT scans, low-attenuation focal areas can

Copyright © 2003, Mosby, Inc. All rights reserved.

be seen in these subcapsular nodal regions (Fig. 36-73). When present, they may be considered a suggestive imaging finding of nodal metastasis.

Extranodal Tumor Extension

Once tumor penetrates the nodal capsule, it extends into the adjacent soft tissues. This tumor growth has been variously referred to as extranodal, extracapsular, or transcapsular tumor spread, and it is associated with a decrease in survival. The presence of such macroscopic extranodal tumor extension is identified on contrast-enhanced CT as an enhancing, often thickened nodal rim, usually with infiltration of the adjacent fat planes (Figs. 36-74 to 36-76). These imaging changes reflect the presence of such macroscopic extranodal tumor spread, and their absence on imaging indicates the lack of this type of macroscopic disease. Histologically, such disease was found in 40% of lymph nodes less than 2 cm in diameter and in 23% of lymph nodes 1 cm in greatest length.[1–8, 48] This means that in approximately one quarter of lymph nodes considered normal by size criteria, extracapsular tumor spread can be present. As the node enlarges, the incidence of extracapsular tumor spread rises, so that it is reported to be present in 53% of lymph nodes 2 to 3 cm in size and in 74% of lymph nodes larger than 3 cm. Overall, such tumor spread occurs in 60% of nodes less than 3 cm in diameter.[52, 53, 241] It is also known that when macroscopic transcapsular tumor spread is present, the patient has a nearly 10 times greater risk of recurrence compared with patients with either microscopic tumor spread or no transcapsular spread.[48] Table 36-17 summarizes these findings.

Several other circumstances can result in imaging findings similar to those of extranodal capsular spread. All of these situations cause an inflammation of the nodal capsule, including recent nodal infection, irradiation, and surgical manipulation (Table 36-18).[242] However, if these clinical possibilities can be eliminated by the history, the contrast CT findings described previously are diagnostic of such extranodal tumor extension. For reasons that remain unclear, such extranodal spread overall is less reliably identified on MR than on CT, especially when present to only a minimal degree. It may simply be that the low attenuation of fat on CT is the best ''background'' in which to identify such early nodal changes. On imaging, it is important to identify if the extracapsular nodal tumor has invaded adjacent structures such as the internal carotid artery, common carotid artery, retropharyngeal soft tissues, or bone.

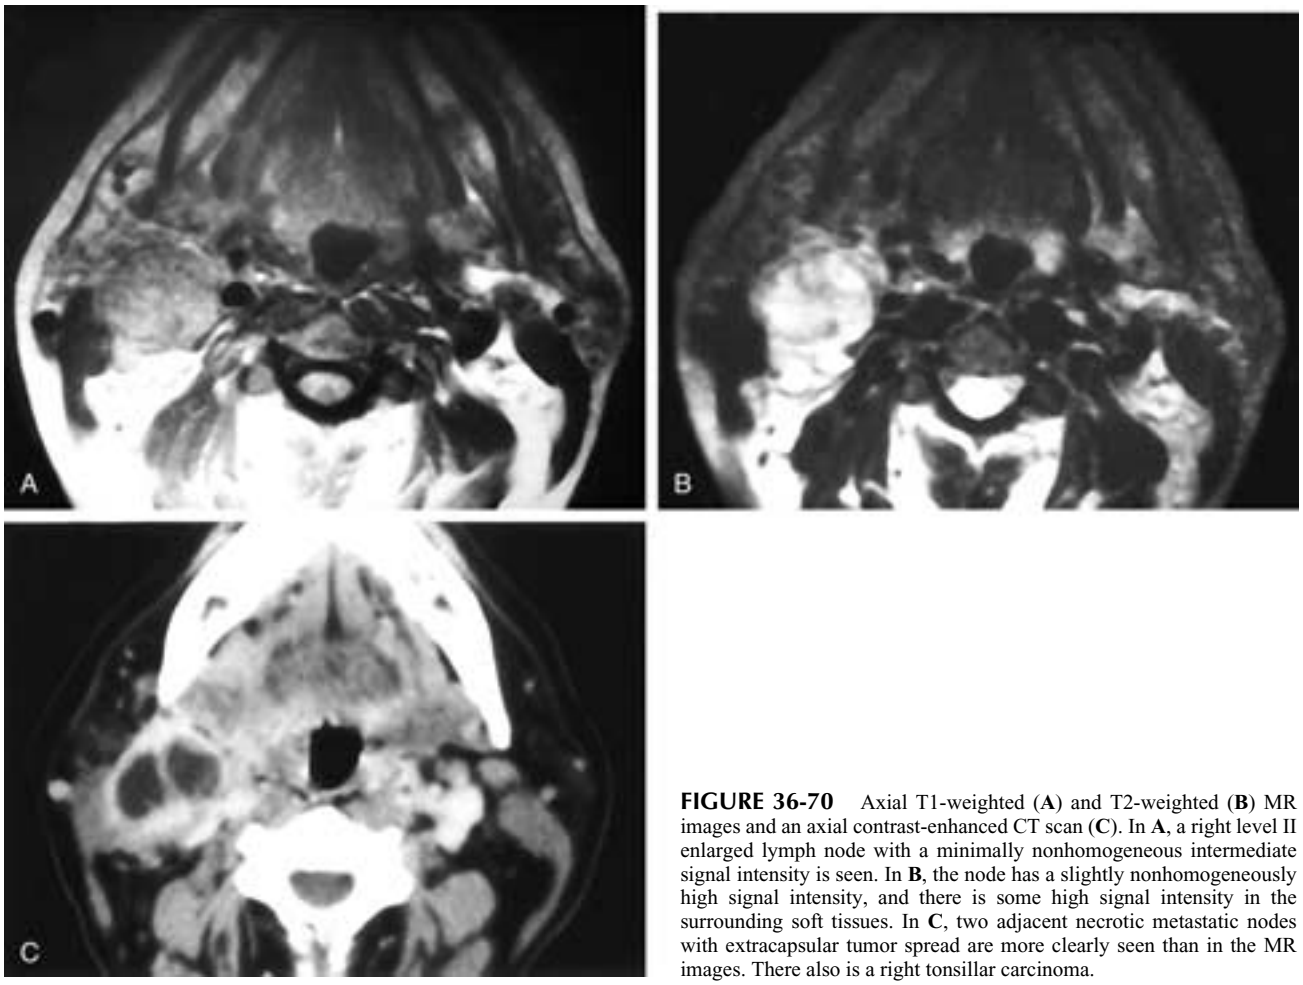

FIGURE 36-70 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images and an axial contrast-enhanced CT scan (**C**). In **A**, a right level II enlarged lymph node with a minimally nonhomogeneous intermediate signal intensity is seen. In **B**, the node has a slightly nonhomogeneously high signal intensity, and there is some high signal intensity in the surrounding soft tissues. In **C**, two adjacent necrotic metastatic nodes with extracapsular tumor spread are more clearly seen than in the MR images. There also is a right tonsillar carcinoma.

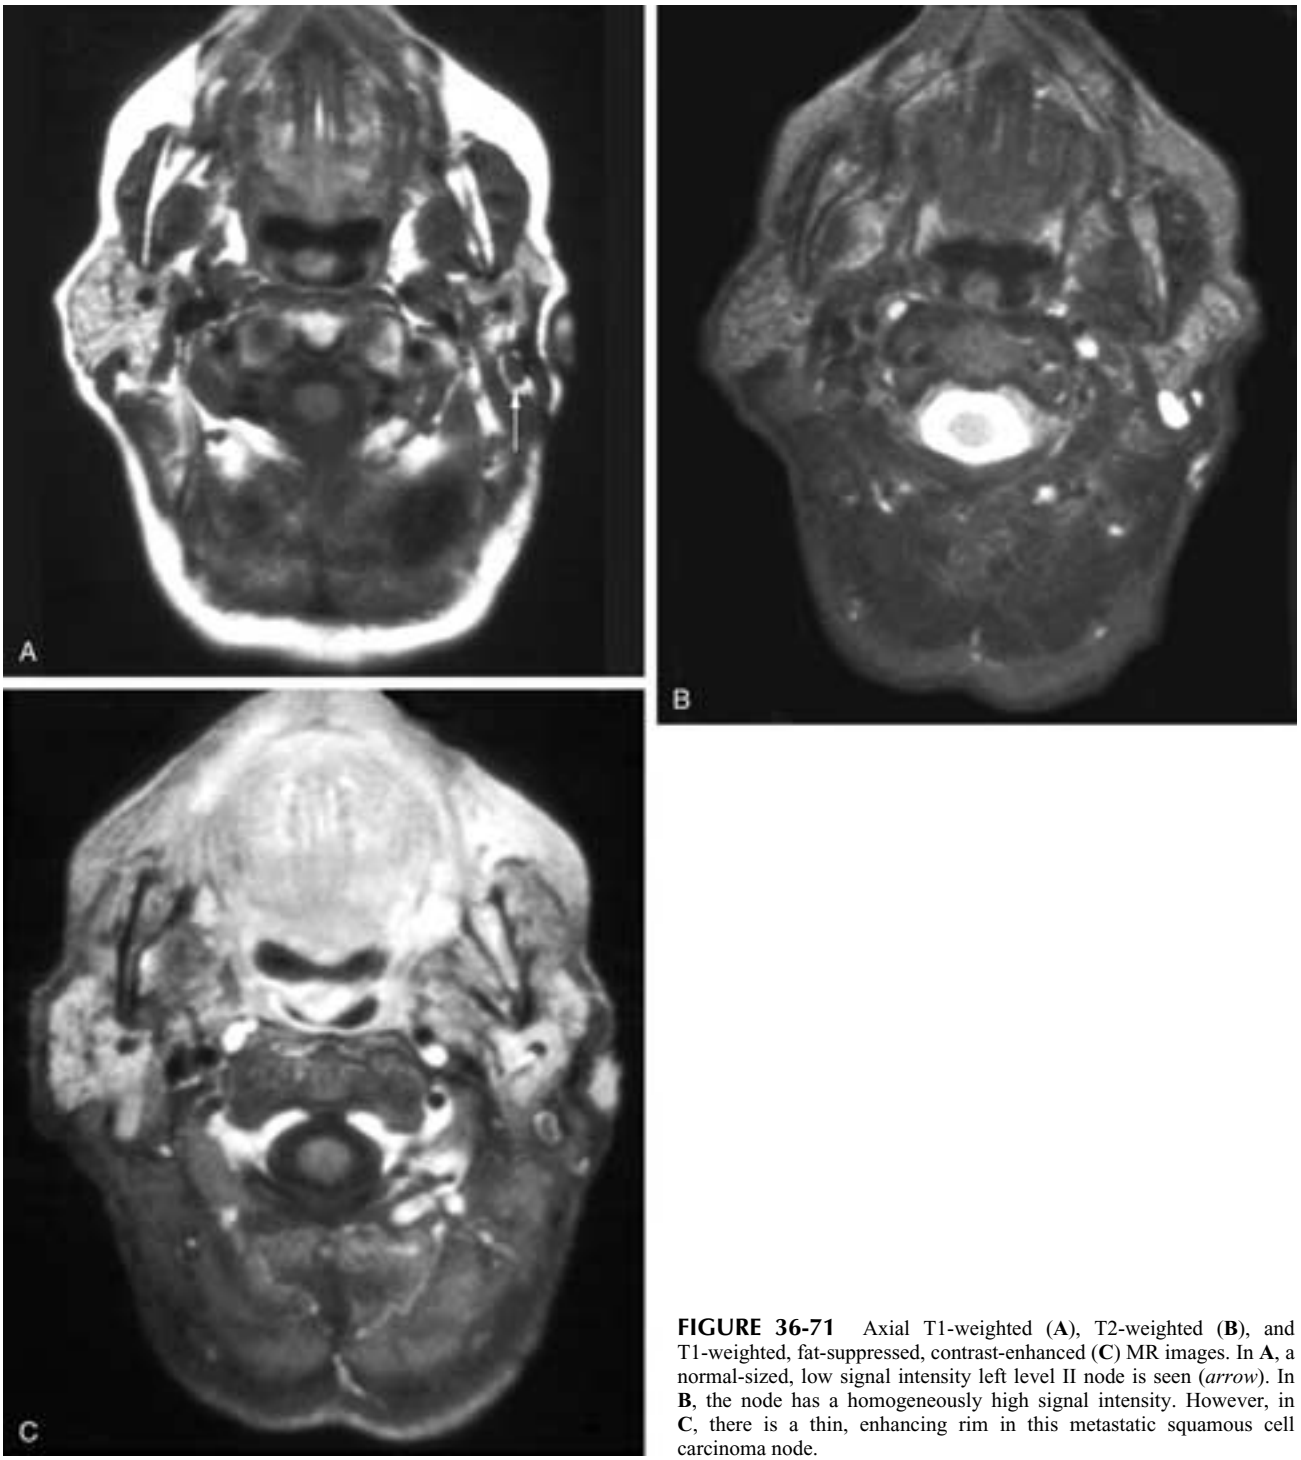

FIGURE 36-71 Axial T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, fat-suppressed, contrast-enhanced (**C**) MR images. In **A**, a normal-sized, low signal intensity left level II node is seen (*arrow*). In **B**, the node has a homogeneously high signal intensity. However, in **C**, there is a thin, enhancing rim in this metastatic squamous cell carcinoma node.

VIEW IMAGE

Arterial Invasion

The extension of nodal tumor to the adjacent internal carotid artery is a grave prognostic finding. Although the salvage of patients with arterial tumor invasion is small, there is evidence to suggest that if the involved artery is resected and, if possible, replaced with a graft at the time of surgery, the patient does better than if the tumor is dissected off of the artery and the patient is irradiated after surgery.[243, 244] However, in either case, this situation is associated with a poor prognosis.

The degree of arterial wall invasion can be variable, but from an oncologic consideration, tumor invasion of the arterial adventitia is as important as greater degrees of arterial invasion into the muscularis and intima that may be seen on imaging as narrowing of the arterial lumen. Because microscopic adventitial tumor infiltration is beyond the scope of current imaging detection, the best one can do is to

FIGURE 36-74 Axial contrast-enhanced CT scan shows a necrotic left level II node with a thick, nodular, enhancing rim. The enhancement extends into the adjacent soft tissues, indicating extracapsular tumor spread. This extranodal disease is adjacent to the carotid artery, suggesting invasion of the arterial wall.

note the degree of the artery's circumference that is potentially involved by tumor. This is noted not only by observing the gross tumor, but also by identifying the degree of obliteration of the normal fat plane that surrounds the artery. If the artery is entirely surrounded by tumor, it is most likely that the artery is invaded, yet there are some cases that at surgery have no adventitial involvement. Conversely, if just a tip of tumor touches the artery, it is unlikely that the arterial wall has been invaded, yet at surgery such cases may have adventitial tumor spread. In general, the greater the tumor extension around the artery,

FIGURE 36-75 Axial contrast-enhanced CT scan shows multiple right level II necrotic metastatic squamous cell carcinoma nodes with extracapsular tumor spread. The right carotid artery is almost surrounded by this disease, making it highly probable that the arterial wall has been invaded. There is also a nonenlarged necrotic right level V node.

the more likely it is that the artery is involved. Thus, when more than 270° of the arterial circumference is surrounded by tumor, it is likely that the arterial wall has been invaded.[244]

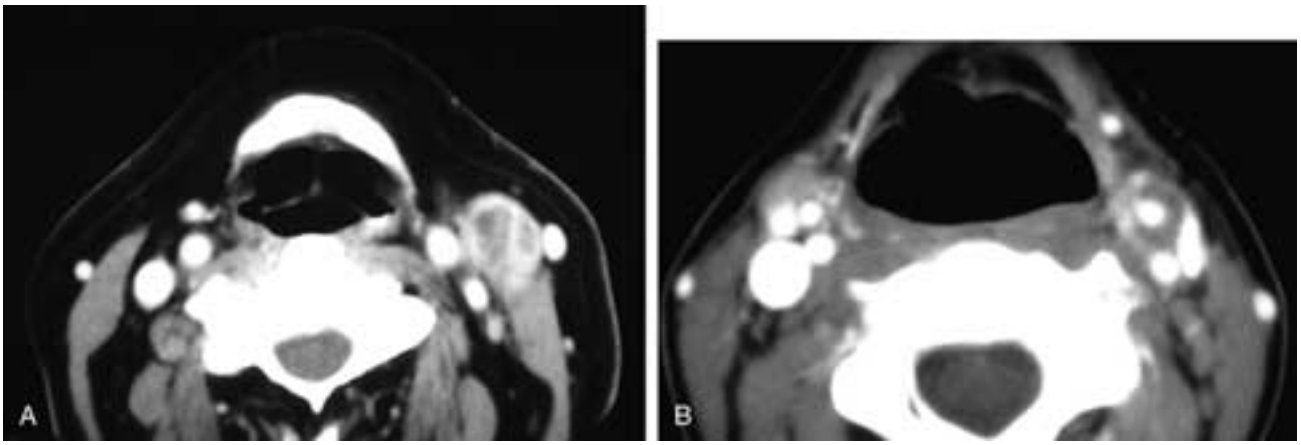

FIGURE 36-76 Axial contrast-enhanced CT scans on two different patients, both of whom had a slightly tender, pulsatile mass in the left neck. In **A**, there is a necrotic metastatic node adjacent to the carotid artery. The arterial pulsations were transmitted by the node to the skin surface. In **B**, there is a nonenhancing zone around the left carotid artery, and the lumen of the artery is slightly reduced compared to the right carotid artery. This patient had an arteritis.

Table 36-17
EXTRANODAL TUMOR SPREAD

Occurs in:
- 23% of lymph nodes <10 mm
- 53% of lymph nodes 20 to 30 mm
- 74% of lymph nodes >30 mm
- Overall occurs in 60% of lymph nodes <30 mm

All measurements are maximal longitudinal diameter

A patient with macroscopic transcapsular (extranodal) tumor spread has nearly a 10 times greater risk of neck recurrence than does a patient with either microscopic extranodal tumor spread or no transcapsular spread.

Metastatic Thyroid Carcinoma

Because of its variable imaging appearance, metastatic thyroid carcinoma deserves special comment. The most common thyroid cancers to metastasize to the cervical lymph nodes are the papillary and follicular types. Less often, medullary carcinoma involves the cervical nodes; this tumor has a predilection for osseous metastasis. Although anaplastic carcinoma may spread to nodes, its locally aggressive nature often causes the demise of the patient prior to imaging evidence of nodal metastases is noted.

The involved lymph nodes from thyroid carcinomas may appear as hyperplastic nodes; or they may have a variety of imaging presentations, including enhancement and small, dystrophic, scattered calcifications (true psammomatous calcifications are identified only microscopically); or they may be completely cavitated, often mimicking the imaging appearance of a benign cyst (Figs. 36-77 to 36-79). Rarely, areas of hemorrhage (also fairly commonly seen in metastatic hypernephroma) may occur (Fig. 36-80). On MR imaging, most metastatic thyroid carcinomatous nodes have a fairly low to intermediate T1-weighted and a high T2-weighted signal intensity. They also usually enhance fairly significantly. However, some of the nodes, especially those from papillary thyroid carcinoma, may have high T1-weighted and T2-weighted signal intensities (Figs. 36-81 and 36-82). This is ostensibly due to high intranodal concentrations of the macromolecular protein thyroglobulin. As previously mentioned, rare intranodal hemorrhage may occur. This also causes high T1-weighted and T2-weighted signal intensities.[245, 246]

Enhancing Nodes

It was once thought that contrast enhancement of a lymph node suggested only a limited differential diagnosis. However, there are a great number of diseases that can be associated with enhancing lymphadenopathy. In general, nodal enhancement seems to imply increased nodal vascularity, and the most common causes are acute infections. Often such nodes are slightly enlarged, are homogeneous, and enhance to a variable degree. If an acute virulent infection such as staphylococcus is present, nodal necrosis may occur and the imaging may simulate a necrotic metastatic lymph node. Lymphomas, tuberculosis, HIV infection, metastatic papillary and medullary thyroid carcinomas, metastatic hypernephroma, KS, and rare diseases such as angioimmunoblastic lymphadenopathy with dysproteinemia, angiolymphoid hyperplasia with eosinophilia (ALHE and Kirmura's disease), ALNH, and Kikuchi's disease all can have enhanced lymph nodes.[66, 175–178, 200, 204–206, 245–247] Although not typically observed, metastatic squamous carcinoma containing nodes may also enhance (Figs. 36-83 and 36-84). These diseases are summarized in Table 36-19.

It has also been suggested that nodal vascularity may be related to the response of nodes to chemotherapy, and there may be evidence to suggest that color flow Doppler may aid in predicting the response of metastatic nodes to chemotherapy.[14] Color flow Doppler imaging is also helpful in diagnosing pulsatile neck masses (separating a node adjacent to the carotid artery from vascular lesions) and in fine-needle aspiration biopsies of nonpulsatile masses.[248]

Nodal Calcifications

Overall, nodal calcifications in the neck are uncommon, occurring in about 1% of cases.[249] Most frequently, such calcifications are still seen in patients with tuberculosis. Nodal calcifications may also be seen with healed necrotic, abscessed nodes and in benign diseases such as amyloidosis and, rarely, sarcoidosis. Of the primary head and neck tumors, the most common ones associated with nodal calcifications are metastatic papillary thyroid carcinomas. Nodal calcifications also occur with both non-Hodgkin's and Hodgkin's lymphomas, particularly after irradiation and chemotherapy. Calcifications may also be seen in metastatic mucinous adenocarcinomatous nodes, primarily from breast, lung, and colon primary tumors. A patient with sinus histiocytosis with massive lymphadenopathy developed nodal calcifications after interferon treatment. If there is extensive pulmonary disease, rarely calcification can also be seen in supraclavicular nodes in patients with silicosis. These diseases are summarized in Table 36-20 (Fig. 36-85). Calcifications have also been reported with metastatic prostate, seminoma, carcinoid, olfactory neuroblastoma, and angiofollicular lymph node hyperplasia. Egg shell–type calcifications (peripheral nodal calcifications) have been reported in silicosis, sarcoidosis, scleroderma, tuberculosis, and amyloidosis. Nodal radiodensities can also be seen on CT in areas of nodal hyalinization and keratinization.[245, 250–276]

Table 36-18
IMAGING EXTRANODAL TUMOR SPREAD

On imaging, there is:
1. Enhancement, thickening, and usually irregularity of the nodal rim
2. Infiltration of the adjacent fat planes

Look for tumor extension to:
1. Internal carotid artery and common carotid artery
2. Retropharyngeal soft tissues
3. Bone

Imaging caution: Recent surgery, irradiation, or infection can cause similar imaging findings.

FIGURE 36-77 Contrast-enhanced CT scans on four different patients. In **A**, there are multiple right, densely enhancing level I and II nodes. There are also bilateral smaller, posterior level II nodes that enhance to a lesser degree. The larger right-sided nodes were metastatic papillary thyroid carcinoma. The smaller posterior nodes were reactive. In **B**, there is an enlarged, densely enhancing left level III node that was a metastatic papillary thyroid carcinoma node. In **C**, there is an enlarged, enhancing right retropharyngeal node that was a metastatic papillary thyroid carcinoma node. In **D**, there is a right, enlarged, and enhancing level II node with calcifications in this patient with metastatic papillary thyroid carcinoma.

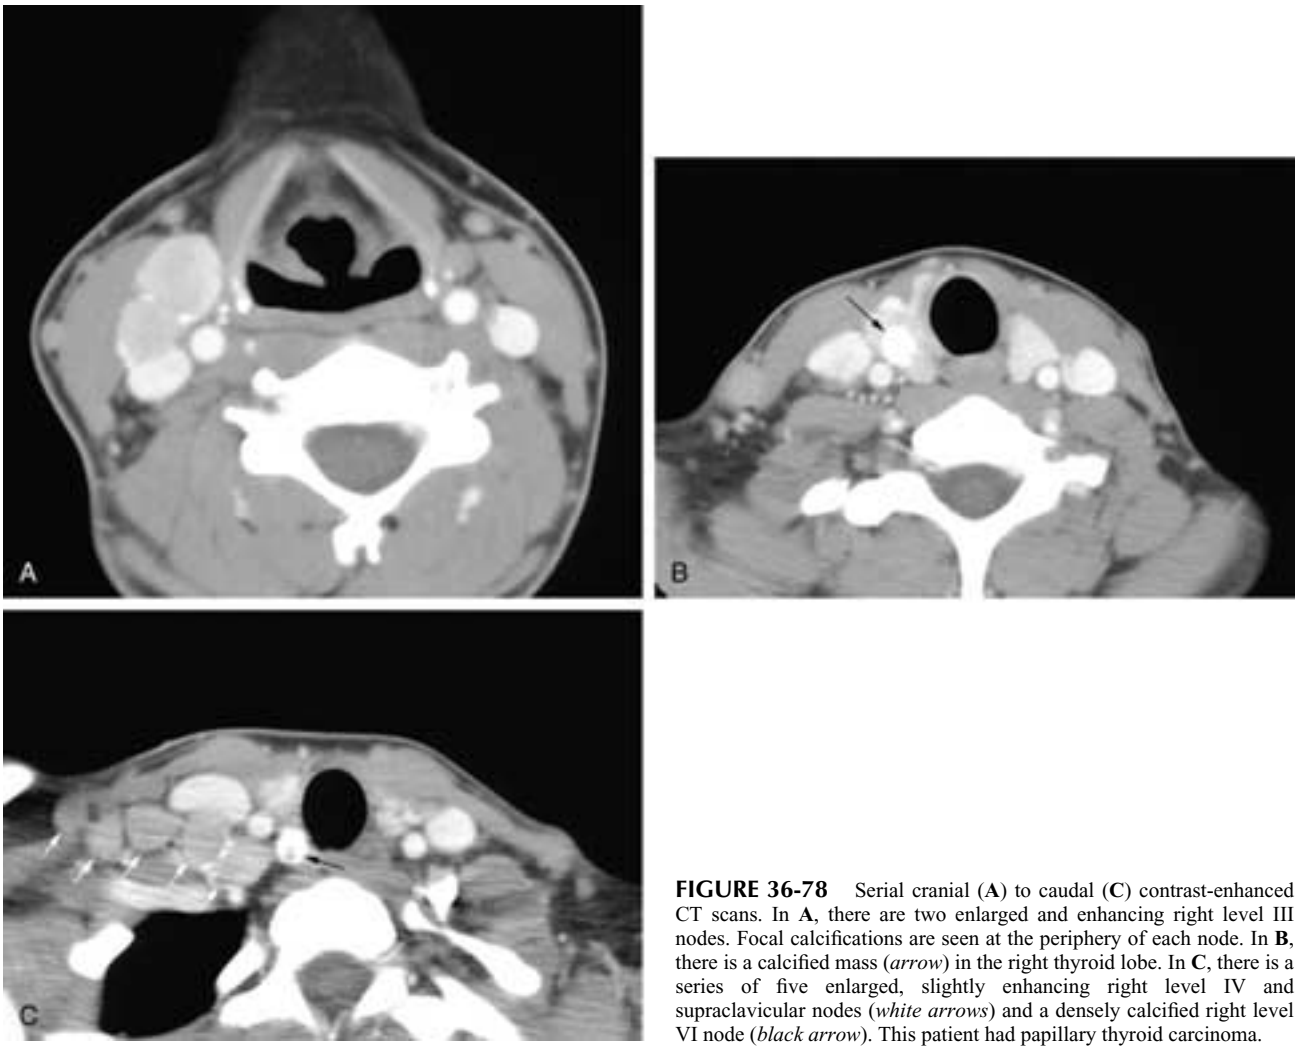

FIGURE 36-78 Serial cranial (**A**) to caudal (**C**) contrast-enhanced CT scans. In **A**, there are two enlarged and enhancing right level III nodes. Focal calcifications are seen at the periphery of each node. In **B**, there is a calcified mass (*arrow*) in the right thyroid lobe. In **C**, there is a series of five enlarged, slightly enhancing right level IV and supraclavicular nodes (*white arrows*) and a densely calcified right level VI node (*black arrow*). This patient had papillary thyroid carcinoma.

VIEW IMAGE

The Retropharyngeal Abscessed Node

Retropharyngeal lymph nodes, especially in children, have a tendency to become necrotic when infected. On imaging, this may at first suggest the presence of a retropharyngeal abscess; however, the findings of these two entities are different. With the necrotic node, there is an enhancing irregular rim about a necrotic nodal center. The remaining margins of the retropharyngeal space are not involved. When a retropharyngeal abscess is present, there is enhancement of the walls of this space, and mucoid attenuation material fills the space (Fig. 36-86). The distinction between these two forms of infection has clinical implications. Today, a necrotic retropharyngeal node is usually initially treated with intensive intravenous antibiotic therapy without surgery. Most patients have an excellent clinical response within 48 hours, and surgery can be avoided. With a retropharyngeal abscess, the initial treatment remains surgical drainage.

NEWER IMAGING APPROACHES

Different imaging approaches beyond conventional CT and MR imaging have been tried in an attempt to further refine the early detection of metastatic lymphadenopathy (also see Chapters 43 and 45). One such technique is to apply magnetization transfer analysis to differentiate benign from malignant disease.[235] This approach presently remains unproven. It cannot be routinely applied on all MR scanners, and necrotic areas within a metastatic node may lead to unreliable results.

A second technique employs a type of functional MR imaging. The patient has a pre-drug MR imaging scan, then is injected intravenously with Dextran-coated superparamagnetic iron oxide particles, and finally gets a 24-hour post-drug MR imaging scan. Normally, hyperplastic lymph nodes filter the superparamagnetic iron oxide, and this gives them very low signal intensity on the MR study. The concept is that the absence of such filtration indicates tumor replacement of nodal tissue (Fig. 36-87). However, the problem of interpreting these studies arises when there is partial ''blackening'' of a node after the superparamagnetic iron oxide is given. Because repeated infections cause nodal scarring and this, like tumor, may cause a lack of nodal filtering of the drug, the ultimate usefulness of this technique remains in question. If one uses the criterion that more than 50% blackening of a node indicates that it is probably metastatic, early reports suggest

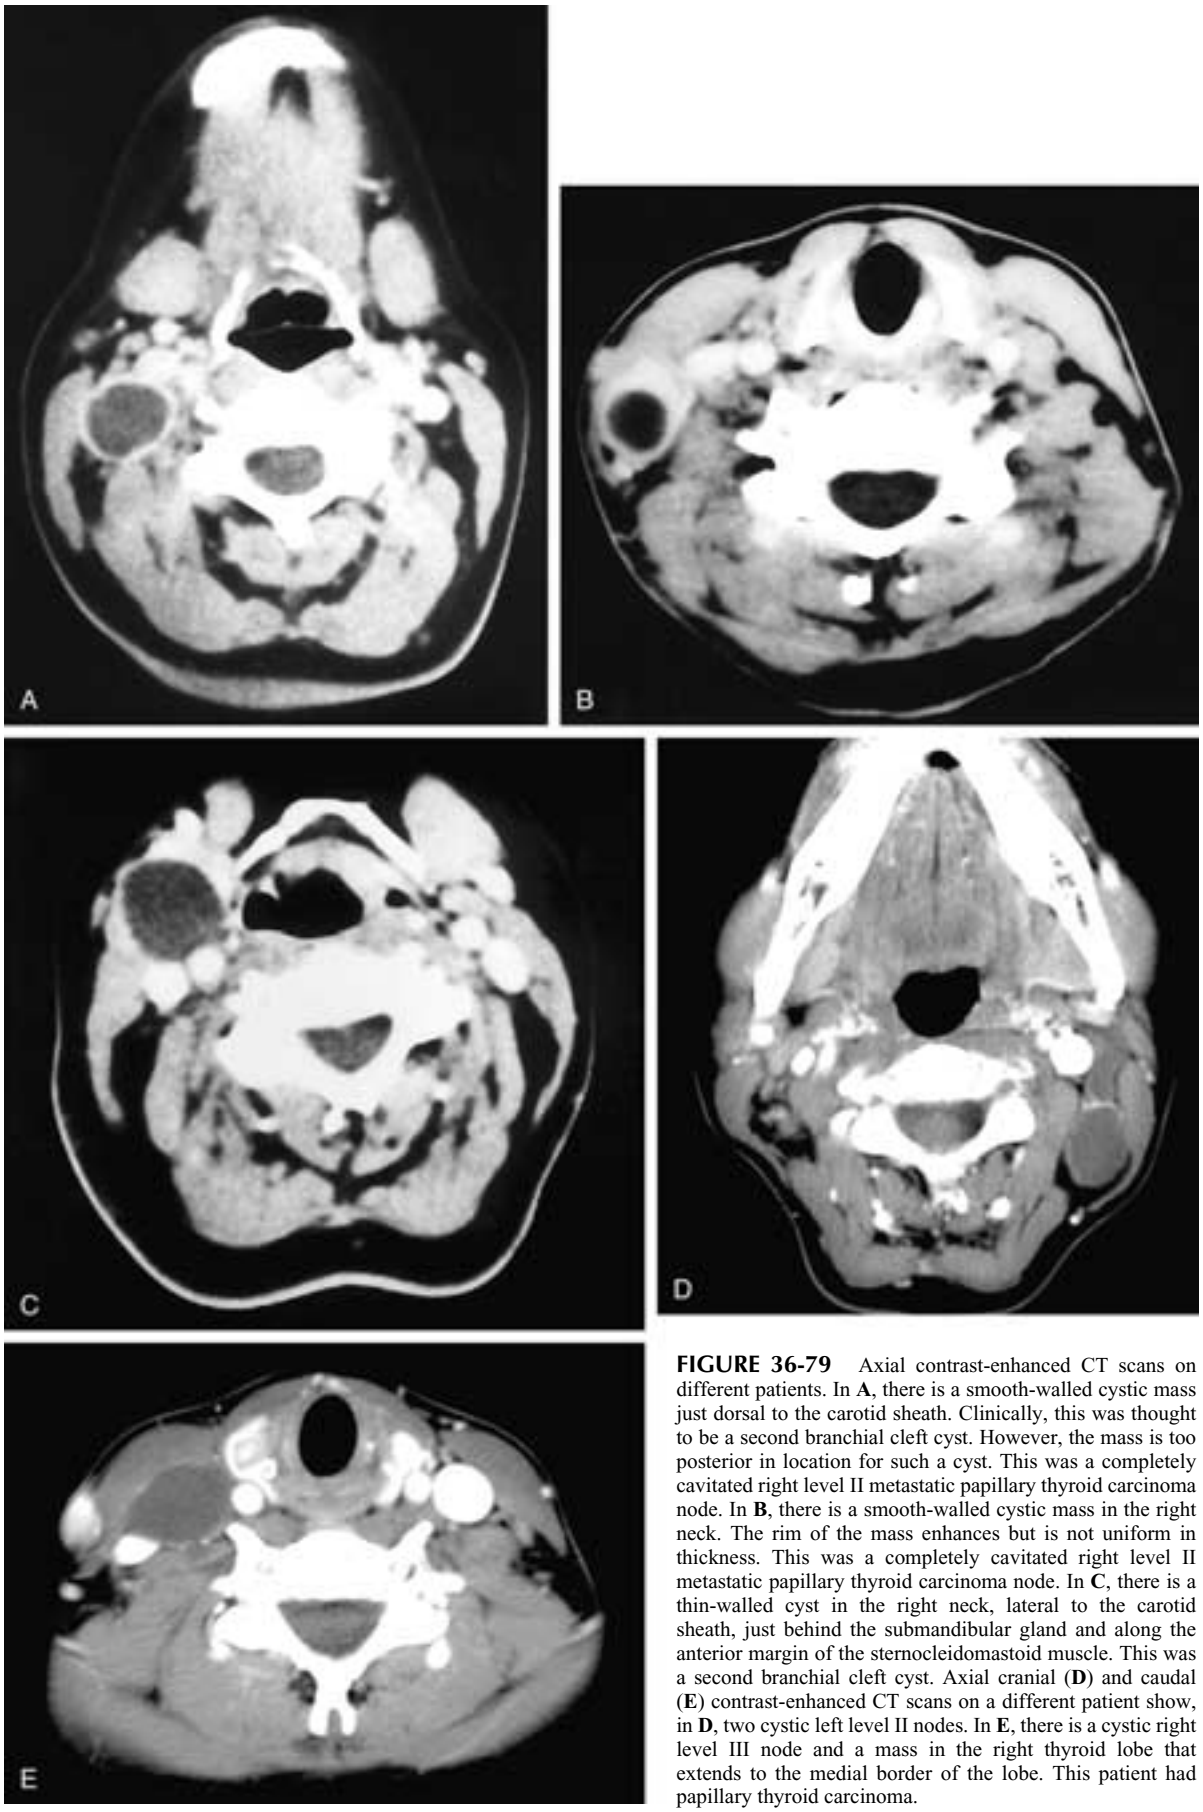

FIGURE 36-79 Axial contrast-enhanced CT scans on different patients. In **A**, there is a smooth-walled cystic mass just dorsal to the carotid sheath. Clinically, this was thought to be a second branchial cleft cyst. However, the mass is too posterior in location for such a cyst. This was a completely cavitated right level II metastatic papillary thyroid carcinoma node. In **B**, there is a smooth-walled cystic mass in the right neck. The rim of the mass enhances but is not uniform in thickness. This was a completely cavitated right level II metastatic papillary thyroid carcinoma node. In **C**, there is a thin-walled cyst in the right neck, lateral to the carotid sheath, just behind the submandibular gland and along the anterior margin of the sternocleidomastoid muscle. This was a second branchial cleft cyst. Axial cranial (**D**) and caudal (**E**) contrast-enhanced CT scans on a different patient show, in **D**, two cystic left level II nodes. In **E**, there is a cystic right level III node and a mass in the right thyroid lobe that extends to the medial border of the lobe. This patient had papillary thyroid carcinoma.

FIGURE 36-80 Axial contrast-enhanced CT scans. In **A**, there is a partially enhancing, partially cystic left level IV node. This was a metastatic papillary thyroid carcinoma node with hemorrhage. In **B**, there is a large, necrotic left level IV node with extracapsular tumor spread. Within the node are areas of higher attenuation that represent hemorrhage in this patient with metastatic hypernephroma.

that this approach increases the sensitivity of this technique compared to CT and more conventional MR imaging for detecting early nodal metastasis.[237, 238] The downside of this approach is that the patient must make at least two visits to the radiology department, one to be injected and one to be imaged.

The use of metabolic imaging has also made strides in the diagnosis of head and neck cancer and in following treatment changes in these patients. Studies have shown that the kinetic characteristics and tracer uptake intensity are similar in both primary tumors and their lymph node metastases. These topics are also dealt with in Chapter 45. In these studies, all tumors were demonstrated by PET, although there was a tendency to overestimate tumor size, and the authors concluded that FDG-PET could be useful in detecting occult primary tumors and nodal metastases.[277, 278] In following metastatic lymph nodes after irradiation, FDG-PET showed an initial increase in nodal metabolic activity. After 30 Gy was given, the deeper nodes returned to their initial levels of activity. The metabolic activity of superficial nodes remained high even after administration of 60 Gy, and anti-granulocyte scans showed intense inflammation in these latter nodes.[279] FDG-PET may thus be useful in predicting a good nodal response to irradiation by identifying such an inflammatory response to treatment. Another study reported results of static, nonattenuation-corrected PET starting 40 minutes after the intravenous injection of 370 MBq of fluorodeoxyglucose F 18. The authors noted that the diagnostic accuracy of PET for detecting ''neck sides'' with malignant involvement was

superior to that of morphologic procedures, with a sensitivity and specificity of 87% and 94%, respectively.[280]

Thallium-201 SPECT may also be useful in head and neck cancer patients, especially for detecting occult tumors and for assessing recurrences.[281] Similarly, thallium-201 SPECT has been shown to be useful in predicting the response of lymph nodes and primary tumors to irradiation.[282] However, when such a scan is utilized, there are other lesions, such as Kimura's disease, that show increased thallium-201 uptake.[283]

SPECT using 99m-technetium-MIBI also demonstrated uptake in both tumors and metastatic lymph nodes. This approach may be a good adjunctive technique to CT and MR imaging.[284] Another approach, with limited testing to date, that may correctly identify both the primary tumor site and nodal metastases involves the use of SPECT immunoscintigraphy with 111In-(Fab′)2-anti-carcinoembryonic-antigen monoclonal antibody, SQ174 monoclonal antibody, and

Table 36-19
DISEASES THAT CAUSE ENHANCED CERVICAL LYMPH NODES ON IMAGING

Nodal angiomatoses
Acute bacterial infections (including tuberculosis, etc.)
Viral infections (mononucleosis, HIV, etc.)
Other infections (Lyme disease, toxoplasmosis, cat-scratch fever, etc.)
Non-Hodgkin's lymphoma and Hodgkin's lymphoma
Squamous cell carcinoma
Vascular metastases (thyroid, renal, melanoma, etc.)
Sarcomas (Kaposi's and angiosarcoma)
Nonneoplastic angiomatoses
Angioimmunoblastic lymphadenopathy
Angiofollicular lymph node hyperplasia (Castleman's disease)
Kimura's lymphadenopathy
Kikuchi-Fujimoto's lymphadenopathy
HIV lymphadenitis, type C
Benign vascular proliferation (distal venous or lymphatic obstruction)
Inflammatory pseudotumor of lymph nodes

Table 36-20
DISEASES ASSOCIATED WITH NODAL CALCIFICATIONS

Infections
Tuberculosis
Healed bacterial nodal necrosis (usually staphylococcal infections in children)
Silicosis (rare)
Unknown etiology
Amyloidosis
Sarcoidosis
Malignancies
Thyroid carcinoma (usually papillary)
Metastatic adenocarcinoma (usually from breast, lung, or colon primaries)
Squamous cell carcinoma (rare)

E48IgG or (Fab′)2 mononclonal antibodies.[285–287] These newer approaches illustrate how adjunctive testing may complement more conventional CT and MR imaging to increase the accuracy of imaging in identifying occult primary tumors, recurrent tumors, and nodal metastases.

Last, but by far not least, ultrasound has been used to detect cervical nodal metastasis.[288] However, the major limitations of this modality remain its great dependence on user technique and skill and its difficulty in precisely imaging the deeper spaces of the neck, especially those adjacent to the airway. Its main current use appears to be in imaging superficial masses in children or in imaging and biopsy of some superficial masses in adults. It is not the mainstay modality for survey studies of the neck to detect nodal disease and to evaluate primary tumor extension.

Recently, the application of power Doppler sonography to detect cervical nodal metastasis has shown some promise.[289] These authors showed that when there was no hilar flow, peripheral nodal flow, and a transverse-longitudinal ratio of more than 0.65, the node was likely to

THE ROLE OF ULTRASOUND FOR EVALUATION OF INFANTS AND YOUNG CHILDREN

Although CT and MR imaging can be used for the evaluation of a variety of head and neck disorders, ultrasound may be the initial modality for evaluating superficial structures. Ultrasound may also be preferred for guiding needle aspirations (punctures) of all types of lesions in the neck. Ultrasound, and if necessary ultrasound-guided fine-needle aspiration cytology, is also useful for evaluating thyroid and parathyroid gland lesions, for evaluating cervical nodes, and for the diagnostic evaluation of salivary gland tumors. The noninvasiveness of ultrasound makes this an ideal modality for evaluating neck masses in infants and children. This chapter will review the potential of ultrasound and ultrasound-guided fine-needle aspiration cytology for evaluating a variety of disorders involving the extracranial head and neck.

EXAMINATION TECHNIQUE OF THE NECK

The patient is examined in a supine position with the neck mildly hyperextended. The neck should be examined with a high-frequency linear array transducer ranging from 7.5 to 10 MHz. Blood flow can be studied using Duplex sonography, in which gray scale 2D sonography is combined with pulsed Doppler. With color Doppler imaging (CDI), the pulsed Doppler information is encoded for flow direction and (mean) flow velocity and displayed in the 2D image. The relative direction of flow (toward or away from the transducer) is shown by the use of a suitable color (e.g., red or blue). Power Doppler shows the intensity of flow, which is proportional to the square of the amplitude of the Doppler signal. It is usually presented in a unidirectional

Copyright © 2003, Mosby, Inc. All rights reserved.

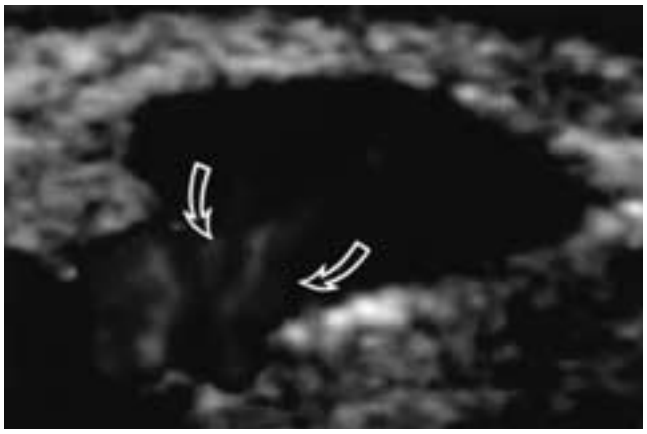

FIGURE 37-1 Power Doppler ultrasound shows hilar flow (*arrows*) inside a small normal lymph node, which is seen with low signal intensity.

VIEW IMAGE

form (Fig. 37-1). CDI is generally used to examine intravascular flow, while the more sensitive power Doppler is used to detect parenchymal flow. Flow patterns (velocity in time) during the cardiac cycle are studied with duplex scanning. Many indices of waveform analysis have been described, but only the *resistance index* (RI = (maximum velocity – minimum velocity) / maximum velocity) is used to characterize parenchymal flow. The RI is particularly sensitive to changes in downstream flow resistance. Neovascularization, as seen in many tumors, causes a decrease in the RI compared to normal tissue. Depending on the indication (swelling of the neck, suspicion of a thyroid or parathyroid lesion, etc.), particular attention should be given to certain regions of the neck. Level I should be evaluated in the coronal plane. Generally, levels II to V should be evaluated longitudinally (craniocaudally) and in the axial plane. The thyroid gland should be imaged entirely in both the transverse and longitudinal planes. Potential enlargement of the parathyroid gland should be evaluated, particularly if there are indications of adenoma, hyperplasia, and so on. The parotid gland should be examined in the axial plane. Sometimes it may be difficult to assess the origin of a lesion (intra- or extraparotid), and imaging in other directions should be performed. Levels I to V of both sides of the neck should be examined for the presence of enlarged nodes, particularly in patients known to have head and neck cancer or parotid lesions or when a suspicious thyroid nodule is encountered. All nodes that are visible on ultrasound are measured in the axial plane. We prefer to measure the minimal axial diameter, since we consider this to be the most accurate size criterion in differentiating between benign and malignant disease.

ULTRASOUND-GUIDED FINE-NEEDLE ASPIRATION CYTOLOGY

Fine-needle aspiration cytology (FNAC) has a major role in the diagnosis of palpable or nonpalpable thyroid lesions because of the absence of reliable clinical or ultrasonographic criteria for differentiation between benign and malignant disease. The procedure is safe and easily performed in an outpatient setting (Fig. 37-2). Ultrasound-guided FNAC can provide a cytologic diagnosis in a large percentage of lesions. We prefer ''freehand'' FNAC using a syringe holder (Cameco, Tayby, Sweden). A 22-gauge (25-mm) noncutting needle equipped with 10- or 20-ml aspiration syringes should be used. A longer needle should be used for deeper lesions. After antiseptic preparation, the needle should be advanced 0.5 to 1 cm from the middle of the long axis of the transducer. After visualization of the needle tip in the lesion, syringe suction should be applied and the needle moved gently but rapidly through the mass. An ideal specimen for cytologic analysis consists of 1 or 2 drops of orange-red fluid. Cutting needles generally yield very cellular specimens but are more difficult to insert than the sharper noncutting needle.[1] The smears are fixed using 70% ethanol, stained with Papanicolaou stain, and air-dried and stained with May-Grunwald-Giemsa solution. The needle and syringe are washed with Carbowax to obtain additional smears. Repeated ultrasound-guided FNAC, possibly with the use of on-site cytopathology review, may reduce the number of nondiagnostic aspirates. Spring-activated automated biopsy guns may also allow more accurate histologic diagnosis without a significant increase in the complication rate.[2]

If the aspirate obtained by ultrasound-guided FNAC contains blood, a nonaspiration technique may be used in which the 22-gauge needle is inserted without suction. Capillary action causes cells to move into the needle as it is moved in a back-and-forth excursion within the mass.[1] This technique may be especially useful when aspirating thyroid nodules.

SONOGRAPHIC ANATOMY OF THE NORMAL NECK

This section describes the normal ultrasonographic anatomy of the thyroid gland, the parathyroid glands, the salivary glands, and the cervical nodes. The axial anatomy

FIGURE 37-2 Ultrasound-guided aspirations are performed by using a syringe holder and preferentially a 0.6 × 25 mm needle. The needle should be introduced 0.5 to 1.0 cm from the middle of the long axis of the 7.5- to 10-MHz linear array transducer.

FIGURE 37-3 Thyroid gland. The thyroid gland consists of two lateral lobes (*arrows*) connected by a median structure, the isthmus. This axial image shows thyroid tissue as highly uniform tissue with medium-level echogeneity, with little identifiable internal architecture. Small, dilated veins may be visualized as small, rounded structures or as small, linear structures. The concave posterior surface of the thyroid is located adjacent to the first tracheal rings.

of the neck has been extensively discussed in Chapter 33. In this chapter, selected topics will be discussed; in particular, potential applications and limitations of ultrasound will be indicated, along with anatomic features of each structure.

Thyroid Gland

The thyroid gland consists of two lateral lobes connected by a median structure, the isthmus, at the junction of the lower and middle thirds of each lobe (Fig. 37-3). The concave posterior surface of the thyroid is applied against the anterolateral surfaces of the larynx and the first tracheal rings. Average lobe dimensions are: height, 4 to 6 cm; width and thickness, 1 to 2 cm. Ultrasound allows volumetric analysis of the thyroid lobes. Each lobe can be considered as a separate sphere whose volume is given by $v = (\pi/6 \times \text{height} \times \text{width} \times \text{depth})$. The average volume has been estimated at between 12 and 40 cm^3. The average distance between the inferior lobe and the sternum may be 1 to 2 cm, but this position varies from one individual to another. If the caudal extreme is much lower, the neck should be extended considerably for accurate examination. The thyroid lobes are often slightly asymmetric, with the right lobe tending to be larger than the left. The isthmus may vary from 1 to 2 cm in height. The pyramidal lobe is an inconstant conical structure projecting upward from the isthmus, either along the midline or off to one side. Normal thyroid parenchyma has a characteristic sonographic appearance of homogeneous medium-level echoes, with little identifiable internal architecture. The use of color Doppler imaging identifies multiple small vessels within and adjacent to the thyroid gland. Parts of the paired superior and inferior thyroid arteries, which provide the blood supply to the thyroid, can usually be visualized as they enter the gland.

The esophagus often projects to the left of the trachea and may be seen at the posteromedial border of the left thyroid lobe. The esophagus is visualized sonographically as a semicircular bull's eye with a hyperechogenic center (esophageal lumen) and less echogenic contours (esophageal wall). However, this image may vary. An esophageal deviation to the left side of the neck should not be mistaken for a cervical mass. The mobility of this structure can be examined by having the patient swallow.

As the internal jugular vein is not always spontaneously visible, a Valsalva maneuver can be performed to dilate the jugular vein. The vagus nerve lies in the posterior angle of the common carotid artery and the internal jugular vein (Fig. 37-4). The posteromedial border of each thyroid lobe is intimately related to the corresponding recurrent laryngeal nerve. Enlargement of the thyroid gland, especially if secondary to malignancy, may cause paralysis of the vocal cord.

FIGURE 37-4 The major neurovascular bundle comprises the common carotid artery, the internal jugular vein (lateral to the artery and more or less spontaneously visible), and the vagus nerve. This axial image low in the neck shows both vascular structures, lateral to the thyroid lobe and deep to the sternocleidomastoid muscle.

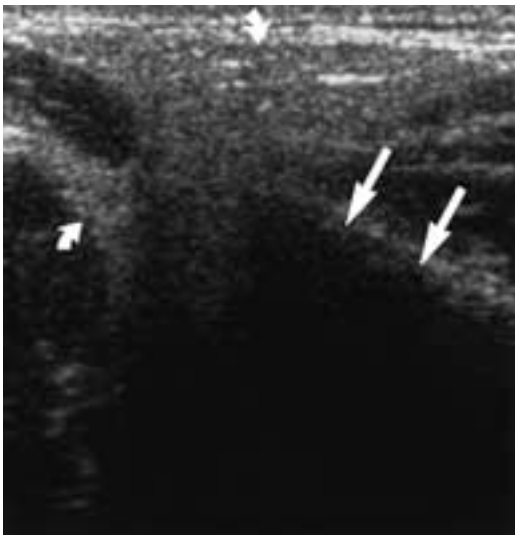
Parathyroid Gland

In most people there are four parathyroid glands (two superior and two inferior ones) dorsal to the thyroid gland and its capsule. In approximately 5% of people there are more than four glands. Normal glands are oval or bean-shaped. The normal parathyroid gland averages 3 to 6 mm in length, 2 to 4 mm in width, and 1 to 3 mm in thickness. However, normal parathyroid glands cannot be visualized because they have an echogenicity similar to that of the thyroid gland. Normally positioned parathyroid glands are characteristically located around the terminal branches of the inferior thyroid artery. Superior glands are located behind the upper pole or midportion of each thyroid lobe. The inferior glands are usually located just inferior to the posterior aspect of the lower thyroid poles. If they fail to dissociate from the adjacent thymus during development, they may migrate more inferiorly into the superior mediastinum. Most frequent sites of ectopic glands are mediastinal, retropharyngeal, or retroesophageal.

Salivary Glands

The parotid gland is the largest salivary gland and is bounded anteriorly by the ascending ramus of the mandible and posteriorly by the mastoid process (Fig. 37-5). This gland has a homogeneous, hyperechoic appearance. Ultrasound cannot visualize the portion of the gland that extends deep to the mandible. The facial nerve emerges from the skull through the stylomastoid foramen. It enters the superior deep portion of the parotid gland anterior to the posterior belly of the digastric muscle. As the nerve courses inferiorly, it is located lateral to the retromandibular vein. After crossing the vein, the facial nerve divides into its branches. The facial nerve is encased in a fibrous sheath that is easily recognized by the surgeon but is indistinguishable sonographically from surrounding parotid gland tissue.[3] The external carotid artery may be visible sonographically, terminating 4 cm above the angle of the mandible, where it divides into the maxillary and superficial temporal arteries. Lymph nodes are also located in the parotid gland. Normal intraparotid lymph nodes cannot be visualized by ultrasonography.



VIEW IMAGE

FIGURE 37-5 This axial image shows the parotid gland (*curved arrows*) with a homogeneous, hyperechoic appearance. Ultrasound cannot visualize the part of the deep portion of the gland that extends deep to the mandible (*straight arrows*), which is the anechogenic area on this image.

FIGURE 37-6 This frontal image shows the submandibular gland adjacent to the anechoic mandible (*curved arrow*), with a homogeneous appearance similar to that of the parotid gland. The entire gland can be seen by ultrasound. Submandibular ducts (*small arrows*) may be visualized inside the gland.

VIEW IMAGE

The submandibular gland (Fig. 37-6) is located in the submandibular region. The submandibular duct (Wharton's duct) emerges from the gland's superior surface and terminates at the side of the frenulum of the tongue. The entire submandibular gland can be seen by ultrasound, with an appearance similar to that of the parotid gland.

The Neck (Cervical Lymph Nodes)

Familiarity with the normal anatomy and features of the cervical nodes is essential for complete evaluation of patients with head and neck malignancies. Of the estimated 800 lymph nodes in the human body, 300 are situated in the neck. Until recently, the regional categorization of lymph nodes, as described by Rouvière, was the most widely used for lymphadenopathy.[4] Today, most centers use the classification into levels proposed by the Memorial Sloan-Kettering Cancer Center and described by Som[5] (Fig. 37-7). Also see Chapter 36 for updated classifications.

In this classification system, level I corresponds to the submandibular and submental regions. Levels II, III, and IV correspond to the jugular chain nodes around the internal jugular vein (high, mid-, and low jugular). Level II is situated above the level of the hyoid bone. Level III lies between the bottom of the body of the hyoid bone and the

Copyright © 2003, Mosby, Inc. All rights reserved.

crossing with the omohyoid muscle and the jugular vein (or the bottom of the cricoid cartilage arch). Level IV lies underneath this crossing and above the clavicle. Level V represents the lymph nodes posterior to the posterior border of the sternocleidomastoid muscle (posterior triangle) and above the clavicle (supraclavicular). The trapezius muscle forms the posterior border of this level. Level VI corresponds to the juxtavisceral, such as the paratracheal lymph nodes. The superficial, facial, parotid, nuchal, and retropharyngeal lymph nodes that were recognized by Rouvière are not outlined in this scheme, as these are not commonly removed in neck dissections.

Although many different pathways and anastomoses of the lymphatics in the neck exist, most primary tumors metastasize via predictable routes following local and deep lymphatic pathways.[6] The primary echelon lymph nodes, that is, the sentinel lymph nodes, are at highest risk of harboring occult metastases in an N0 neck. For anterior oral and nasal cavity as well as lip carcinomas, level I is at highest risk. In posterior oral cavity and oropharyngeal tumors, level II lymph nodes are at highest risk, whereas in laryngeal and hypopharyngeal tumors, levels II and III can both harbor the sentinel lymph node. Hypopharyngeal and proximal esophageal as well as subglottic tumors can also spread to the paratracheal nodes in an early stage. Tumors from the skin of the face and scalp often spread to parotid, facial, or nuchal lymph nodes. For the radiologist, it is important to look for lymph nodes especially in the first echelon, and if ultrasound-guided FNAC is used, preferably to aspirate from lymph nodes in these regions.

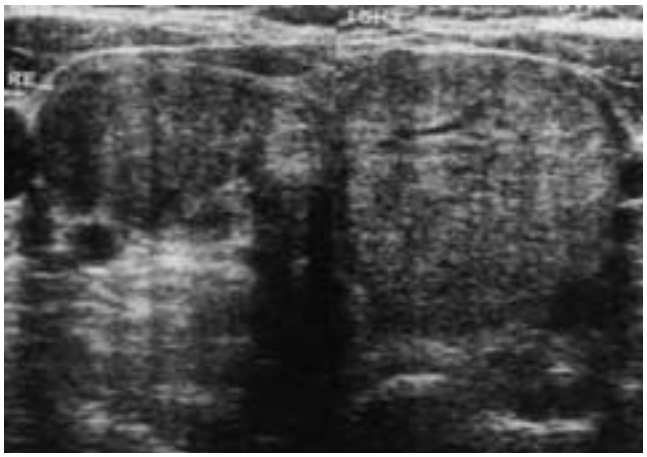

FIGURE 37-8 Multinodular goiter. Both lobes of the thyroid gland are enlarged, and are seen with moderate heterogeneity (mainly solid).

ULTRASONOGRAPHY OF NECK PATHOLOGY

Thyroid Gland

The thyroid gland is ideally situated for high-frequency sonography due to its superficial location. High-resolution ultrasound permits excellent visualization of the thyroid parenchyma. Ultrasound is generally the first choice for evaluation of thyroid morphology because of its sensitivity in detecting both small nodules and subtle variations like nodularity, calcifications, septations, and cyst formations. Many thyroid nodules discovered incidentally at sonography may not be clinically significant.[7] Sonography is an excellent tool for evaluating the thyroid gland to assess the volume of thyroid tissue, to provide image guidance for punctures and follow-up during and after therapy (thyroidectomy or prior neck irradiation). Ultrasound is less expensive than scintigraphy, allows easier comparison during follow-up, and has no accompanying radiation exposure or intravenous injections.

Diffuse Thyroid Disease

Generalized thyroid enlargement, or goiter, may be caused by a number of distinct entities, including multinodular goiter, Graves' disease, Hashimoto's thyroiditis, and infectious thyroiditis.[8, 9] A goiter is simply an enlarged thyroid gland, which may be seen with hyperthyroidism or hypothyroidism. Multiple hyperplastic nodules exhibiting varying degrees of colloid, necrosis, or hemorrhage characterize pathologically multinodular goiter (Figs. 37-8 and 37-9). Generally, laboratory values, the clinical history, and the physical examination differ in these entities. However, ultrasound findings may demonstrate mixed solid and cystic zones within an enlarged nodular thyroid gland. Calcifications may occasionally be present.[10] Sonography provides information regarding the size of the thyroid gland, disease extent, and surrounding lymphadenopathy. The incidence of carcinoma in a multinodular goiter is very low (less than 3%), and on scintigraphy the characteristic appearance of multiple cold areas interspersed with hot areas in a large gland will usually obviate the need for aspiration. FIGURE 37-9 Multinodular goiter. The thyroid gland is minimally enlarged. A large cystic lesion is located in the right lobe of the thyroid.

dominant, hard, or growing mass amid a goiter should probably be sampled. Serial ultrasound examination can monitor the disease progression and the therapeutic response.[11, 12]

Graves' disease (diffuse toxic goiter) is characterized clinically by signs and symptoms of thyrotoxicosis and enlargement of the thyroid gland (Fig. 37-10). The most common cause of hyperthyroidism, Graves' disease is an autoimmune disorder mostly found in women. Carcinoma of the thyroid gland in a patient with Graves' disease is rare, reported in only 0.15% to 0.5% of patients. The gray-scale sonographic pattern ranges from normal echogenicity to diffusely hypoechogenic. The thyroid tends to be more heterogeneous in patients with multinodular goiter than in patients with Graves' disease. The diagnosis is made clinically. Color Doppler imaging of the thyroid gland affected by Graves' disease may show a striking pattern of increased vascularity, both in systole and in diastole.[13] Some studies suggest that thyroid vascularity and thyroid artery blood flow are significantly higher in the active stage of Graves' disease. These findings suggest that color Doppler could be a useful marker for inflammatory activity, independent of hormone production.[14]

Another cause of thyroid enlargement is Hashimoto's thyroiditis, the most common form of thyroiditis (Fig. 37-11). It is mostly found in middle-aged women as a painful, diffusely enlarged gland. Gland size may also be normal. About 50% of patients are hypothyroid. The disease shows no greater risk of thyroid carcinoma, but patients appear to be at greater risk of developing non-Hodgkin's lymphoma. On ultrasound, the thyroid gland is enlarged and hypoechoic. Multiple ill-defined hypoechoic areas separated by thickened fibrous strands may be seen. A diffuse micronodular pattern is suggestive of Hashimoto's disease. However, the diagnostic accuracy of this finding has not been reported.[15] The final diagnosis still requires serologic tests. An enlarged thyroid gland may also be seen with acute infectious thyroiditis. Ultrasound may be useful for patients with a painful thyroid gland, particularly those with focal tenderness, to evaluate for the presence of a thyroid abscess.

Focal Thyroid Disease

Nodular disease in the thyroid gland is characterized by the presence of one or more palpable or nonpalpable nodules (Fig. 37-12). In the general population, thyroid nodules are exceedingly common. Noncystic nodules were detected on sonography in about 20% in a large prospective study of patients who had a normal thyroid gland on palpation. Clinical assessment is generally considered to be unreliable in attempting to differentiate a benign from a malignant nodule. The primary role of scintigraphy in the evaluation of focal thyroid masses is to determine whether a lesion is ''hot'' (a relatively low incidence of malignancy: less than 5%) or ''cold'' (a relatively high incidence of malignancy: 20% to 30%).[16] The low accuracy of radionuclide scanning has led to an effort to define reliable sonographic criteria to differentiate between malignant and benign thyroid nodules.

High-resolution ultrasonography can detect very small nodules. However, no single sonographic criterion enables reliable differentiation between benign and malignant thyroid nodules.[9, 11, 14, 17, 18] Nevertheless, there are certain findings that can help to make this important differentiation. The presence of microcalcifications is highly suggestive of malignancy.[18] An irregular, thick margin, especially in the presence of a halo or microcalcification, suggests malignancy.[14] Ultrasonography is accurate in distinguishing solid from cystic thyroid nodules. Malignant thyroid cysts are rare. Most cystic masses arise from preexisting solid nodules and are therefore complex.[19] The presence of colloid material within the cyst can cause a series of closely spaced, discrete echoes (a particular form of reverberation), the so-called comet tail artifact. Conversely, the presence of coarse calcifications, a regular margin, and a thin-rimmed anechoic cyst with a well-defined halo suggests benignity.[19–22] Multiplicity of nodules has not been shown to affect the likelihood of malignancy.[23] There may be considerable overlap in the sonographic appearance of

FIGURE 37-10 Graves' disease. Diffuse enlargement of both lobes (*curved arrows*) of the thyroid gland is present. The thyroid gland has low echogeneity.

benign and malignant nodules. Therefore, caution should be used in relying on sonographic features alone to characterize thyroid nodules. There are also many similarities in the appearances of benign and malignant nodules on color Doppler imaging.[24] Often an ultrasound-guided puncture is required to obtain cytologic evidence.

During routine ultrasound examination of the neck, nonpalpable (incidental) thyroid nodules that are less than 1 cm in diameter may often be detected.[14] The question arises as to what should be done with the many unsuspected, mostly benign thyroid nodules. Radiologists should be familiar with the above-mentioned morphologic features that increase the probability of malignancy. Based on the work of several authors,[25, 26] an algorithm for dealing with incidental nodules was developed. Patients with nodules at least 1.5 cm in size, or with nodules with suspicious ultrasound features or a history of thyroid cancer, should undergo ultrasound-guided FNAC. Patients with nodules smaller than 1.5 cm, or with nodules with benign-appearing features and without a history of thyroid cancer, can be followed by physical examination. If during follow-up the nodule is found to be increasing in size, patients should undergo ultrasound-guided FNAC. Most papillary carcinomas, which account for 55% to 75% of thyroid cancer, grow slowly and remain definitely curable if and when they become clinically apparent at approximately 1.0 to 1.5 cm in size.

Percutaneous Aspiration Under Ultrasound Guidance

FNAC has a major role in the management of palpable thyroid nodules because of the absence of reliable clinical or ultrasonographic criteria for differentiation of benign from malignant thyroid nodules.[14] Aspiration findings can be classified as benign (no evidence of malignancy), suspicious (features suggestive of but not diagnostic for malignancy, including Hurthle cell neoplasms and follicular neoplasms), malignant (definite evidence of papillary, anaplastic, or metastatic cancer), or nondiagnostic. Regarding the majority of palpable thyroid nodules, FNAC can be performed under palpation guidance with a high degree of accuracy (up to 85%). Ultrasound-guided FNAC has been reported to have higher accuracy than conventional FNAC.[27] Ultrasound-guided FNAC is useful for patients in whom conventional FNAC was not successful; for patients with suspicious, nonpalpable nodules; and for patients with a worrisome clinical history, such as significant neck irradiation. Approximately 60% of the nondiagnostic, palpation-guided nodule biopsies are reported to be diagnostic when repeated using ultrasound guidance.[9]

Tumor Recurrence After Thyroidectomy

Whole body scanning using radioiodine has traditionally been the mainstay in diagnosing recurrent tumor following surgery. However, Antonelli et al. have reported that ultrasound is capable of detecting recurrent tumor in the thyroid bed as well as cervical lymph node metastasis[28] (Fig. 37-13). Some studies suggest that ultrasound may have higher diagnostic accuracy than scintigraphy.[29] Routine ultrasonography may be used for follow-up of patients with thyroid cancer.[14] Because of the considerable overlap in the size and appearance of benign and malignant lymph nodes, we recommend percutaneous ultrasound-guided FNAC of all suspicious lymph nodes.

Ultrasound-Guided Sclerotherapy of Thyroid Cysts

True thyroid cysts can be punctured and aspirated. However, these cysts will very often regain their original size within a few days. An alternative approach is to sclerose the cyst wall by injecting absolute ethanol or tetracycline hydrochloride. After aspiration of the cystic fluid with a 22-gauge needle, approximately one-half to two-thirds of the original volume is replaced by a sclerosing agent. A small amount of saline is injected before the needle is

retracted. In this manner, pain due to spilling of the sclerosing agent in the surrounding tissue is avoided. In approximately 80% to 90% of cases, the cyst will be reduced in size or disappear. Large cysts respond better than small cysts.[30]

Parathyroid Gland

Primary Hyperparathyroidism

The main indication for ultrasonography of the parathyroid glands is the evaluation of patients with hypercalcemia. Hypercalcemia is a fairly common disorder that may occur in the absence of clinical symptoms in 1 out of 1000 cases. About 80% of cases are related to hyperparathyroidism. Females are affected twice as often as males, and although the condition can occur at any age, most patients are over 40 years of age.[31] Primary hyperparathyroidism is caused by an excess of parathyroid hormone secretion by a parathyroid adenoma (nearly 80% of cases and almost always limited to one gland), hyperplasia (less than 20% of cases and affecting all four glands), or carcinoma (only 1% and affecting one gland).

The typical parathyroid adenoma may be seen in a patient with biochemical evidence of hyperparathyroidism as an oval, solid mass of homogeneously low echogenicity. The size of the adenoma usually ranges between 0.8 and 1.5 cm in length; however, larger lesions may occasionally be encountered.[32] They may occasionally be multilobular and heterogeneous and may contain internal calcification or cysts.[33] An echogenic line separating thyroid and parathyroid tissue may allow the distinction between adenoma and adjacent thyroid.

The sensitivity of sonography for localizing parathyroid adenomas in patients with primary hyperthyroidism has been reported to range between 70% and 80%.[34, 35] Sonographic examination of a patient with hyperparathyroidism may give a false-negative result in three situations: minimally enlarged adenomas, adenomas displaced and obscured by an enlarged thyroid goiter, and adenomas in ectopic parathyroid glands located in regions difficult to evaluate by ultrasonography. Such areas include locations behind air-containing viscera (pharynx, esophagus) or bone (sternum, clavicle).

Posterior exophytic thyroid nodules and cervical lymph nodes may cause false-positive sonographic results. Thyroid nodules have mixed echogenicity, including cystic and calcified components, and are usually intrathyroid. Lymph nodes may contain a characteristic hilum and are generally more lateral in the neck. Ultrasound-guided FNAC may be performed to differentiate suspected parathyroid adenomas from lymph nodes and thyroid nodules.

Imaging Indications

Routine preoperative imaging is not performed because morbidity is rare when an experienced surgeon performs parathyroidectomy. Ultrasound may occasionally be used in preoperative evaluation of patients with primary hyperparathyroidism. Unilateral parathyroid exploration with adenoma removal and identification of a normal parathyroid gland is an accepted surgical approach for the treatment of patients with primary hyperparathyroidism. In experienced hands, high-resolution sonography can be a cost-effective means of localizing parathyroid adenomas when unilateral exploration is considered an accepted surgical approach.[36] In contrast, preoperative imaging may be beneficial in patients undergoing a second surgical procedure for persistent or recurrent hyperparathyroidism (Fig. 37-14). In this patient group, ultrasound has demonstrated higher sensitivity (60% to 82%) than MR imaging or CT.[37] Ultrasound may also be used to guide the fine-needle aspiration of suspicious lesions.

SALIVARY GLAND

Sialolithiasis

Inflammatory disease can be best investigated by other modalities, such as CT or sialography, and is not an indication for ultrasound. However, ultrasound may be beneficial for evaluating patients with sialolithiasis. Plain films or CT are usually performed first. If they are negative, sialography remains a reliable method for detecting sialolithiasis.[38] Ultrasound is a noninvasive method for detecting calculi and assessing the surrounding parenchyma. A dilated duct can be identified, as can nonradiopaque calculi. Ultrasound may detect calculi in up to 91% of cases.[39] It may also be helpful when ductal cannulation is impossible.

Tumors and Tumor-Like Conditions

Tumors are 10 to 15 times more common in the parotid gland than in the submandibular glands. Benign lesions account for about 80% of all parotid tumors. In contrast, the frequency of malignant tumors in the submandibular gland is much higher (approximately 33% to 50%). Pleomorphic adenoma is the most frequent tumor (60% to 70%) of the salivary glands. Warthin's tumor, also called adenolymphoma, accounts for 6% to 10% of all parotid tumors. Only 5% of cases are bilateral. Benign nonepithelial tumors may arise within glandular spaces and include lipomas, schwannomas, and vascular tumors. Like benign tumors, epithelial lesions are the most frequent forms of malignancy. Metastases and lymphomas of the salivary glands are rare. Pleomorphic adenomas have a tendency to recur if the capsules are damaged at surgery. For that reason, partial or total parotidectomy should be performed. Warthin's tumor has an excellent prognosis and almost never recurs; malignant degeneration is extremely rare. Therefore, enucleation or continuous follow-up without removal may be sufficient.

High-resolution ultrasound is considered by some authors to be the modality of first choice for detection of neoplasms in the salivary glands. However, ultrasound is unable to evaluate that portion of the parotid gland situated deep to the mandible. If the lesion needs to be identified before surgery, ultrasound-guided FNAC may be performed. MR imaging is an important adjunct for evaluating the full extent of tumor and evaluating for perineural spread. In cases of malignancy, the neck should also be examined for enlarged lymph nodes.

Pleomorphic Adenoma

Approximately 90% of pleomorphic adenomas are located in the superficial lobe (Fig. 37-15). Consequently, ultrasonography may detect the large majority of these lesions. The possibility of malignant transformation of pleomorphic adenomas remains controversial. Small (<3 cm) pleomorphic adenomas are usually visualized as a homogeneous, well-delineated, lobular nodule of decreased signal intensity compared to surrounding parotid gland tissue.[40, 41] The absence of either sharp margins or homogeneity may suggest malignancy. Reports from the literature regarding the potential of color Doppler sonography to differentiate malignant and benign tumors are contradictory.[42, 43] Large tumors (>3 cm) are prone to cystic and hemorrhagic degeneration, which modifies their internal architecture. In cases of recurrent tumor, ultrasound examination may be hindered by echogenic scar. MR imaging is indicated in these cases.

VIEW IMAGE

Warthin's Tumor

Ultrasound shows a well-defined, anechoic mass or a mass with multiple anechoic areas, often at the lower pole of the parotid[40, 41] (Fig. 37-16). However, the pattern may vary. In certain cases, multiple septa and the thickness of

intratumoral fluid give an inhomogeneous echogenic pattern (Fig. 37-17). Because Warthin's tumor may be bilateral, the contralateral gland should always be examined carefully.

Malignant Tumors

There are many types of malignant epithelial tumors. The most frequent are mucoepidermoid cancer (5% to 10% of all salivary gland tumors), adenoid cystic carcinoma, acinic cell tumors (Fig. 37-18), undifferentiated carcinoma, and epidermoid carcinoma. Malignant tumors may often show attenuated posterior echoes, heterogeneous internal echoes, or a polygonal shape. There are no consistent criteria to differentiate between malignant and benign lesions. MR imaging is necessary to show the extent of disease, particularly to demonstrate perineural spread of tumor tissue.

NODAL NECK DISEASE

Nonneoplastic Lymphadenitis

As the neck lymphatics play a key role in upper aerodigestive tract infections, reactively enlarged lymph nodes are very common (Fig. 37-19). Most often these are caused by viral or bacterial infections. The history, serology, and cultures of the primary infection, together with intracutaneous testing (e.g., Mantoux testing for mycobacteria), and, if needed, cytology can in general establish the diagnosis. However, ultrasound can sometimes help in the diagnostic workup of cervical lymphadenopathy. In suppurative lymphadenitis, the assessment of abscess formation and eventually ultrasound-guided drainage can be of great importance.[44] In this respect, the hypervascularity shown using Doppler sonography is a reliable diagnostic criterion. In a study of 50 lesions, a peripheral blood flow pattern was observed only in abscesses. Other patterns, such as a mixed pattern (flow within and around the lesion) and a central pattern (flow in the central region of the mass), were seen most frequently in lymphadenitis but were not specific for that diagnosis.[45] Ultrasound-guided drainage is especially useful if the abscess is located deep and is difficult to reach surgically.[46, 47] For this indication, CT-guided drainage can be used as well. A single mass with central heterogeneous reflection patterns is most often caused by a suppurative lymph node, an (atypical) mycobacterial infection, or cat-scratch disease caused by *Bartonella henselae*. Multiple enlarged, conglomerate lymph nodes that are hypoechoic or have inhomogeneous echotexture with enhanced through-transmission may be indicative of tuberculous lymphadenopathy (Fig. 37-20). In these cases, nonspecific abscess-forming lymphadenitis, lymph node metastases, and malignant lymphoma still should be excluded.[48, 49] Bilateral diffuse lymph node enlargement without necrosis is most frequently caused by viral infections, such as mononucleosis, herpes, cytomegalovirus, rubella, or HIV. HIV infections can also present with cystic lesions in the parotid

FIGURE 37-20 **A** and **B**, Tuberculous lymphadenopathy. Multiple enlarged, conglomerating lymph nodes that are hypoechoic, with enlarged through-transmission, are seen. This large submandibular node appears to be partly calcified (*arrow*). (Courtesy of Dr. F.B.L.M. Joosten.)

glands or with associated malignancies. Toxoplasmosis and sarcoidosis are rare causes of multiple cervical nodal enlargement. In sarcoidosis the salivary glands can be swollen, and a chest x-ray may reveal mediastinal lymph node enlargement. The diagnosis is made by serologic tests (angiotensin converting enzyme, muramidase), bronchial lavage, and histopathology. In cases of single or multiple nodal enlargements with homogenous reflection patterns, Castleman's disease should be in the differential diagnosis.[50]

Malignant Lymphomas

Hodgkin's and non-Hodgkin lymphomas can present with multiple or single abnormal nodes in the neck, either as the initial presenting symptom or as part of a more generalized disease. Ultrasound shows clearly delineated lymph nodes with a homogeneous, weak internal echo pattern, although spotty or dendritic hyperechoic areas can sometimes be seen. Power Doppler sonography shows highly perfused nodes with color signals in the center as well as in the nodal periphery in most lymphomas. However, this flow pattern with a reduced resistance index is not specific. It is reported that contrast-enhanced Doppler sonography can be useful in differentiating lymphoma from reactive nodes.[52]

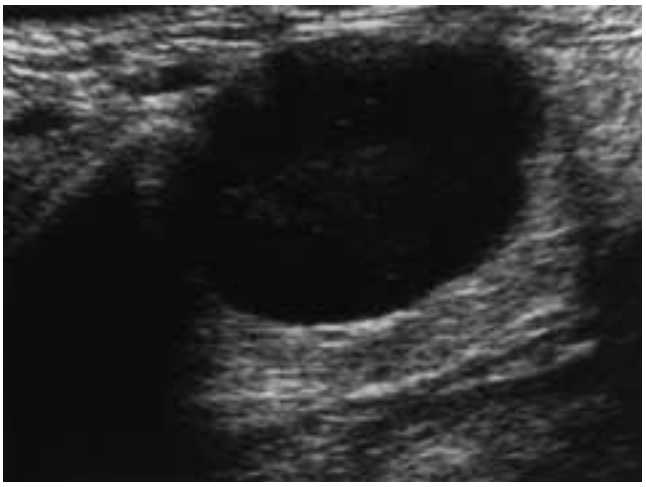
Metastatic Lymphadenopathy

Metastases to the cervical lymph nodes most frequently originate from squamous cell carcinomas of the mucosal lining of the upper aerodigestive tract. Other primary sites of metastases are salivary gland, thyroid, and skin neoplasms. Metastatic patterns from skin melanomas differ from and are more variable than metastases from mucosal carcinomas.[53] Metastases from skin tumors are more often located in the superficial lymph nodes, such as those in the parotid gland, the nuchal area, or the posterior triangle. Their appearance on ultrasound, CT, and MR imaging is identical to that of squamous metastases, although melanoma metastases are more often hypervascular. Well-differentiated thyroid carcinomas have a very high rate of neck metastases, although these are often clinically occult. On ultrasound, every slightly enlarged node should be regarded as suspicious. Discrete calcifications or internal cysts may occasionally be seen. Imaging has relatively little utility in the management of papillary carcinoma in patients with N0 necks since the treatment is radioactive iodine.

Head and neck squamous cell carcinomas metastasize primarily to the cervical lymphatic system. The number and extent of metastases are important for the prognosis. Whereas only 7% of patients without lymph node metastases develop distant metastases, almost 50% of patients with more than three tumor-positive lymph nodes do so.[53] Palpation is the most widely used staging technique for the neck, but its sensitivity and specificity are both between 60% and 70%. As a consequence, there is a substantial risk of clinically occult metastases.[54, 55] For T1 to T3 oral, oropharyngeal, and supraglottic tumors, the risk of occult metastases is between 20% and 50%. In many head and neck primaries, both the ipsilateral and contralateral sides are at substantial risk of developing nodal metastases. The risk increases further if the primary has grown close to or extends across the midline.

Imaging can play a significant role in the staging and management of cervical nodal metastases. An accurate imaging method can help to detect occult metastases in the clinically N0 neck or to lower the risk of occult metastasis. In the latter case, one should realize that imaging can only decrease the risk of occult metastases; it can never reduce the risk to zero. In general, ultrasound is reported to be superior to palpation in detecting lymph node metastases.[56, 57] Whereas some authors report ultrasound to be superior to contrast-enhanced CT and MR imaging,[57, 58] others have found similar accuracy rates.[56, 59] Ultrasound examination of level I is assumed to be more difficult because of the presence of the submandibular gland and artifact caused by the adjacent mandible (Fig. 37-21).

Copyright © 2003, Mosby, Inc. All rights reserved.



VIEW IMAGE

FIGURE 37-21 B-cell lymphoma. Adjacent to the mandible, a clearly delineated lymph node with homogeneous low echogeneity is seen. No hilar pattern can be seen. (Courtesy of Dr. F.B.L.M. Joosten.)

In patients with palpable suspicious lymph nodes, the role of imaging is quite limited, although it can help determine the tumor extent. If lymph nodes are fixed to the deep structures, most authors cite preference for CT or MR imaging to assess the extent of the tumor. However, it has been reported that ultrasound, in combination with palpation (i.e., sonopalpation),[60] can identify carotid wall invasion. The accuracy of ultrasound and other imaging techniques for the neck is dependent on the diagnostic criteria used in assessing for lymph node metastases.[61, 62] Although the resolution has improved in recent years, it is still not possible to detect small tumor deposits within lymph nodes.

Table 37-1
CRITERIA CONCERNING THE SIZE, SHAPE, AND GROUPING OF LYMPH NODES, AS REPORTED BY DIFFERENT AUTHORS

Author	Criteria
Van den Brekel[59]	Ax-min 11 mm at level II or 10 mm elsewhere or a grouping of three or more measuring 8 to 10 mm
Vassallo[63]	No size criterion; long/ax-min <2 or absence of a hilus or focal cortical widening
Bruneton[67]	8 mm ax-max and long/ax-max <1.5
Stern[97]	15 mm at all levels
Som[98]	15 mm at levels I and II or 10 mm elsewhere
Mancuso[99]	8 mm retropharyngeal or 15 mm at all other levels
Hillsamer[100]	Grouping of three or more measuring 8 to 15 mm
Friedman[101]	10 mm at all levels
Close[102]	30 mm ovoid shape or 10 mm round shape or a grouping of two or more measuring 10 to 30 mm
Steinkamp[103]	8 mm ax-min or 8 mm ax-max and long/ax-min <2
Tachimori[104]	5 mm minimal diameter and long/ax-min <2

Abbreviations: long, longitudinal diameter; ax-max, maximal axial diameter; ax-min, minimal axial diameter.

Diagnostic criteria include an increased size, a rounder shape, and the presence of irregular ultrasound reflection patterns caused by the tumor or by tumor necrosis or keratinization (Table 37-1). An echogenic hilus can be seen in 60% of nonmetastatic nodes and is not present in lymph nodes totally replaced by tumor. However, the hilus can remain when small tumor deposits are present. Focal cortical widening by tumor is reported to be a reliable criterion, as is a cystic pattern.[63, 64] In general, a round shape is considered more suspicious than an oval or flat shape.[65, 66] In reactive nodes, a transverse to longitudinal ratio of less than 0.5 is present in more than 80% of the cases.[67] However, most of the characteristic ultrasound features cannot be appreciated in lymph nodes smaller than 1 cm. As a consequence, for the clinically N0 neck, the size of lymph nodes remains an important criterion as well.[66] In this respect, the minimal diameter is the preferred axis to measure. However, any size criterion is a compromise, as a small cutoff point has high sensitivity and low specificity and vice versa. In a recent study on the ultrasound size criteria in the N0 neck,[69] it was shown that the often used 1-cm criterion provides a low sensitivity for this patient category. For level II nodes, a size criterion of 7 mm was optimal, whereas for the rest of the neck, lymph nodes with a minimal diameter of 6 mm were considered suspicious. In spite of these refinements, it is clear that size, shape, and irregular echo patterns are not very accurate for the clinically N0 neck.

In recent reports on power Doppler sonography, a parenchymal blood flow signal throughout the entire lymph node was present in over 80% of the larger metastatic lymph nodes, whereas reactively enlarged lymph nodes showed characteristic hilar perfusion.[70] Other characteristics that have been reported in metastatic lymph nodes include avascular areas, displacement of intranodal vessels, aberrant course of central vessels, and accessory peripheral vessels.[71] However, again with the use of Doppler sonography, it is not possible to make a histopathologic diagnosis, and some authors found skepticism about the applicability of this modality.[72, 73] Administration of galactose-based ultrasound contrast may improve the assessment of hilar and other adjacent vascularity. However, measured Doppler indices do not add to the criteria for a differential diagnosis. A combination of peripheral parenchymal nodal flow, internal architecture, and size will probably be the most accurate. However, application of these criteria to small lymph nodes may be impossible.

To enhance the accuracy of ultrasound, ultrasound-guided aspiration of lymph nodes has been used. To use this technique, considerable training is required.[74, 75] It is, of course, mandatory to be aware of the patterns of lymphatic spread from different tumors in order to select the lymph nodes at highest risk. It has been shown that ultrasound-guided FNAC has a very high specificity, approaching 100%. To obtain a high enough sensitivity, lymph nodes as small as 4 to 5 mm in the first two echelons should be aspirated. If ultrasound is used during follow-up, not only the size of the node is important, but also its evolution over time. In a previous report, we found that the diagnostic accuracy of ultrasound-guided FNAC had a sensitivity of 73% and a specificity of 100% in N0 necks.[59, 74] This was significantly better than the results obtained with CT or MR imaging. Only one other study compared ultrasound-guided

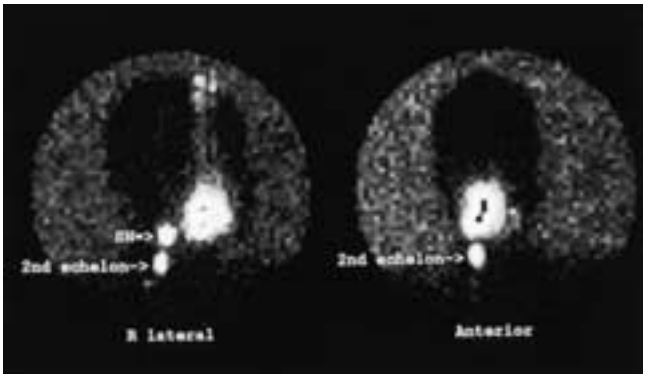
VIEW IMAGE

FIGURE 37-22 The sentinel node procedure. Initially, technetium-99-labeled colloidal albumin should be injected around the tumor in three or four locations.

FNAC to CT and MR imaging and found it to be superior as well.[76] Recently, however, in a multi-institutional study using ultrasound-guided aspiration, Takes et al. reported a sensitivity of only 42% in the N0 neck.[77, 78] However, in this series, only a few elective neck dissections were included in most centers, and some patients were irradiated before surgery. Righi et al. found a sensitivity of 50%, which was worse than the 60% for CT in their relatively small study.[79] However, in their study, most false negatives were found at the beginning of the study, and some of these involved irradiated patients or non–squamous cell carcinoma patients.

As these different sensitivities at least shed doubt on the accuracy of the technique, we recently started a study to define the causes of false-negative results. Using very sensitive molecular markers for the detection of tumor cells in the aspirate, preliminary results show that only a few positive aspirates are missed by the pathologist.[80] Recently, the most likely nodal drainage of a particular tumor has been identified by injecting a radiotracer into the region of the primary tumor and measuring the activity over various nodal regions. With the use of scintigraphic detection of this sentinel lymph node (Figs. 37-22 and 37-23) and subsequent



VIEW IMAGE

FIGURE 37-23 Several minutes after injection of technetium-99, the first-echelon node may be located with a gamma camera on lateral and posteroanterior (PA) images. It is essential to obtain both PA and lateral images; otherwise, the sentinel node may be missed by overprojection of the injection site.

Note: Only Van den Brekel et al. used ultrasound-guided FNAC in the initial assessment and follow-up.

ultrasound-guided aspiration of the node, we found that it is possible to aspirate from the sentinel node reliably and to confirm its identity by scintillation counting of the aspirate.[81] The aspirate is then examined for tumor cells. The use of sentinel node scintigraphy and the use of different aspiration techniques or needles might thus further improve the ultrasound-guided aspiration technique.

We have found ultrasound-guided FNAC to be highly specific and quite sensitive in detecting palpably occult metastases. In selected patients who can be treated with transoral excision for T1 and T2 oral, oropharyngeal, and supraglottic carcinomas, we rely on the ultrasound-guided FNAC findings and do not routinely treat the neck electively. These patients are followed very meticulously, using ultrasound-guided FNAC at regular intervals during the first year. So far, our preliminary experiences with this ''wait and see'' policy have been encouraging. Of the 77 patients who underwent a transoral excision without neck treatment in the last 4 years, and who have been followed for at least 1 year, 14 have failed in the neck (18%). Ten of these 14 were salvaged and are alive without tumor (a 71% salvage rate). This high salvage rate is certainly related to the short delay of the diagnosis of these 14 neck failures. These figures compare favorably to those quoted in the literature (Table 37-2).

The role of ultrasound in evaluating the posttreatment neck is controversial. The use of ultrasound or duplex Doppler for the follow-up of the treated neck has been investigated by several authors.[82–86] Westhofen showed that ultrasound-guided FNAC was superior to CT in detecting neck recurrences after previous treatment.[82]

OTHER CERVICAL SITES: CONGENITAL CYSTIC LESIONS AND NONNODAL MASSES OF THE NECK

In neck masses of unknown etiology, ultrasound provides a noninvasive method that can help differentiate between solid and cystic masses and may help in identifying the origin of a mass. Depiction of anatomic structures often allows differentiation of lymphadenopathy from tumors of the salivary glands or other soft tissues of the neck. Exact

localization of a mass, as well as typical ultrasound or Doppler sonography characteristics, can help differentiate between a primary mass such as a carotid body tumor and an enlarged lymph node.[87, 88] Congenital cystic masses such as branchial cleft cysts, thyroglossal duct cysts, and plunging ranulas have a characteristic sonographic appearance. Extralaryngeal laryngoceles can be followed through the thyrohyoid membrane and can be filled with air as well as fluid. Ultrasound can also be used to guide aspiration cytology of small masses or masses in proximity to the large vessels.

Cystic Lesions

This section describes the cysts in the neck apart from those in solid organs: the thyroglossal duct cyst, ranula, branchial cyst, cystic lymphangioma, and dermoid cyst.

The thyroglossal duct cyst (Fig. 37-24) accounts for the majority of cystic neck lesions. The cysts may occur at almost any age. They may be complicated by fistulas. Carcinomatous change occurs in 1% of cases. The anatomic location along the course of the thyroglossal duct usually suggests the diagnosis. The cysts may occur anywhere along the course of the duct remnant, from the base of the tongue to the suprasternal region, but most are located in the region of the hyoid bone. Most commonly, they are located in the midline, but approximately 33% may be located slightly off midline. The majority of off-midline cysts are located adjacent to the outer surface of the thyroid cartilage, deep to the strap muscles. High-resolution ultrasonography remains the ideal imaging modality. The sonographic appearance may vary from truly anechoic, to predominantly anechoic but containing internal debris (due to proteinaceous content), to a complex heterogeneous pattern and a uniformly heterogeneous appearance.[89] Posterior enhancement, a characteristic feature of an uncomplicated cyst, is reported to be present in approximately 90% of cases.[89, 90] Often it is difficult to identify this enhancement, particularly if the lesions occur in proximity to the airway. The cysts are well defined. The walls may be thin, thick (probably due to infection or cellular debris), or, rarely, imperceptible. The presence of a solid component is suspicious for carcinoma. Ultrasound-guided FNAC may not be necessary in patients undergoing surgery.

Ranulas are of two types. The simple ranula occurs in the floor of the mouth above the mylohoyoid muscle in the region of the sublingual gland and is truly an epithelium-lined cyst. A ''diving'' or ''plunging'' ranula results after the rupture of the simple ranula's wall. These are pseudocysts lined by dense connective tissue or granulation tissue. On ultrasound, ranulas are usually well-defined, cystic-appearing lesions. When simple they are confined to the sublingual region. When diving, the bulk of the lesion is typically identified in the submandibular region (Fig. 37-25).

Branchial cysts can be classified on the basis of their location (see Chapter 35). Superficial cysts may be seen in the region of the parotid or anterior to the sternocleidomastoid muscle. Deeper cysts are seen anterior to the great vessels (type 2 is the most frequent type) (Fig. 37-26). Extensions between the carotid arteries and toward the pharyngeal wall can be followed on ultrasound. Branchial cysts are most commonly discovered in young adults between 15 and 40 years of age. Clinically, branchial cysts appear rapidly over a period of several days as a mostly painless swelling in the upper region of the neck. Less often, the diagnosis is suggested by a history of a recurrent inflammatory neck mass, always at the same location. Ultrasound can usually confirm the diagnosis of a branchial cyst. Branchial cleft cysts may be difficult to distinguish from thyroglossal duct cysts (Fig. 37-27). However, the characteristic location and FNAC are helpful in differentiating the two cystic lesions.

A dermoid cyst is usually located at or near the midline around the hyoid bone. These cysts have an echogenic,

FIGURE 37-24 **A**, Thyroglossal duct cyst. Ultrasonography shows a large midline bilobular cystic lesion immediately caudal to the hyoid bone. The sonographic appearance is anechoic. **B**, CT confirms the ultrasonographic findings. (Courtesy of Dr. F.B.L.M. Joosten.)

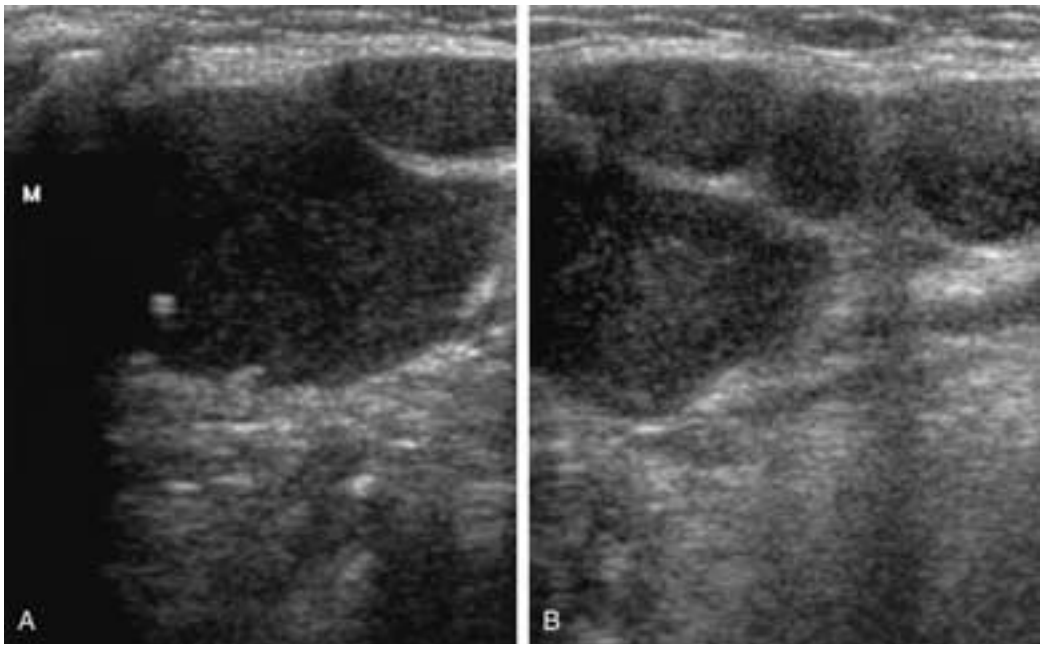

FIGURE 37-25 **A** and **B**, Plunging ranula. Coronal ultrasound demonstrates a multilobular cystic lesion in the submandibular space adjacent to the mandible (**M**) but extending beyond the mylohyoid muscle. The cysts are well defined and are not truly anechoic due to their high protein content.

VIEW IMAGE

pseudosolid appearance similar to that of a thyroglossal duct cyst. Preoperative differentiation between the two is not necessary, as this can be done at surgery.

Cystic hygroma and lymphangioma are discussed in the last section of this chapter.

Infectious Disease

In our experience, ultrasonography should not be the modality of first choice when there is a suspicion of inflammatory disease or abscesses in the neck. The appearance of abscesses may be misleading on ultrasonography, and they may be underdiagnosed. We recommend CT for confirming the diagnosis of a neck abscess or suppurative adenitis and for delineating the extent of disease. In selected cases, ultrasound may be used to guide aspiration or drain placement.

Lipomas

Lipomas are the most common benign mesenchymal tumor. They can arise in any location where fat is located.

FIGURE 37-28 Carotid body paraganglioma. A large mass with vascular channels (*small arrows*) fills the crotch of the carotid artery, splaying the external carotid artery (*large curved arrow*) and the internal carotid artery (*large straight arrow*).

Fifteen percent of all lipomas occur in the head and neck. They are uncommon in children and most commonly present in the fifth and sixth decades. They are multiple in 5% of cases.

Clinical examination is often insufficient to identify the nature and exact origin of the mass, in which case imaging is necessary. The sonographic appearance of head and neck lipomas appears to be characteristic.[91, 92] Ahuja and coworkers found that head and neck lipomas are compressible. In most cases they are well-defined, elliptical masses parallel to the skin surface and hyperechoic relative to adjacent muscle. They typically have linear echoes at right angles to the ultrasound beam and display no distal enhancement or attenuation.[89] FNAC may be indicated if the diagnosis is not compatible with clinical symptoms. CT or MR imaging may be indicated to show the extent of the mass.

The differential diagnosis of lipoma includes epidermoid cysts, branchial cleft cysts, thyroglossal duct cysts, hemangiomas, and lymph nodes. In epidermoid, branchial cleft, and thyroglossal cysts, the linear echogenic lines so characteristic of a lipoma are not seen.[91] Hemangiomas may have a similar shape and similar echogenic lines but are hypoechoic, with a heterogeneous echo pattern, and contain cystic and sinusoidal spaces as well as the occasional phlebolith.[93] Normal nodes in the neck are hypoechoic and may have an anechoic hilum. Nodes from papillary carcinoma are hyperechoic relative to adjacent muscle. However, they do not have echogenic lines parallel to the skin surface.[94]

Neurogenic Tumors

Neurogenic lesions are relatively rare. The most commonly encountered neurogenic tumors in the neck are schwannomas, neurofibromas, and paragangliomas. Small neurofibromas and schwannomas appear as solid nodules. However, the diagnosis can be obtained with high certainty by performing MR imaging.

Color Doppler ultrasound may suggest the diagnosis of paraganglioma by showing flow in the vascular channels and the characteristic relationship of the mass to the carotid arteries (Fig. 37-28). Sonographic findings alone are insufficient for a conclusive diagnosis of these tumors. In practice, the value of ultrasound appears limited compared to MR imaging and angiography for the diagnosis of paraganglioma.

THE ROLE OF ULTRASOUND FOR EVALUATION OF INFANTS AND YOUNG CHILDREN

Ultrasound examination of neck masses in infants and children is very useful and is often the initial imaging modality.[95, 96] It provides immediate information regarding the location of a mass and determines whether the mass is cystic or solid. An indication of blood flow to the lesion can be assessed by color Doppler. Ultrasound is especially useful for soft, fluctuant masses (i.e., lymphangiomas, hemangiomas, and lipomas), because the ultrasonographic pattern of each of these lesions is quite distinct.

The characteristic appearance of many cystic lesions, including branchial cleft and thyroglossal duct cysts, has been discussed. Cystic hygromas or lymphangiomas are predominantly cystic, with multiple septations and loculations that can be variable in size.[96] Hemangiomas are solid lesions and are the most variable of all of these lesions sonographically; the appearance depends mainly on the size of vascular lesions. Cavernous hemangiomas consist of feeding vessels and larger sinuses that are seen as round or linear hypoechogenic areas within the otherwise echogenic mass (Fig. 37-29). Color Doppler imaging readily detects flow within this type of hemangioma. Capillary hemangiomas usually consist of small vessels that are not clearly resolved with ultrasound, giving the lesion a coarse, echogenic aspect.[96] Hemorrhage may occur often in lym-

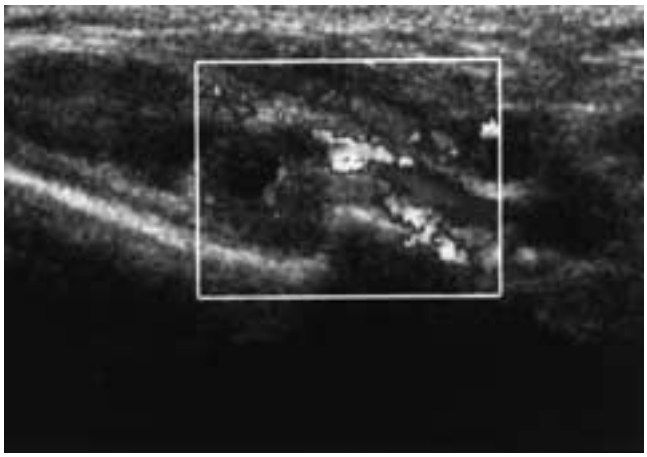

FIGURE 37-29 Cavernous hemangioma. Duplex Doppler ultrasonography shows a large, inhomogeneous lesion consisting of feeding vessels and larger sinuses that are seen as round or linear vascular areas. (Courtesy of Dr. F.J.A. Beek.)

FIGURE 37-30 Fibromatosis colli. Oblique coronal ultrasound-image (**A**) shows that part of the caudal area (*curved arrow*) of the sternocleidomastoid muscle is enlarged. The axial image (**B**) shows the abnormality in the sternocleidomastoid muscle (*curved arrows*), which is slightly inhomogeneous and isoechoic. (Courtesy of Dr. F.J.A. Beek.)

phangiomas. If it is present, the normal anechoic fluid may become echogenic. Generally, CT or MR imaging is indicated in fluctuant lesions to demonstrate the extent of disease, particularly infiltration of surrounding structures.[96]

Fibromatosis colli or fibroma is a common benign tumor in a young infant (Fig. 37-30). Ultrasonography often shows an oval echogenic mass located in the sternocleidomastoid muscle. The clinical picture of torticollis combined with this ultrasound appearance secures the diagnosis.

In infants, carotid body tumors, malignant tumors of the neck such as sarcomas and neuroblastoma, may occur but are relatively uncommon. On ultrasonography, malignant tumors generally are echogenic, but if necrosis occurs, hypoechoic foci may be scattered throughout the tumor. CT and particularly MR imaging are usually required for delineation of the tumor extent.

INTRODUCTION

By the 1930s, the parapharyngeal and masticator spaces had been described; their anatomy is presented in Chapter 34.[1–5] In the past few decades, further refinement of knowledge regarding their anatomy has helped explain either the containment or spread of diseases affecting these spaces.[6–9] As pathology, either inflammatory or neoplastic, involving one of these spaces often affects the other, it is appropriate to discuss these two important spaces together.

CLINICAL AND IMAGING ASSESSMENT OF THE PARAPHARYNGEAL SPACE

Of the two spaces, the parapharyngeal space is the more difficult to examine clinically, as it lies buried deep in the upper neck. It is immediately lateral to the pharynx and deep to the mandibular ramus, the pterygoid muscles, and the parotid gland (Figs. 38-1 and 38-2). Thus protected, it is often only by bimanual palpation that one can detect clinically even a moderate-sized mass (1 to 1.5 cm). When a mass becomes sufficiently large, usually 1.5 to 4 cm, it initially displaces the lateral pharyngeal wall and tonsil medially and then pushes the parotid gland laterally. It is only when a very large parapharyngeal space mass (5 to 6 cm) fills the entire space that a fullness near the angle of the mandible can be detected clinically. Thus, clinical evaluation of this space is quite limited, and over the past three decades the clinician has turned to the radiologist for help in assessing pathology in this region.

Prior to the CT era, very limited radiologic information could be gleaned from plain films and multidirectional tomograms. The degree of lesion vascularity could be identified on a conventional angiogram; however, only a lesion such as a paraganglioma, with its characteristic

VIEW IMAGE

hypervascular appearance, or an aneurysm could be confidently diagnosed. A lesion could also be identified as being hypovascular, but a salivary gland tumor could not be differentiated from a schwannoma or other such pathology. If there was parotid gland fullness, a conventional sialogram could, in most cases, distinguish an intraparotid from an extraparotid mass. This was accomplished by noting if the parotid ducts encircled the mass completely or only partially. A completely encircled mass arose within the parotid gland, while a partially encircled mass could be of either intraparotid or extraparotid origin. Using this diagnostic approach, it is estimated that a preoperative diagnosis was possible in only 20% to 40% of cases and necessitated performing angiograms and sialograms on virtually all patients.[10–15]

In the late 1970s, the clinical application of CT scanning to head and neck lesions allowed the radiologist for the first time to visualize directly a soft-tissue mass in the parapharyngeal space. However, the relatively low resolution of these early CT scanners made the use of CT sialography necessary to clearly identify the parotid gland parenchyma and to distinguish it from the fat in the parapharyngeal space.[16–18] When high-resolution CT scanners were developed, CT sialography was no longer required to accomplish this localization.[7, 19]

Concurrent with the development of CT scanning, surgery also experienced new advances. Prior to the late 1970s, all parapharyngeal space lesions were approached via a parotid incision, regardless of whether or not the tumor was truly of parotid origin. This approach reflected the surgeon's belief that a confident preoperative distinction between an intraparotid and an extraparotid mass could not be made. As most of these tumors were parotid in origin, a transparotid approach was deemed necessary to protect the facial nerve. However, even in the best hands, manipulation of this nerve was accompanied by a small but significant morbidity. If this could be avoided, it would be better for patient and physician alike.

In the late 1970s and early 1980s the surgical philosophy changed, in part, because of the new developments in sectional imaging. If the surgeon could know preoperatively that a mass was extraparotid in origin, then a transcervical approach could be used without manipulation of the facial nerve (Fig. 38-3). The result was that only those patients with true intraparotid tumors would require a transparotid approach.[7, 20] Because of this new surgical concept, the surgeon relied even more on the imaging diagnosis, and this in turn prompted the radiologist to develop sectional imaging criteria that distinguished intraparotid from extraparotid masses.

The most reliable CT criterion used to make this distinction was the observation of the effect of a mass on the fat within the prestyloid compartment of the parapharyngeal space. If this fat was seen separating the deep portion of the parotid gland and a mass on all axial scans through the lesion, the mass was of extraparotid origin. If this fat was not visualized on all scans, the lesion was probably of parotid origin. However, a very large extraparotid mass could so compress this fat that the fat was not seen on CT. Assessing these circumstances, most surgeons concluded that if the fat plane was not seen on all scans, a transparotid approach should be used to protect the facial nerve during surgery.

CT also provided information about the internal architecture of the lesion, so that a solid mass could be differentiated from a cystic one, and the size of the mass could be accurately evaluated for proper surgical planning. In addition, clinically silent lymph nodes or other pathology could be identified.

Dynamic CT also gave information on the rate of contrast enhancement within a lesion. This enhancement may result either from the progressive extravascular accumulation of contrast material in a hypovascular mass (a schwannoma or salivary gland tumor) or from the rapid intravascular accumulation of contrast in a hypervascular mass (a paraganglioma).[8, 21, 22] To differentiate between a vascular and a hypovascular mass, dynamic scans

In particular, note the relationship of the masticator space to the parapharyngeal space and the temporal extension of the masticator space.

must be obtained during the vascular filling phase, which occurs within the first seconds after contrast administration. After this time, the contrast is in an equilibration phase in both vascular and hypovascular lesions, and any distinction between the mode of contrast accumulation is impossible (Fig. 38-4).

Hypervascular lesions have a very rapid filling phase and, because of their rich venous drainage, a rapid washout phase. By contrast, hypovascular lesions have a slow ''shoulder'' of contrast filling and, because of a paucity of veins, a prolonged washout phase. Thus, on scans taken after the contrast filling phase, the hypovascular mass often has more retained contrast than the hypervascular lesion and on CT appears more enhanced. For this reason, routine contrast-enhanced CT scans should not be used to critically assess lesion vascularity.

As a result of these advances, radiologists were now able to improve the rate of preoperative diagnosis of parapharyngeal space masses to 80% to 90%. In most cases, parotid tumors could now be distinguished from extraparotid lesions and paragangliomas could be distinguished from hypovascular tumors. However, the confident differentiation of a schwannoma from an extraparotid salivary gland tumor remained impossible.

MR imaging provided an even more reliable distinction between intraparotid and extraparotid lesions, and it allowed differentiation between most schwannomas and extraparotid salivary gland tumors. This was possible because compared to CT, MR imaging more consistently visualized the parapharyngeal space fat, and the internal carotid artery (ICA) was more reliably identified by its MR signal flow void than by its enhancement on CT.[9, 23–26] The more consistent visualization of the ICA was key to the imaging differential diagnosis, as both parotid and extraparotid salivary gland tumors displaced the ICA posteriorly. By comparison, the paragangliomas and most schwannomas displaced the ICA anteriorly.[8, 27–35] An additional advantage of MR imaging over CT was the observation that the contour of a mass was usually better identified on MR imaging, and

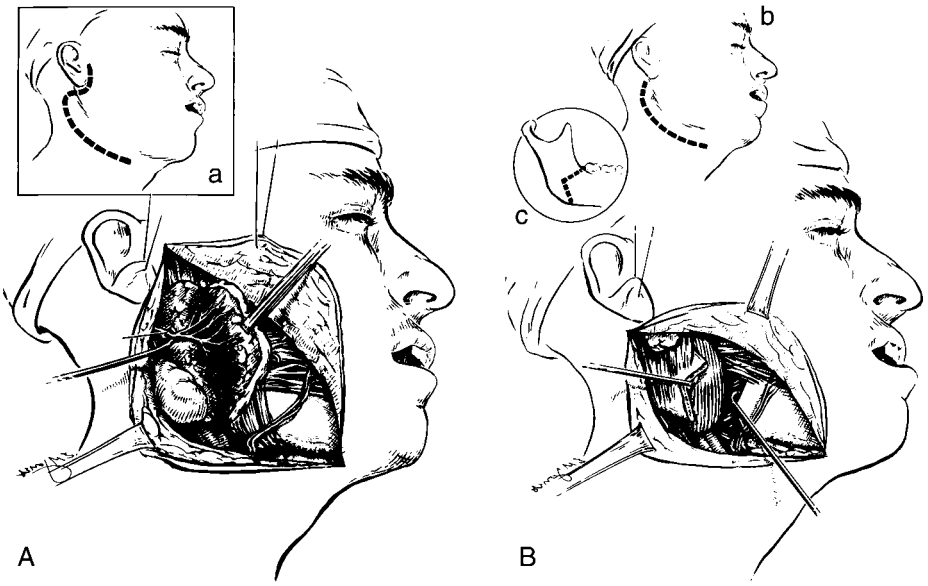

FIGURE 38-3 Diagrams of the right neck illustrating the typical parotid incision (a) and the typical parotid exposure of the facial nerve (**A**). The typical transcervical incision is shown in (b) and the typical transcervical exposure is illustrated in **B**. Note that in the transcervical exposure, the facial nerve is not within the surgical field. A variety of mandibular surgical maneuvers allow delivery of the intact tumor. An angle mandibulotomy is illustrated in (c).

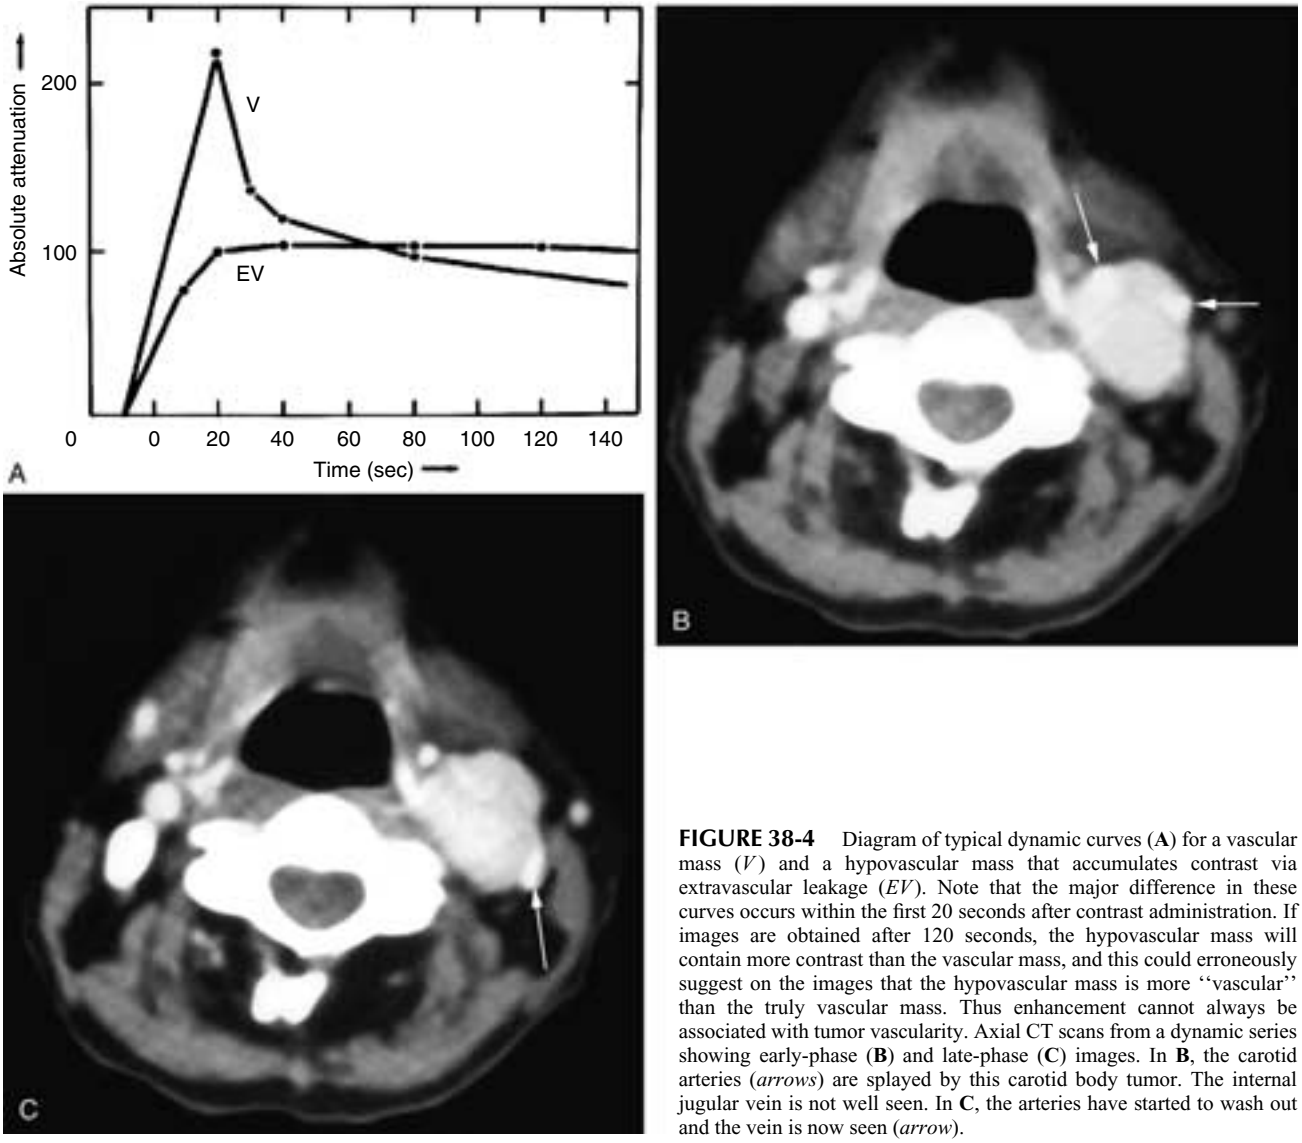

FIGURE 38-4 Diagram of typical dynamic curves (**A**) for a vascular mass (*V*) and a hypovascular mass that accumulates contrast via extravascular leakage (*EV*). Note that the major difference in these curves occurs within the first 20 seconds after contrast administration. If images are obtained after 120 seconds, the hypovascular mass will contain more contrast than the vascular mass, and this could erroneously suggest on the images that the hypovascular mass is more ''vascular'' than the truly vascular mass. Thus enhancement cannot always be associated with tumor vascularity. Axial CT scans from a dynamic series showing early-phase (**B**) and late-phase (**C**) images. In **B**, the carotid arteries (*arrows*) are splayed by this carotid body tumor. The internal jugular vein is not well seen. In **C**, the arteries have started to wash out and the vein is now seen (*arrow*).

VIEW IMAGE

the smooth contours of a paraganglioma could be differentiated from the invasive margins of a vascular metastasis.[9] Lastly, with MR imaging, moderate- to large-caliber, rapid-flow vessels could be identified by their flow voids, using flow-sensitive sequences, or by MR angiography. Only small-caliber, slow-flow vessels could not be visualized on MR imaging; their identification required conventional angiography.

At present, if the radiologist utilizes both clinical and imaging information, a correct preoperative diagnosis can be made in 90% to 95% of patients with a parapharyngeal space mass. These figures reflect the dramatic influence that CT and MR imaging have had on the diagnosis and surgical planning of these cases.

Inherent in the imaging localization of a parapharyngeal space mass is a precise assessment of the size of the lesion, as this helps determine the surgical approach.[36] This information applies primarily to the deep parotid masses; this topic is discussed in Chapter 39.

PARAPHARYNGEAL SPACE ANATOMY

The anatomy of the parapharyngeal space is discussed in detail in Chapter 34. In summary, the parapharyngeal space extends on either side of the neck from the skull base to the styloglossus muscle at the level of the angle of the mandible. The space extends along the sides of the nasopharynx up to the pterygomandibular raphe anteriorly. The parapharyngeal space is separated from the retropharyngeal space by the sagittally oriented cloison sagittale fascia. It is also separated from the danger space by the deep layer of the deep cervical fascia (Figs. 38-1, 38-2, and 38-5).

Each fat-filled parapharyngeal space is subdivided by the tensor-vascular-styloid fascia into a prestyloid and a retrostyloid compartment. For the purposes of this discussion, the carotid sheath will be considered to be in the retrostyloid compartment, as described in Chapter 34. The deep portion of the parotid gland bulges into the lateral aspect of the prestyloid compartment, extending through the

Copyright © 2003, Mosby, Inc. All rights reserved.

stylomandibular tunnel anterior to the styloid process, the styloid muscles, and the retrostyloid compartment.

CLINICAL PRESENTATIONS OF PARAPHARYNGEAL SPACE MASSES

The most pliable border of the parapharyngeal space is its medial wall. The pharyngeal constrictor muscles are immediately adjacent to the medial aspect of the prestyloid compartment of the parapharyngeal space. Most masses greater than 1.5 cm in diameter cause some medial displacement of the nasopharyngeal and oropharyngeal walls, often depressing the ipsilateral soft palate.

Most of the lateral wall of the parapharyngeal space is rigid, supported by the ramus of the mandible and the pterygoid muscles. However, long-standing lesions can remodel the mandible, displacing it laterally and anteriorly. The only truly pliable portion of the lateral wall is where the retromandibular portion of the parotid gland protrudes into the prestyloid compartment, and almost any parapharyngeal space mass can displace this gland laterally. In such cases, a clinician may mistake an extraparotid mass, and its resulting parotid fullness, for a parotid lesion. Only a very large parapharyngeal space mass can distend the most caudal aspect of this space, producing a fullness near the angle of the mandible.[15, 18, 37–41] If the lesion is large enough, the temporomandibular joint may also be dislocated.

Parapharyngeal space masses produce relatively few symptoms, which may explain why such lesions often grow

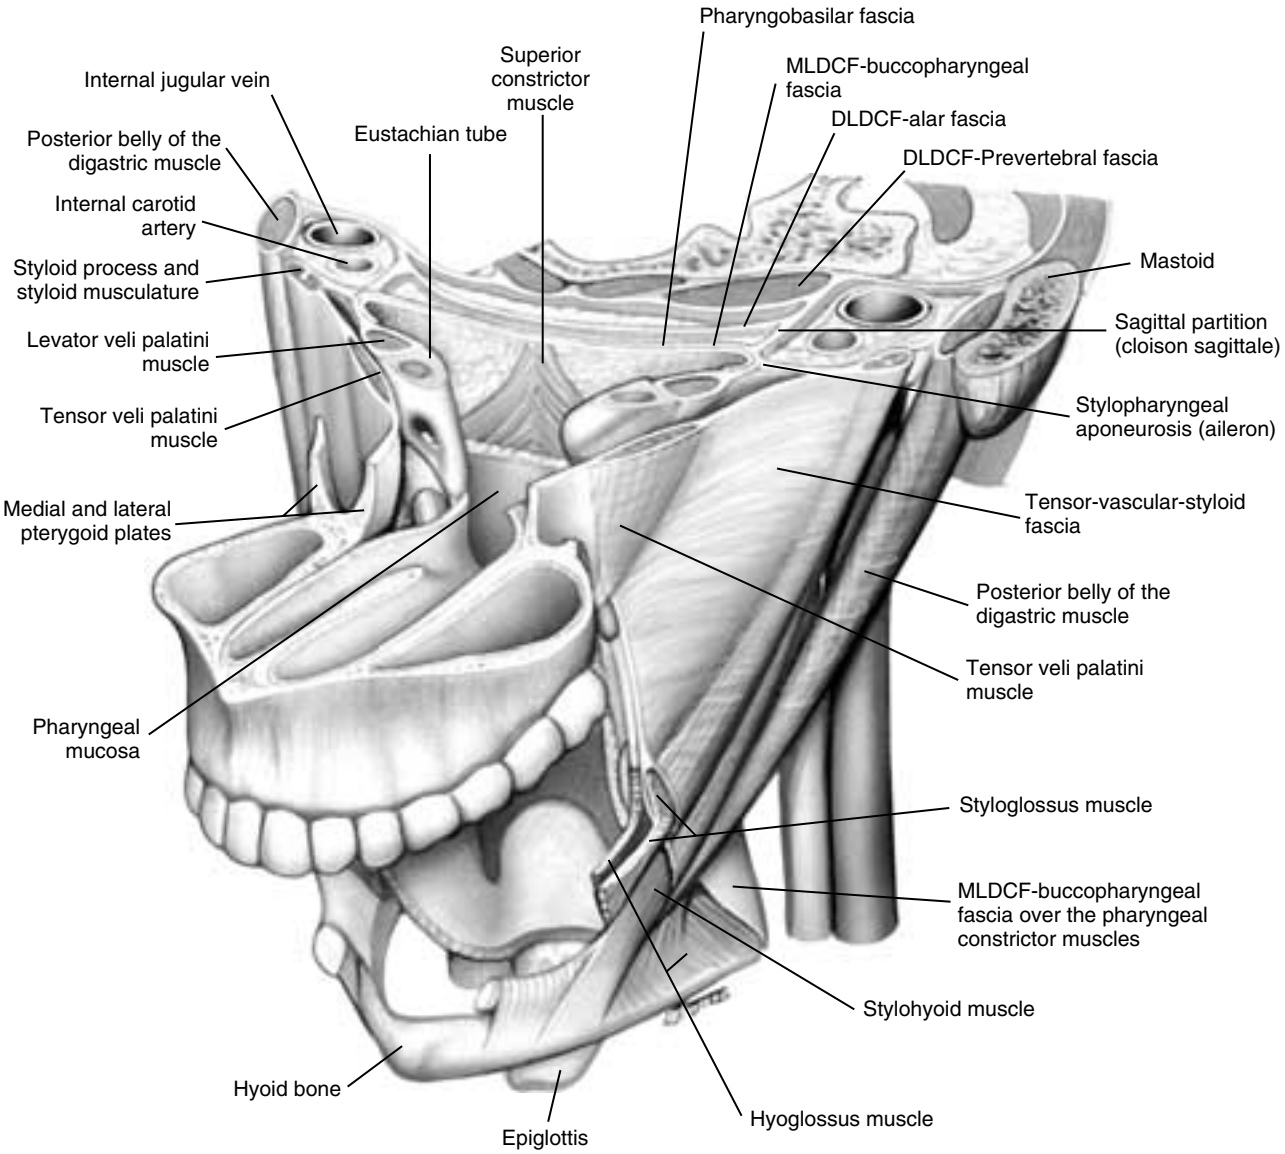

FIGURE 38-5 Drawing of the face and upper neck as seen from the left oblique view and from above. The parotid glands and the masticator space structures have been removed, as has the fat in the prestyloid compartment of the parapharyngeal space. This fat would have been just lateral to the tensor-vascular fascia. A horizontal cut has been made just below the level of the skull base, and an additional horizontal cut has been made through the lower maxillary sinuses, removing the facial structures.

to 4 to 6 cm in diameter before diagnosis. The displacement of the pharyngeal wall and the parotid gland rarely produces pain, and these masses are usually discovered incidentally either by the patient or by a clinician during a routine examination. However, patients with parapharyngeal space masses may have specific complaints such as sore throat, a change in voice quality, dysphagia, trismus, nasal obstruction, or a sensation of aural fullness. With schwannomas, paragangliomas, and malignant lesions, deficits of any or all of the last four cranial nerves may occur, and if the skull base is involved by a malignancy or an infection, headache or local pain may be present.[13, 41, 42]

In terms of imaging, the most important landmarks to note when evaluating a parapharyngeal space mass are (1) the deep portion of the parotid gland and the stylomandibular tunnel region; (2) the ICA, its size, shape, and the direction of any displacement; (3) the direction of any displacement of the fat of the prestyloid compartment; and (4) the effect of a mass on the surrounding structures, including the pharynx, masticator space, mandible, and skull base.

A discussion of the differential diagnoses of diseases that affect the prestyloid and retrostyloid compartments of the parapharyngeal space follows. A summary of these differential diagnoses is given in Tables 38-1 and 38-2.

Table 38-1
PARAPHARYNGEAL SPACE MASSES: PRESTYLOID COMPARTMENT

Tumors of Salivary Gland Origin	
Deep portion of parotid gland	
Common benign:	pleomorphic adenoma
Rare malignant:	mucoepidermoid carcinoma
	adenoid cystic carcinoma
	acinic cell carcinoma
Salivary rest:	pleomorphic adenoma
Lipoma	
Prominence of Pterygoid Venous Plexus	
Common:	normal variant
Uncommon:	reflecting venous hypertension in the neck
Branchial Cyst	
Abscess Of:	
Pharyngeal origin (primarily tonsillitis)	
Parotid origin (acute sialadenitis)	
Masticator space origin (primarily odontogenic in origin)	
Extension of abscess in lower neck	
Spread From:	
Pharyngeal tumor:	squamous cell carcinoma
	minor salivary gland carcinoma
	lymphoma
	common: non-Hodgkin's lymphoma
	uncommon: Hodgkin's lymphoma
Metastatic nodes:	level II nodes
	retropharyngeal nodes
Parotid tumor:	mucoepidermoid carcinoma
	squamous cell carcinoma
	adenocarcinoma not otherwise specified
Masticator space tumor:	metastatic squamous cell carcinoma
	sarcoma
Intracranial origin:	meningioma
	rare glioma
Skull base:	osteochondroma
	osteoma
	chondrosarcoma
	chordoma
Neurogenic Tumor	
Uncommon: schwannoma, usually of the sympathetic plexus	
Rare: neurofibroma	

IMAGING PATHOLOGY AFFECTING THE PARAPHARYNGEAL SPACE

Diseases and Tumors Arising in the Parapharyngeal Space

Infections

Most infections that involve the parapharyngeal space arise in adjacent spaces and spread via the parapharyngeal space pathway to other areas. In one series, 50% of the patients with abscesses in the parapharyngeal space had received antibiotics for an infection of the ear, nose, or throat prior to the development of the abscess.[43] In another study, most patients had a history of a recent upper aerodigestive tract infection, especially tonsillitis, with or without treatment, prior to the spread of disease to the parapharyngeal space. The most common isolates were *Streptococcus*, *Staphylococcus*, *Bacteroides*, *Micrococcus*, *Neisseria*, *Candida*, *Enterobacter*, *Enterococcus*, *Peptostreptococcus*, *Proteus*, *Proprionobacter*, and *Pseudomonas*. There were patients with no growth on culture but with organisms found on Gram's stain. The main complications of parapharyngeal space infections were jugular vein thrombosis, carotid artery aneurysm and rupture, mediastinitis, and, rarely, meningitis from a large retropharyngeal-parapharyngeal space abscess.[43]

In another study of adult patients, the distribution of abscesses in the major deep spaces of the neck was five sublingual, four parapharyngeal, three retropharyngeal, three submaxillary, three visceral, and one in the deep posterior triangle. The source of infection was odontogenic in six patients, pharyngeal in three, otogenic in one, and not identified in six. Most patients presented with pain and neck swelling; a positive culture was obtained in only 56.2%, with no predominant organism identified. Antibiotic therapy and surgical drainage were the mainstay of treatment, and two cases were complicated by internal jugular vein thrombophlebitis.[44]

In one review, intraoperative findings confirmed the CT diagnosis of parapharyngeal space abscess in 76.3% of the patients. The false-positive rate was 13.2%, and the false-negative rate was 10.5%. The sensitivity of CT for detection of parapharyngeal space or retropharyngeal space abscess was 87.9%. This study's documentation emphasizes the importance of correlating the imaging interpretation with the clinical examination findings before surgical intervention, a belief shared by most clinicians.[45, 46]

In still another study, the spaces involved by abscesses were the peritonsillar space (72 patients), the parapharyngeal space (8 patients), the submandibular space (7 patients), the retropharyngeal space (1 patient), the subcutaneous region (1 patient), the anterior visceral compartment (1 patient), and the carotid sheath (1 patient). Of the 19 patients who did not have a peritonsillar space infection, the origin of the infection was found in 8, and 4 of these were

Copyright © 2003, Mosby, Inc. All rights reserved.

odontogenic. Thirty-eight patients required surgical drainage of the abscess, and five patients underwent a tracheotomy for dyspnea. The combination of early imaging diagnosis, effective antimicrobial therapy, and intensive surgical management contributed to the good prognosis.[47]

Finally, in a study involving the incidence of deep space abscesses in children, peritonsillar abscesses were the most common (49%), followed by retropharyngeal (22%), submandibular (14%), buccal (11%), parapharyngeal (2%), and mandibular (2%) space infections. The most common pathogens isolated were the aerobes beta-hemolytic streptococcus (18%) and *Staphylococcus aureus* (18%), the anaerobes *Bacteroides melaninogenicus* (17%) and *Veillonella* (14%), and the gram-negative organism *Haemophilus parainfluenzae* (14%). Beta-lactamase production by aerobic pathogens was detected in 22% of cultures. In this study, the sensitivity of CT in detecting the presence of an abscess versus cellulitis was high (91%); however, the specificity was low (60%). It was concluded that the treatment of head and neck space infections in children should consist of accurate physical diagnosis aided by imaging studies, empiric antibiotic therapy that covers gram-negative and beta-lactamase-producing organisms as well as gram-positive organisms and anaerobes, and timely surgical intervention when indicated.[48]

Thus, most infections that result in a parapharyngeal space abscess arise either in the palatine tonsil or pharynx or are odontogenic in origin. The CT findings of cellulitis involving the parapharyngeal space are those of ''dirty'' fat and often some swelling of the fat in the prestyloid compartment (Fig. 38-6). On MR imaging, there usually is a decrease in the normal high T1-weighted signal intensity of fat and an increase in the T2-weighted signal intensity due to fluid accumulation.

Identification of an abscess is the critical contribution that imaging adds to these cases. The abscess cavity, as elsewhere in the body, has a low-attenuation necrotic, pus-filled center with a thick, irregular, enhancing rim on CT. On MR imaging, the central pus or necrotic region has a low or intermediate T1-weighted and a high T2-weighted signal intensity, and there is enhancement of a thick, irregular abscess rim. The presence of the abscess rim differentiates phlegmon from an abscess, and this is best identified on a contrast-enhanced study, either CT or MR imaging. In fact, many authors believe that the imaging diagnosis of an abscess should be made only when an enhancing rim is identified about the central region of pus. If no such rim is seen, the imaging diagnosis should be that of phlegmon and cellulitis.

The differentiation of a parapharyngeal space abscess from cellulitis is clinically important because an abscess should be drained expeditiously, as a mycotic aneurysm of the internal carotid artery has been reported to occur in as few as 10 days after the development of such an abscess. On the other hand, surgical exploration of cellulitis in the vain pursuit of a nonexistent abscess is inadvisable.[49, 50]

Tumors

Almost all of the tumors that occur in the parapharyngeal space arise either from the deep portion of the parotid gland

Table 38-2
PARAPHARYNGEAL SPACE MASSES: RETROSTYLOID COMPARTMENT

Neurogenic Origin:	common:	schwannoma of cranial nerves IX, X, XI, XII
	uncommon:	neurofibroma of cranial nerves IX, X, XI, XII
	rare:	neurosarcoma

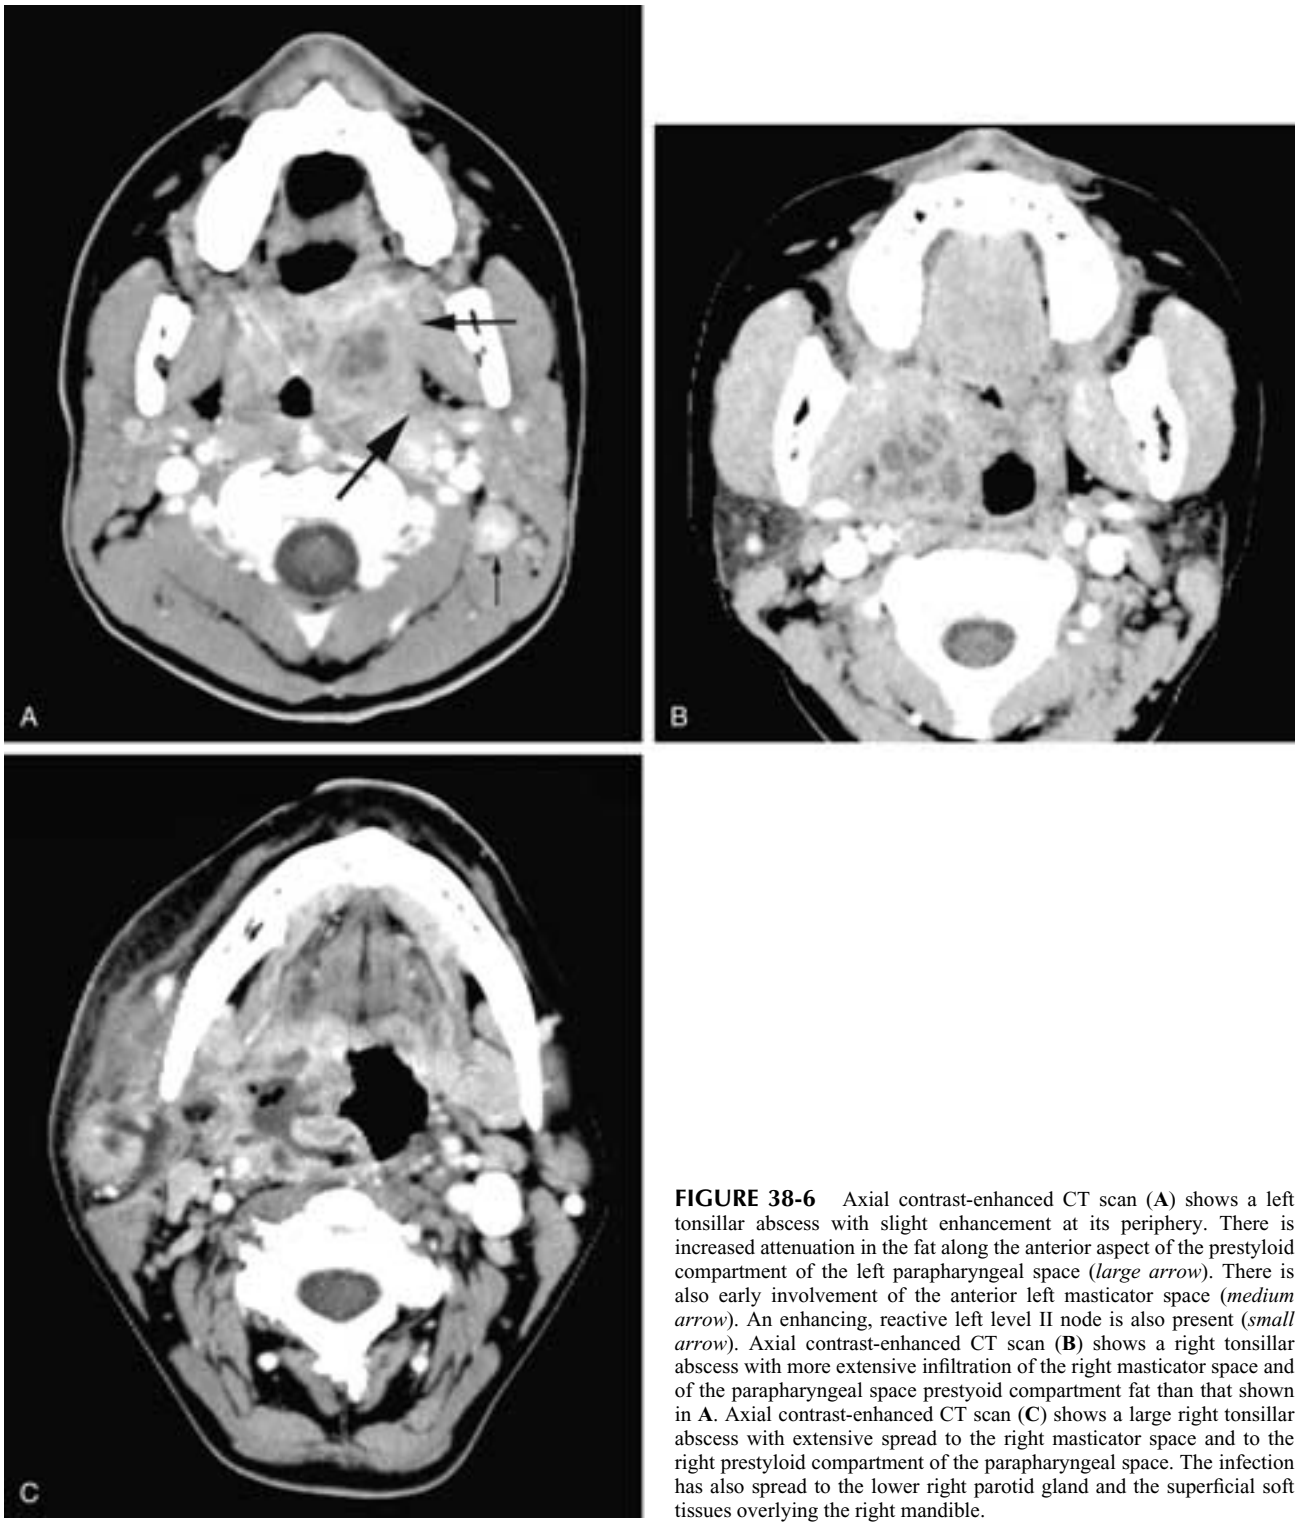

FIGURE 38-6 Axial contrast-enhanced CT scan (**A**) shows a left tonsillar abscess with slight enhancement at its periphery. There is increased attenuation in the fat along the anterior aspect of the prestyloid compartment of the left parapharyngeal space (*large arrow*). There is also early involvement of the anterior left masticator space (*medium arrow*). An enhancing, reactive left level II node is also present (*small arrow*). Axial contrast-enhanced CT scan (**B**) shows a right tonsillar abscess with more extensive infiltration of the right masticator space and of the parapharyngeal space prestyoid compartment fat than that shown in **A**. Axial contrast-enhanced CT scan (**C**) shows a large right tonsillar abscess with extensive spread to the right masticator space and to the right prestyloid compartment of the parapharyngeal space. The infection has also spread to the lower right parotid gland and the superficial soft tissues overlying the right mandible.

VIEW IMAGE

in the prestyloid compartment or from neural–related elements in the retrostyloid compartment. Although statistically the most common masses in the parapharyngeal space are hyperplastic or metastatic level II lymph nodes, they are not included in most clinical series of parapharyngeal space masses, as they are not considered to be primary lesions of this space. The imaging of such lymph nodes is discussed in Chapter 36. They are mentioned in this chapter only as they pertain to the differential diagnosis of other parapharyngeal space masses. There are also a number of reviews of imaging of the parapharyngeal space. They all agree that MR imaging should be the initial study of choice and that CT is better for detecting the presence of early bone changes and calcifications.[9, 27, 51–55]

VIEW IMAGE

FIGURE 38-7 Drawing of a lateral view of the left side of the mandible and skull base. The stylomandibular ligament (*arrow*) is shown extending from the styloid process to the inner aspect of the ramus of the mandible. The curved arrow extends through the stylomandibular tunnel. It is through this tunnel that the deep portion of the parotid gland extends. This always places this portion of the parotid gland ventral to the styloid process and its muscles. Since the carotid sheath (or retrostyloid compartment of the parapharyngeal space) is dorsal to the styloid process, the ICA is always dorsal to the deep portion of the parotid gland.

Salivary Gland Tumors

The most common primary neoplasms to arise in the parapharyngeal space are of salivary gland origin. These include tumors arising in the parotid gland, in salivary rests within the prestyloid compartment fat of the parapharyngeal space, and in the minor salivary glands of the pharyngeal mucosa. As a group, they account for 40% to 50% of all parapharyngeal space masses, and 80% to 90% of these tumors are benign pleomorphic adenomas. The most common malignancies are mucoepidermoid carcinomas, adenoid cystic carcinomas, and acinic cell carcinomas. Hughes et al. found that 40% of their series were benign salivary gland tumors and 13% were malignant salivary gland lesions.[56] Those salivary gland tumors that arise in the pharyngeal mucosa and then spread into the parapharyngeal space are not usually considered in the analysis of parapharyngeal space lesions. Those tumors are discussed in Chapter 28.

The vast majority of primary tumors affecting the parapharyngeal space arise from the deep portion of the parotid gland, and almost all of them are pleomorphic adenomas. The next most common benign lesions arise in extraparotid salivary rests in the prestyloid compartment fat, and they are also predominantly pleomorphic adenomas. The tumors that arise from the pharyngeal mucosal minor salivary glands are primarily malignant, and they, along with nasopharyngeal carcinoma, account for most of the malignancies that affect the parapharygneal space.

The deep or retromandibular portion of the parotid gland (deep to the facial nerve) lies behind and just medial to the mandibular ramus (Fig. 38-1). The parotid gland actually passes through the rigid stylomandibular tunnel, whose margins are the posterior edge of the ramus of the mandible, the undersurface of the middle cranial fossa, and the styloid process and stylomandibular ligament (Fig. 38-7). Thus, the deep portion of the parotid gland lies in the lateral aspect of the prestyloid compartment of the parapharyngeal space and anterior to the retrostyloid compartment and the internal carotid artery.[8, 27] Most of the tumors arising in the deep portion of the parotid gland are roughly ovoid in shape; however, occasionally they have a dumbbell shape, with the waist of the tumor lying in the plane of the rigid stylomandibular tunnel (Figs. 38-8 and 38-9). In such dumbbell tumors, the deep portion of the mass is often clinically unappreciated, and imaging studies are necessary to fully identify the extent of the lesion. Most surgeons believe that any large or relatively immobile parotid mass requires an imaging study so that the palpable portion of the mass is not clinically misinterpreted as representing the entire tumor.

An unusual case of a Warthin's tumor of the deep portion of the parotid gland was reported, with extensive protrusion into the parapharyngeal space. The tumor was partially cystic and had the MR imaging characteristics suggestive of a Warthin's tumor, as discussed in Chapter 39. This is an atypical location for this tumor, and rarely does it grow large enough to present as a parapharyngeal space mass.[57]

On imaging, pleomorphic adenomas have noninfiltrating margins. When small, they are spherical in shape and primarily homogeneous (Figs. 38-8 and 38-9). When larger than 1.5 to 2 cm in diameter, they tend to develop lobulated contours; are nonhomogeneous, with sites of cystic degeneration and necrosis; and may contain areas of hemorrhage (Fig. 38-10). Occasionally calcification within the tumor

FIGURE 38-8 Drawing of a large pleomorphic adenoma of the deep portion of the left parotid gland as viewed from obliquely and above. The mass displaces the pharyngeal wall toward the midline and lies anterior to the internal carotid artery. See Figure 38-1B.

FIGURE 38-9 Axial contrast-enhanced CT scan (**A**) shows a pleomorphic adenoma (*arrows*) with near-water attenuation in the deep portion of the left parotid gland extending into the prestyloid compartment of the parapharyngeal space. The mass has displaced the internal pterygoid muscle (*M*) ventrally and had widened the stylomandibular tunnel. *S* represents the styloid process. The left pharyngeal wall has been displaced medially. Axial T1-weighted, fat-suppressed, contrast-enhanced MR image (**B**) shows a slightly dumbbell-shaped pleomorphic adenoma extending from the deep portion of the left parotid gland into the prestyloid compartment of the parapharyngeal space. The waist of the tumor is at the level of the rigid stylomandibular tunnel.

matrix—not around the periphery, as seen in aneurysms—is present; rarely, areas of ossification can occur (Fig. 38-11). Typically, the cystic areas are small and multiple rather than large and solitary. If the mass has a solitary large cystic region with a thin, fairly uniform wall and a localized tumor nodule, a Warthin's tumor is a more likely diagnosis. If the mass has a large central cystic region with thick, irregular walls, a high-grade malignancy is a more likely diagnosis.

On CT, pleomorphic adenomas are of a soft-tissue attenuation. The cystic and necrotic areas are of a lower attenuation, while calcifications, or the rare ossification, are clearly seen as high-attenuation regions. However, the contours of the tumor are better identified on MR imaging than on CT and, regardless of homogeneity, overall these tumors have low to intermediate T1-weighted and high T2-weighted signal intensities. If the tumor suddenly increases in size, hemorrhage has probably occurred. Because it is unusual for patients to come to scanning with fresh intratumoral hemorrhage, most such hemorrhagic sites are usually more than a day old and have high T1-weighted and high T2-weighted signal intensities (Fig. 38-10D). If fresh blood is imaged, the appearance is similar to that of necrosis and cystic change, with low T1-weighted and high T2-weighted signal intensities.

If a tumor is seen on imaging to lie in the prestyloid compartment of the parapharyngeal space and there is no intervening fat between the tumor and the parotid gland, the tumor must be considered to arise from the parotid gland. Actually, one of four possibilities may account for the nonvisualization of the fat: (1) the tumor is truly of parotid origin (about 80% of cases); (2) the tumor is extraparotid but is so large that it compresses the fat, preventing its identification on the images; (3) the tumor is adherent to the gland's capsule but not truly arising from the parotid gland (about 20% of cases); or (4) the tumor is extraparotid but has invaded the parotid gland. The last is considered a rare occurrence. In all of these cases, most surgeons employ a transparotid approach to protect the facial nerve from inadvertent damage during surgery.

In some patients, only a thin isthmus of tissue can be seen connecting the parotid gland to the pedunculated parapharyngeal space portion of the tumor (Fig. 38-9B). If this isthmus is not identified on the images, an erroneous diagnosis of an extraparotid tumor could be made, and this could lead the surgeon to approach the tumor from the neck. However, once the tumor is exposed, attempted extirpation through the neck could pull on the attached parotid gland, which in turn would put tension on the facial nerve and lead to avulsion of the nerve. To avoid this problem, thin-section 3-mm contiguous axial scans should be used through the tumor; this soft-tissue detail is much better seen on MR images than it is on CT scans.[9, 27] In almost all of these cases, the fat of the parapharyngeal space will also be seen separating the medial contour of the lesion from the pharyngeal musculature. This indicates that the mass is not arising from the pharyngeal wall. Lastly, if fat is clearly seen surrounding a prestyloid mass, the lesion is not arising either from the parotid gland or from the pharyngeal wall.

Only a relatively few extraparotid, prestyloid compartment, parapharyngeal space salivary gland tumors have been reported, and traditionally they were regarded as developing directly from the minor salivary glands of the pharyngeal wall.[58–60] However, this belief now seems to require a qualifying statement. These tumors are believed to arise

FIGURE 38-10 Axial T2-weighted MR image (**A**) shows a pleomorphic adenoma of the right parotid gland extending into the parapharyngeal space and displacing the right pharyngeal wall across the midline to the left side. The tumor has cystic areas of high signal intensity, and the mass is ventral to the ICA (*arrow*). Axial T1-weighted, contrast-enhanced MR image (**B**) shows a mass in the left parotid gland and parapharyngeal space. Although the fat planes around the tumor are displaced but otherwise normal, the interface of the lesion with the parotid parenchyma is indistinct. This was an adenoid cystic carcinoma. Axial T1-weighted, contrast-enhanced MR image (**C**) shows a large left parapharyngeal space mass that lies anterior to the ICA artery and is inseparable from the deep portion of the left parotid gland. The left pharyngeal wall is displaced far to the right. Parotid pleomorphic adenoma. Axial T2-weighted MR image (**D**) shows the lobulated contour of a left pleomorphic adenoma extending from the deep portion of the parotid gland into the prestyloid compartment of the parapharyngeal space. This silhouette is highly suggestive of a pleomorphic adenoma. Axial T1-weighted MR image (**E**) shows a left parotid pleomorphic adenoma extending into the prestyloid compartment of the parapharyngeal space. Clinically there was a sudden enlargement of this mass. There is an area of high signal intensity in the lateral portion of the tumor, which at surgery was found to be hemorrhage. Axial T1-weighted MR image (**F**) shows a huge mass arising in the left parotid gland and extending into all of the deep spaces of the upper neck. Despite the aggressive appearance of the tumor, at surgery it was diagnosed as a pleomorphic adenoma. This case illustrates that when such tumors become very large, the extreme distortion of the adjacent imaging landmarks may falsely suggest a malignancy.

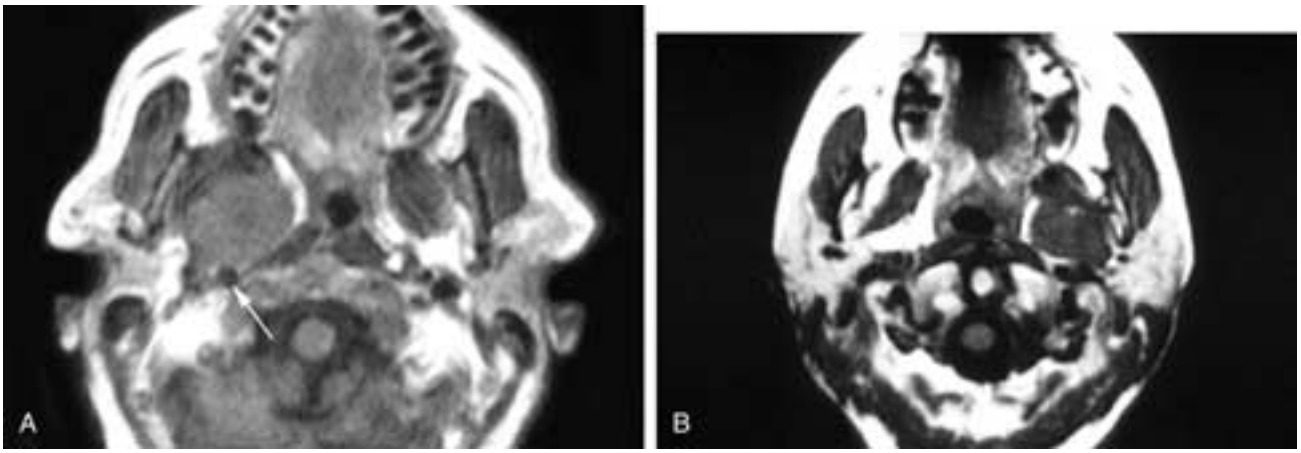
FIGURE 38-11 Coronal contrast-enhanced CT scan (**A**) shows a right pleomorphic adenoma that arose within the deep portion of the parotid gland and extended into the parapharyngeal space. Areas of dystrophic calcification are seen within the tumor matrix, as are areas of cystic degeneration. This appearance is highly suggestive of a pleomorphic adenoma, but occasionally it can be seen in a schwannoma. Coronal CT scan (**B**) viewed at wide window settings shows a circular area of calcification around the periphery of a right parapharyngeal space mass. Note the difference in the pattern of calcification compared to **A**. This was an aneurysm of the ICA. Whenever calcifications are seen at the periphery of a mass, an aneurysm must be ruled out by other studies.

from salivary epithelial rests within the prestyloid compartment fat. Although it was thought that these rests were derivatives of the parotid anlagen migration, it now appears that they may be derived from the minor salivary glands of the pharyngeal mucosa. Since these tumors arise within the prestyloid fat, they have fat on both their medial and lateral margins (Fig. 38-12). These extraparotid tumors are almost always benign pleomorphic adenomas, and their imaging characteristics are those of the parotid pleomorphic adenomas, except that they are located in the prestyloid compartment fat. If the margins of the tumor are not clearly defined, the possibility of an uncommon malignancy must be considered; such tumors are likely to be mucoepidermoid, adenoid cystic, or adenocarcinomas. The rare tumor that arises directly from the pharyngeal wall has fat only on its lateral contour (Fig. 38-13). Most of these tumors are malignancies of the minor salivary glands, and they usually have infiltrative margins into the prestyloid fat.

All of these salivary gland tumors, regardless of whether they arise from the parotid gland, from salivary rests in the prestyloid fat, or from the pharyngeal minor salivary glands, are anterior to the ICA and, if large enough, will displace the ICA posteriorly.[27]

Neurogenic Tumors

Neurogenic lesions comprise 17% to 25% of the lesions. In Hughes et al.'s series, they represented 14% of the cases.[56] Most are schwannomas of the vagus nerve, less



VIEW IMAGE

FIGURE 38-12 Axial T1-weighted MR image (**A**) shows an ovoid mass in the right prestyloid parapharyngeal space fat. A fat plane is present along its medial side, separating it from the pharyngeal constrictor muscles. A fat plane also separates the mass from the parotid gland. This was an extraparotid pleomorphic adenoma arising from minor salivary gland rest cells. The ICA is dorsal to the mass (*arrow*). A rare schwannoma, usually of the sympathetic chain, can also have this imaging appearance. Axial T1-weighted MR image (**B**) shows an ovoid mass in the left prestyloid parapharyngeal space fat. Fat planes are present along both its medial and lateral sides, separating it from the pharyngeal constrictor muscles and the parotid gland. The mass is ventral to the ICA. This was an extraparotid pleomorphic adenoma.

FIGURE 38-13 Drawing viewed obliquely and from above shows a large minor salivary gland tumor arising from the pharyngeal submucosal glands. The mass displaces the prestyloid parapharyngeal space fat and the parotid gland laterally. Since the tumor arises from the mucosal margin of the pharynx, no fat plane is present between the mass and the pharyngeal constrictors.

commonly of the glossopharyngeal nerve, and uncommonly of the superior sympathetic chain. By comparison to schwannomas, neurofibromas are rare, and although they can occur as solitary lesions, they usually are associated with neurofibromatosis (Fig. 38-14). A solitary parapharyngeal space neurofibroma is reported to be one of the rare complications of neurofibromatosis. Such tumors represent less than 5% of all parapharyngeal space neoplasms.[61]

The vagus nerve is situated behind the ICA within the carotid sheath. As a result, tumors of this nerve tend to displace the ICA ventrally and usually medially. The superior sympathetic chain lies along the medial and posterior border of the carotid sheath, and although these tumors may displace the ICA anteriorly, they can also displace it posteriorly.[27] In the latter instance, a sympathetic schwannoma may be indistinguishable on imaging from an extraparotid salivary gland tumor arising in the prestyloid compartment of the parapharyngeal space. Both of these lesions are ovoid, well-defined masses with fat planes on their medial and lateral sides that displace the ICA posteriorly. Thus, the displacement of the ICA is an important imaging finding differentiating tumors of salivary gland origin from the most common schwannomas arising within the parapharyngeal space (Fig. 38-15).

When a schwannoma arises within the jugular fossa, there can be both caudal and cranial growth creating a dumbbell-shaped mass whose waist is at the rigid skull base. Multiple benign schwannomas also rarely occur within the parapharyngeal space.[62–67]

Most schwannomas are fairly homogeneous soft-tissue masses. However, areas of necrosis and hemorrhage can occur, just as in pleomorphic adenomas. Thus, on imaging, with the possible exception of the displacement of the ICA, these two lesions may have the same appearance. By comparison, some neurofibromas undergo significant fatty degeneration and, on imaging, may appear as predominantly lipid-containing lesions (Fig. 38-14A).

As previously discussed, despite the fact that schwannomas are hypovascular, they can enhance significantly on both CT and MR images and mimic the appearance of a vascular lesion such as a paraganglioma (Fig. 38-15). The enhancement of these schwannomas is seen on images taken at least 2 minutes after the administration of contrast. The reason appears to be related to the hypovascular nature of these lesions and their associated poor venous drainage of the contrast. Once contrast enters the schwannoma's tumor bed, it remains in the equilibrium phase for several minutes. This phase occurs well after a vascular tumor, with its rich venous component, has lost most of its contrast enhancement due to a rapid washout phase. Thus, on images taken after the vascular filling phase, paradoxically the hypovascular schwannoma will appear to be more enhanced than the vascular lesion.[8, 68] The only way to identify the true nature of the lesion's vascularity is to examine the mode of contrast accumulation within the first 30 to 60 seconds after contrast administration. This can be accomplished by using either a dynamic scan technique, helical CT, or a conventional angiogram.

If a schwannoma extends through a skull base foramen, the foramen is smoothly enlarged. This differentiates it from a paraganglioma, which, when it extends through a skull base foramen, causes irregular, shaggy-appearing bony margins, not unlike those caused by a malignancy.

Ganglioneuromas have also rarely been reported in the parapharyngeal space. On imaging, they are indistinguishable from schwannomas.[69, 70]

Malignant peripheral nerve sheath tumors are rare, and although they can occur as sporadic tumors, 25% to 50% are associated with von Recklinghausen's disease.[71] Between 9% and 14% of these malignant tumors occur in the head and neck, with the cranial nerves, large cervical nerves, the sympathetic chain, and the inferior alveolar nerve being most commonly affected.[72] These tumors usually have the same imaging findings as schwannomas, and it is only at pathologic examination that their malignant nature is identified. Rarely, they have infiltrative margins suggesting their invasive nature.[73, 74] Although continuity with a major nerve cannot often be confidently seen on imaging, if such continuity can be established the neurogenic origin of the lesion is identified (Fig. 38-15H).

The presence of neurologic symptoms relating to the last four cranial nerves or the superior sympathetic chain can be a useful aid in distinguishing salivary gland tumors from neurogenic tumors. This statement reflects the observation that most salivary gland tumors are benign and thus rarely cause neurogenic complaints. When small, schwannomas rarely cause symptoms. However, when they are large, as is commonly found in the parapharyngeal space, neurogenic symptoms may be present. Neurologic symptoms are not a useful differentiating point when a malignancy is present, as both salivary gland tumors and schwannomas tend to invade nerves.

Paragangliomas

Paragangliomas represent 10% to 15% of all the lesions in this region, although Hughes et al. found them to

Copyright © 2003, Mosby, Inc. All rights reserved.

represent 20% of their series.[56] They occur in three different varieties, depending on their site of origin. The most common form is the glomus vagale tumor, which arises from the paraganglionic cells about the nodose ganglion (Fig. 38-16). This ganglion is the more caudal of the two vagal ganglia and is located just below the skull base. These tumors usually lie entirely within the parapharyngeal space, although, when large, they may have a relatively small extension through the jugular foramen into the posterior fossa. Lateral bone destruction in the skull base, extending toward the middle ear cleft, is uncommon with these tumors but is common with the glomus jugulare paraganglioma (Fig. 38-17).

Some large vagale tumors may extend caudally toward the carotid bifurcation, splaying the internal and external carotid arteries. However, the vagale tumors, unlike the carotid body tumors, rarely fill the crotch of the carotid bifurcation.[75] Rarely, these vagale tumors may become very large, extending down into the lateral neck as far caudally as the larynx. In these cases, the internal and external carotid arteries, the carotid bifurcation, and the common carotid artery all may be displaced around the tumor (Fig. 38-18).

The second most common paraganglioma of this region is the carotid body tumor, which originates from the carotid body cells near the carotid bifurcation (Fig. 38-19). Classically, this tumor completely fills the splayed carotid bifurcation, which distinguishes it from almost all glomus vagale tumors. Only 8% of carotid body tumors are large enough to present clinically as a parapharyngeal space mass. The carotid body cells are variably located about the carotid bifurcation, usually being situated in the crotch between the internal and external carotid arteries. However, in some patients, the carotid bodies may entirely surround the external carotid artery or, rarely, the ICA.

Glomus jugulare tumors are the third most common paraganglioma of this region, and they arise from the paraganglionic cells around the jugular ganglion. This ganglion is the more cranial of the two vagal ganglia and is located in the jugular fossa. Both intracranial and extracranial tumor growth occurs, even in relatively small lesions, and spread above and below the skull base is usually nearly of equal bulk, distinguishing these neoplasms from glomus vagale tumors. In addition, glomus jugulare lesions tend to erode the skull base laterally, extending into the middle ear cleft (Fig. 38-17).

Apparently, the chronic, minimally invasive nature of these tumors can cause developmental anomalies if the tumor arises early enough in life. There is a report of a

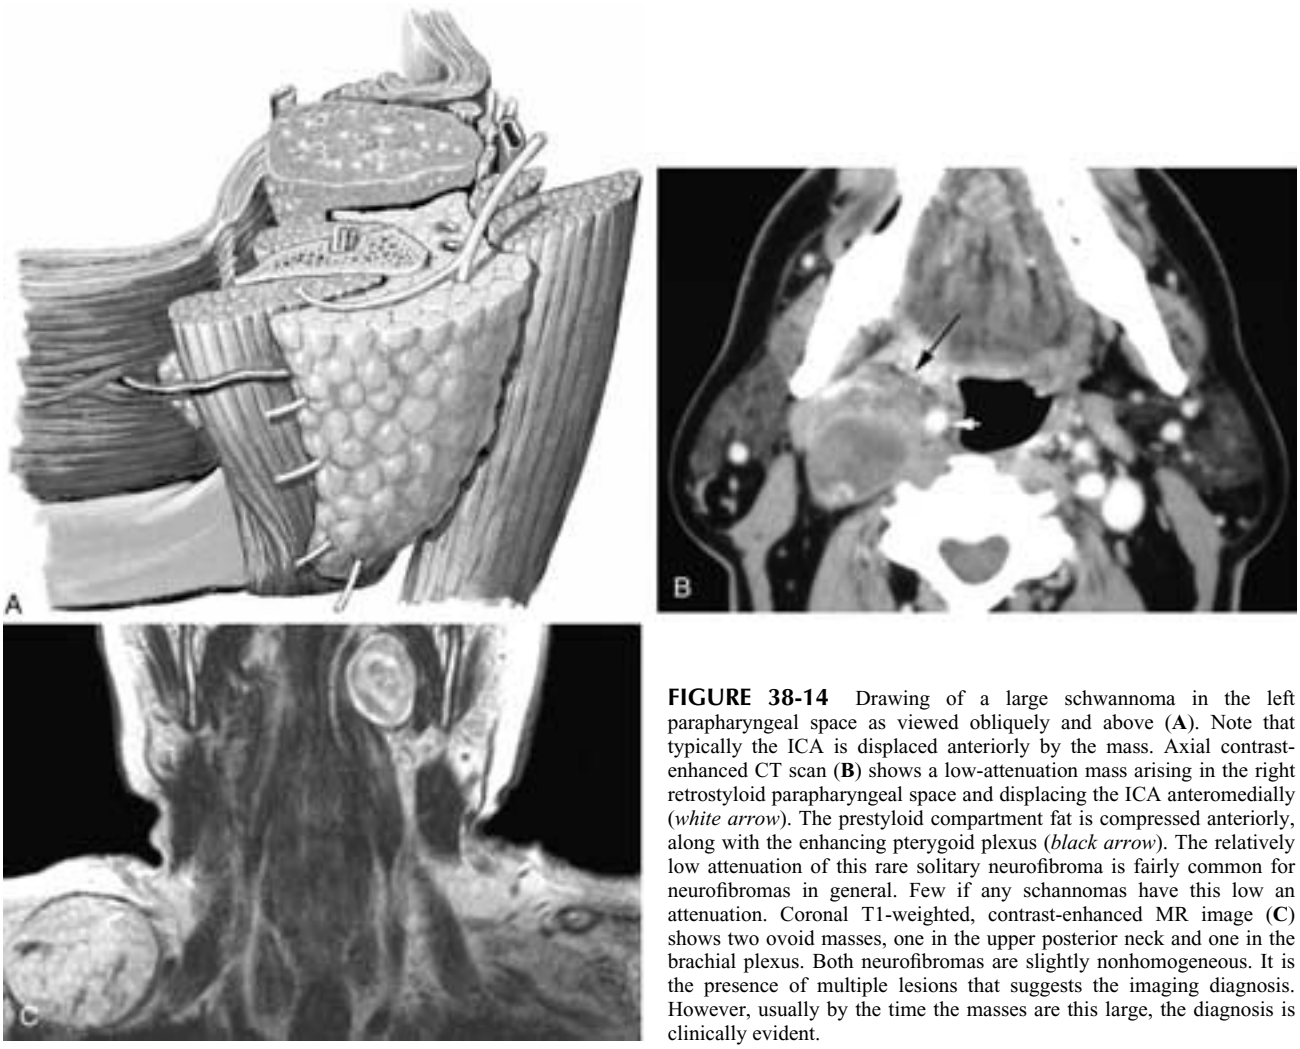

FIGURE 38-14 Drawing of a large schwannoma in the left parapharyngeal space as viewed obliquely and above (**A**). Note that typically the ICA is displaced anteriorly by the mass. Axial contrast-enhanced CT scan (**B**) shows a low-attenuation mass arising in the right retrostyloid parapharyngeal space and displacing the ICA anteromedially (*white arrow*). The prestyloid compartment fat is compressed anteriorly, along with the enhancing pterygoid plexus (*black arrow*). The relatively low attenuation of this rare solitary neurofibroma is fairly common for neurofibromas in general. Few if any schannomas have this low an attenuation. Coronal T1-weighted, contrast-enhanced MR image (**C**) shows two ovoid masses, one in the upper posterior neck and one in the brachial plexus. Both neurofibromas are slightly nonhomogeneous. It is the presence of multiple lesions that suggests the imaging diagnosis. However, usually by the time the masses are this large, the diagnosis is clinically evident.

FIGURE 38-15 *Continued.* Sagittal T1-weighted MR image (**G**) shows a parapharyngeal space mass that bows the ICA (*arrow*) anteriorly. This vagal schwannoma has a fairly homogeneous signal intensity. This appearance of arterial bowing on sagittal images is fairly typical of schwannomas and glomus vagale tumors. Sagittal T1-weighted, fat-suppressed, contrast-enhanced MR image (**H**) shows a vagal schwannoma. The tail of this tumor extends cranially up the nerve into the jugular fossa. When such a relationship to the nerve can be identified, the diagnosis of a schwannoma is virtually assured. Axial T1-weighted MR image (**I**) shows an ovoid right parapharyngeal space mass that displaces the ICA anterolaterally (*arrow*). This was a schwannoma of the sympathetic chain.

VIEW IMAGE

24-year-old female with a right carotid body tumor that had been present since she was 9 years old. Presumably the chronic pressure of the tumor caused a disturbance of the osseous development of her occipito-atlantoaxial complex, resulting in anterior basilar invagination, hypoplasia of the clivus, kyphoscoliosis, and aplasia of the posterior arch of the atlas.[76]

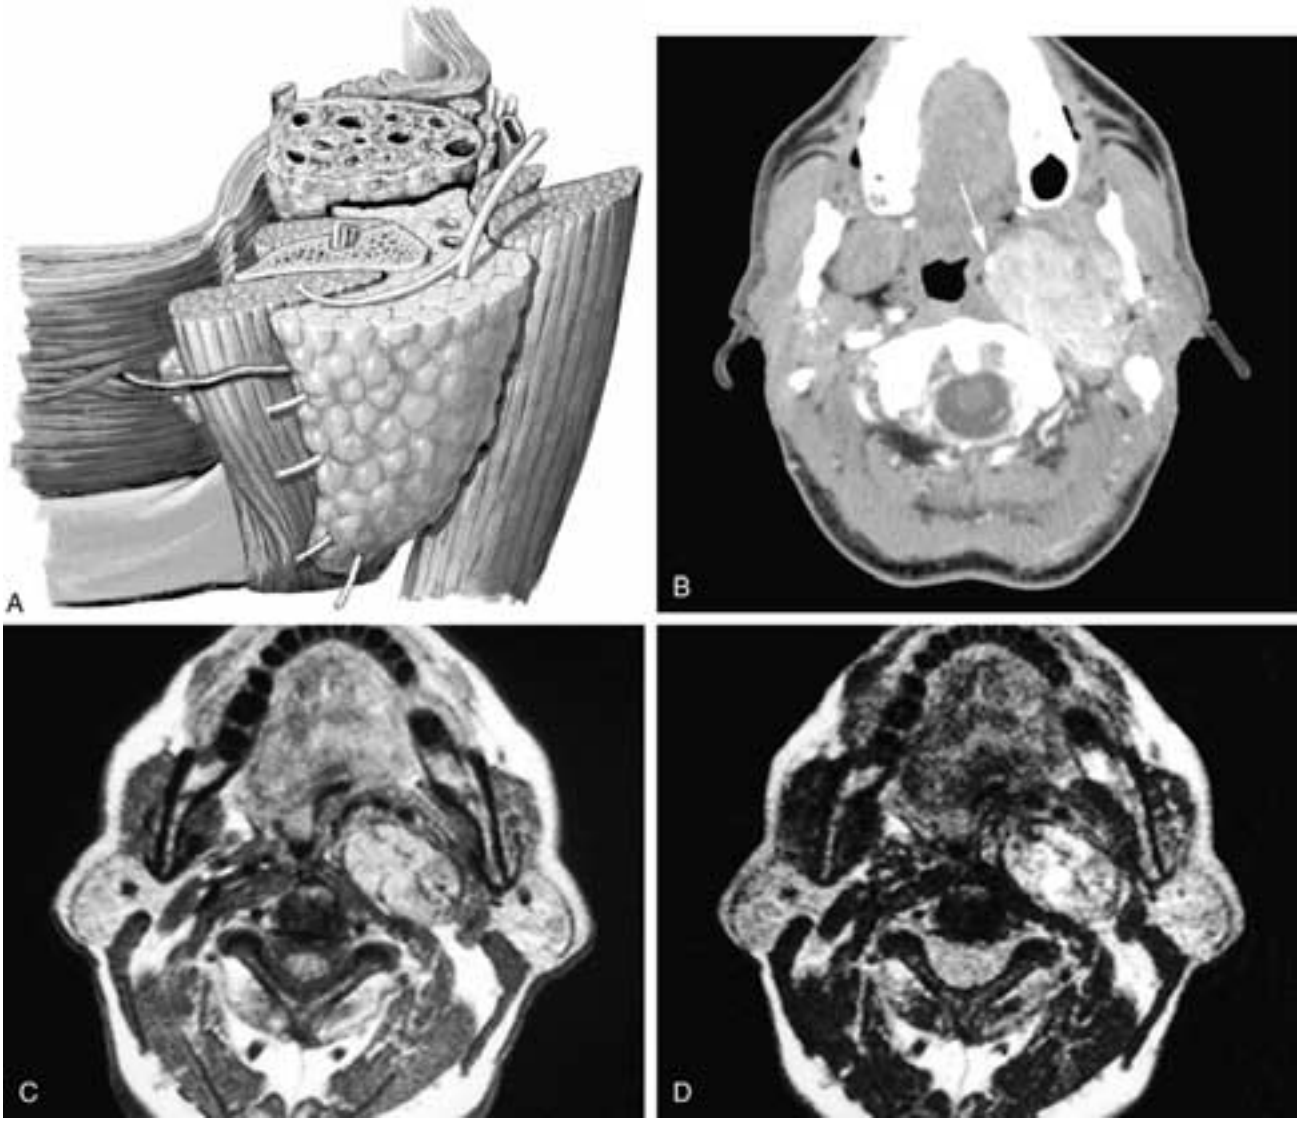
Paragangliomas can occur sporadically or as autosomal dominant familial tumors, and the incidence of multicentric tumors is higher in the familial cases. Bilateral carotid body tumors can occur in 5% to 14% of sporadic tumors (Fig. 38-20). Multiple tumors may develop within a period ranging from several months to a few years of each other or up to 20 years later. Bilateral carotid body tumors may occur in 26% to 33% of patients with familial cases, and the combination of a carotid body tumor, a glomus vagale tumor, or a glomus jugulare tumor is less common than bilateral carotid body tumors. For this reason, both the left and right carotid arteries should be routinely examined in patients with a suspected paraganglioma to rule out multiple tumors.[75] The imaging study should extend from the temporal bones down to the lower neck.

The specific function of most of the extraadrenal paraganglia remains unknown. Unlike the adrenal medulla, they are sparsely innervated and are believed to be directly responsive to chemical signals such as changes in pH (hence the term *chemodectoma* suggested by Mulligan in 1950).[77] Compensatory hypertrophy of the paraganglia is known to occur only in the parasympathetic carotid body in patients with prolonged hypoxia and hypercapnia.[78] In fact, populations living at high altitudes and chronically exposed to hypoxic conditions also have a 10-fold increased prevalence of carotid body paragangliomas but no increase of such tumors at other sites.[79] Carotid body tumors occurring at altitudes higher than 2000 m above sea level in Mexico City were found to differ significantly from those in inhabitants of cities in the United States or Europe less than 1500 m above sea level. Those tumors occurring at high altitudes have an evident female predominance (8.3∶1), a low rate of bilaterality (5%), and a family history of 1% versus a discrete female predominance (2∶1), bilaterality ranging from 10% to 20%, and a family history ranging from 7% to 25% in tumors occurring at low altitudes.[80]

As previously discussed, these hypervascular tumors have significant enhancement on routine contrast CT and MR scans. However, if there is a delay of more than several minutes in imaging after contrast administration, the rich tumor blood flow may wash out the contrast, and these lesions may not appear to be highly enhanced. Dynamic scanning will reveal a hypervascular curve, with a sharp filling peak and a rapid washout phase.[8, 20, 21] Such a curve differentiates this vascular tumor from a hypovascular lesion such as a schwannoma, which enhances because of the slow extravascular accumulation of contrast in the tumor bed.

Copyright © 2003, Mosby, Inc. All rights reserved.

When small, these tumors enhance homogeneously. However, when large, they are usually nonhomogeneous, with areas of both necrosis and hemorrhage. They tend to be ovoid or pear-shaped, and they are smoothly contoured. If the tumor extends through the skull base, it usually has an hourglass shape, with the waist at the level of the skull base. The margins of the skull base involvement have irregular, infiltrative contours, differentiating these tumors from schwannomas. On MR imaging, they have an overall intermediate signal intensity background matrix on all imaging sequences, usually with some ''brightening'' on T2-weighted images. Scattered sites of high T2-weighted signal intensity can be seen, which help give the tumor a ''salt and pepper'' appearance. These high-signal regions primarily appear to be areas of slow flow within the tumor. In larger tumors, a characteristic MR finding is serpentine, channel-like areas of signal void within the tumor matrix, which are present on all imaging sequences. These vascular flow voids represent the larger-caliber, rapid-flow dominant vessels of the tumor (Figs. 38-16 to 38-18).[9, 27, 81] These flow voids often are not seen in lesions smaller than 2 cm in diameter, and occasionally they may not be seen in large tumors. Such tumors have a predominance of small-caliber, slower-flow vessels that can only be identified on a



VIEW IMAGE

FIGURE 38-16 Drawing of a large glomus vagale tumor in the left parapharyngeal space as viewed from obliquely and above (**A**). Note that the mass is separate from and displaces the pharyngeal wall medially while also being separate from and displacing the parotid gland laterally. Thus, fat planes will separate such a mass from both the pharyngeal wall and the deep portion of the parotid gland. Typically, the ICA is anteriorly displaced. This tumor configuration also applies to a schwannoma within the parapharyngeal space. Axial contrast-enhanced CT scan (**B**) shows an enhancing mass in the left parapharyngeal space that has displaced the ICA (*arrow*) anteromedially. This glomus vagale tumor extended from the skull base to near the carotid bifurcation. Axial T1-weighted (**C**) and T2-weighted (**D**) MR images show an ovoid glomus vagale tumor in the left parapharyngeal space. The carotid arteries have been displaced anteriorly, and within the mass are serpiginous areas of signal void. In **D**, intermixed with the areas of signal void are areas of high signal intensity. This gives the ''salt and pepper'' appearance associated with these glomus tumors.

FIGURE 38-16 *Continued* Axial T1-weighted MR image (**E**) shows a spherical mass in the right parapharyngeal space. There are signal voids within the mass, and the carotid arteries have been displaced anteromedially. This was a glomus vagale tumor. Axial T1-weighted (**F**) and sagittal T1-weighted (**G**) MR images show an oblong mass with a large central region of signal void. In **F**, there are also smaller scattered signal voids. The ICA is displaced anteriorly (*arrow* in **F** and **G**). In **H**, a lateral subtraction angiogram film, the hypervascular nature of this glomus vagale tumor is seen. There is also considerable internal atrioventricular shunting into a large internal draining vein.

conventional angiogram, which is still considered the gold standard for evaluating tumor vascularity. It has been suggested that MR contrast is unnecessary in studying paragangliomas and that the diagnosis is most reliably made on T2-weighted images. This study also confirmed that flow voids are more likely to be found in tumors greater than 2 cm in diameter and on T2-weighted images.[82]

Both glomus vagale and glomus jugulare tumors arise around the vagus nerve that is dorsal to the ICA. Thus, these tumors tend to displace the ICA anteriorly. The carotid body tumors also usually displace the internal carotid artery anteriorly; however, splaying of the internal and external carotid arteries is a more constant feature.[27] This splaying causes a lyre-shaped widening of the carotid bifurcation, a distinctive imaging feature well seen on MR imaging, CT scanning, and on CT, MR, and conventional angiography. When there is gross asymmetry in the splaying of the internal and external carotid arteries, the possibility of a vascular-type nodal metastasis should be considered. In these cases, the metastatic node is usually lateral to the carotid vessels.

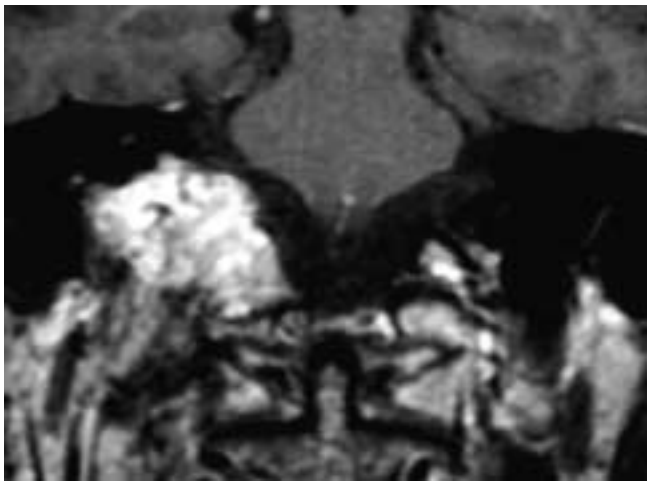
The classic imaging diagnosis of a paraganglioma is

Copyright © 2003, Mosby, Inc. All rights reserved.

based on the presence of a smoothly contoured, ovoid parapharyngeal space mass, with vascular flow voids, anterior displacement of the ICA, and possibly a ''salt and pepper'' T2-weighted appearance. This imaging appearance usually obviates the need for an invasive angiogram, which remains necessary for a definitive diagnosis in those cases without vascular flow voids on MR imaging or MR angiography (MRA). A further indication for a conventional angiogram is preoperative tumor embolization, which reduces blood loss at surgery, especially for the larger tumors. The tumors most often embolized preoperatively are the glomus jugulare and vagale lesions. Because of concern that the embolization material may reflux into the ICA, the carotid body tumors are less frequently embolized.

Compared to the conventional digital subtraction angiograms, multislice 3D time-of-flight (TOF) MRA was superior to 3D phase-contrast and 2D TOF MRA for identifying the first- and second-order vessels in the neck. However, the sensitivity of MRA was too low to replace conventional angiography, especially for carotid body tumors.[83] Today, CT angiography (CTA) is also being utilized to demonstrate the blood vessels associated with these tumors, and this technique appears to be comparable to MRA.

Paragangliomas may cause disabling symptoms and even death by slow, progressive enlargement, with encroachment on vital organs and contiguous structures, or by the development of regional and distant metastases.[84] Carotid body tumors are malignant in 10% to 15% of cases. Most metastases are to regional lymph nodes. Distant metastases have been reported in the lungs, liver, pleura, heart, kidney, skin, thyroid, spinal dura, pancreas, trachea, and brain. Glomus vagale tumors also have an approximately 10% incidence of malignancy, with regional lymph node metastases and distant metastases to lung and bone. Glomus jugulare tumors have a metastatic frequency of only about 3%, with regional cervical metastases and distant metastases to lung, liver, bone, brain, parotid, nasopharynx, and the posterior neck.[75]



VIEW IMAGE

FIGURE 38-17 Coronal T2-weighted MR image shows a mass centered in the right jugular fossa. This glomus jugulare tumor has high signal intensity and serpiginous areas of signal void. Laterally, the tumor extends into the middle ear, and the lesion extends about as much into the posterior fossa as it does below the skull base.

The presence of a hypervascular tumor on CT and MR imaging is not specific for a paraganglioma. If the lesion has invasive margins, a vascular metastasis from a renal cell or thyroid carcinoma should be considered (Fig. 38-21). Some venous hemangiomas may also have a similar hypervascular imaging appearance, although the flow voids on MR imaging may not be as dominant a feature as in the other tumors.[9]

Other Tumors

A large number of cellular lesions have been reported to involve the parapharyngeal space, usually infiltrating and obliterating the tissue planes. Among these, nasopharyngeal and oropharyngeal carcinomas are the most common in adults, while in children, the most common tumors are either rhabdomyosarcomas or lymphomas.[85, 86] Rare tumors such as hemangiopercytoma and synovial sarcoma have also been reported.[87, 88] In the case of synovial sarcoma in a 21-year-old man, CT was found to be very useful for identifying the presence of tumoral calcifications, which may portend a favorable prognosis. CT was also useful in excluding involvement of cortical bone. The CT and MR imaging findings were nonspecific, but MR imaging was superior to CT for assessing the topographic relationships of the tumor (Fig. 38-22).[87] Extramedullary plasmacytoma has also been reported in the parapharyngeal space and showed significant enhancement, a finding possibly suggestive of this rare diagnosis.[89] Rarely, liposarcomas can occur in the parapharyngeal space. They are identified on imaging by their fatty content, which often may comprise only about half of the tumor mass (Fig. 38-23). Aggressive fibromatosis can also involve the parapharyngeal space, and parotid malignancies can invade this space.[90–92] Solitary fibrous tumors arise in the pleura and, less commonly, in extrapleural sites that in the head and neck regions have included the nose and paranasal sinuses, soft palate, epiglottis, thyroid, parotid gland, and submandibular gland, as well as the infratemporal fossa and the parapharyngeal space. A solitary fibrous tumor arising in the parotid gland and extending to the parapharyngeal space was documented on CT and MR imaging.[93] A rare aggressive juvenile laryngeal papillomatosis was reported in a patient who had had laryngeal papillomas since the age of 3 years. The papillomas gradually spread to the entire respiratory system, and over 30 years the patient was operated on more than 80 times. MR imaging documented an invasive tumor spreading from the tongue into the parapharyngeal space and extending to the cranial base.[94] A very rare osteolipoma has also been reported in the lower parapharyngeal space.[95] Metastases from distant primary tumors to the parapharyngeal space come most commonly from primary tumors in the kidney and the thyroid gland.

Benign tumors such as rhabdomyomas and processes other than tumors, such as the granulomatous reaction from a malignant external otitis, can also occur in the parapharyngeal space.[96, 97] Pseudotumors have rarely been reported in the parapharyngeal space. They appear on imaging as infiltrating lesions that are indistinguishable from carcinomas.[98]

Unfortunately, for the most part, the CT and MR imaging findings of these entities are nonspecific. On CT, almost all of these lesions are fairly homogeneous, with an attenuation

FIGURE 38-18 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show a huge left glomus vagale tumor in the left parapharyngeal space. The ICA is displaced anteromedially, and there are vascular signal voids within the tumor. In **C**, a coronal T2-weighted MR image, the massive extent of the tumor can be appreciated as it extends down almost to the level of the supraclavicular fossa. In **D**, a left oblique view of an MRA, the lateral bowing of the common carotid artery (*large arrow*) is seen. There is also slight splaying of the carotid bifurcation as a portion of the tumor bulges laterally between the internal and external carotid arteries (*small arrows*). Coronal T1-weighted MR image (**E**) on a different patient than in **A** to **D** shows another huge glomus vagale tumor in the right neck. A few vascular flow voids are present within the tumor.

similar to that of muscle, show minimal enhancement, and diffusely infiltrate the region. When they are large, areas of necrosis may develop. On MR imaging, these processes also tend to be homogeneous, and most have a low to intermediate T1-weighted and a slightly higher T2-weighted signal intensity. Although the degree of enhancement is variable, most of these tumors enhance.

As a general rule, lymphomas tend to be less infiltrative and cause relatively little bone erosion compared to carcinomas and most sarcomas. Often their MR imaging signal intensities are the same as those of normal adenoidal tissue, thereby suggesting the possible diagnosis.[8, 9] There is no consistent difference between the signal intensities of lymphomas and carcinomas to use these MR findings as a differentiating point.

Tumors of the nasopharynx are discussed in depth in Chapter 28. These carcinomas are mucosal tumors that may have extensive submucosal and parapharyngeal space extension, often with skull base erosion and intracranial spread.[24]

Lymph Nodes

Lymph nodes within the parapharyngeal space are part of either the upper spinal accessory or upper internal jugular chains and are now all classified as level II nodes. The retropharyngeal nodes, as the name implies, are not within the parapharyngeal space. Most lymph nodes in the parapharyngeal space do not occur in isolation; they are usually part of a more extensive lymphadenopathy in the neck, and the source of a causative infection or the primary tumor is often also identified in the pharynx.[99] As mentioned earlier in this chapter, a necrotic lymph node and an abscess

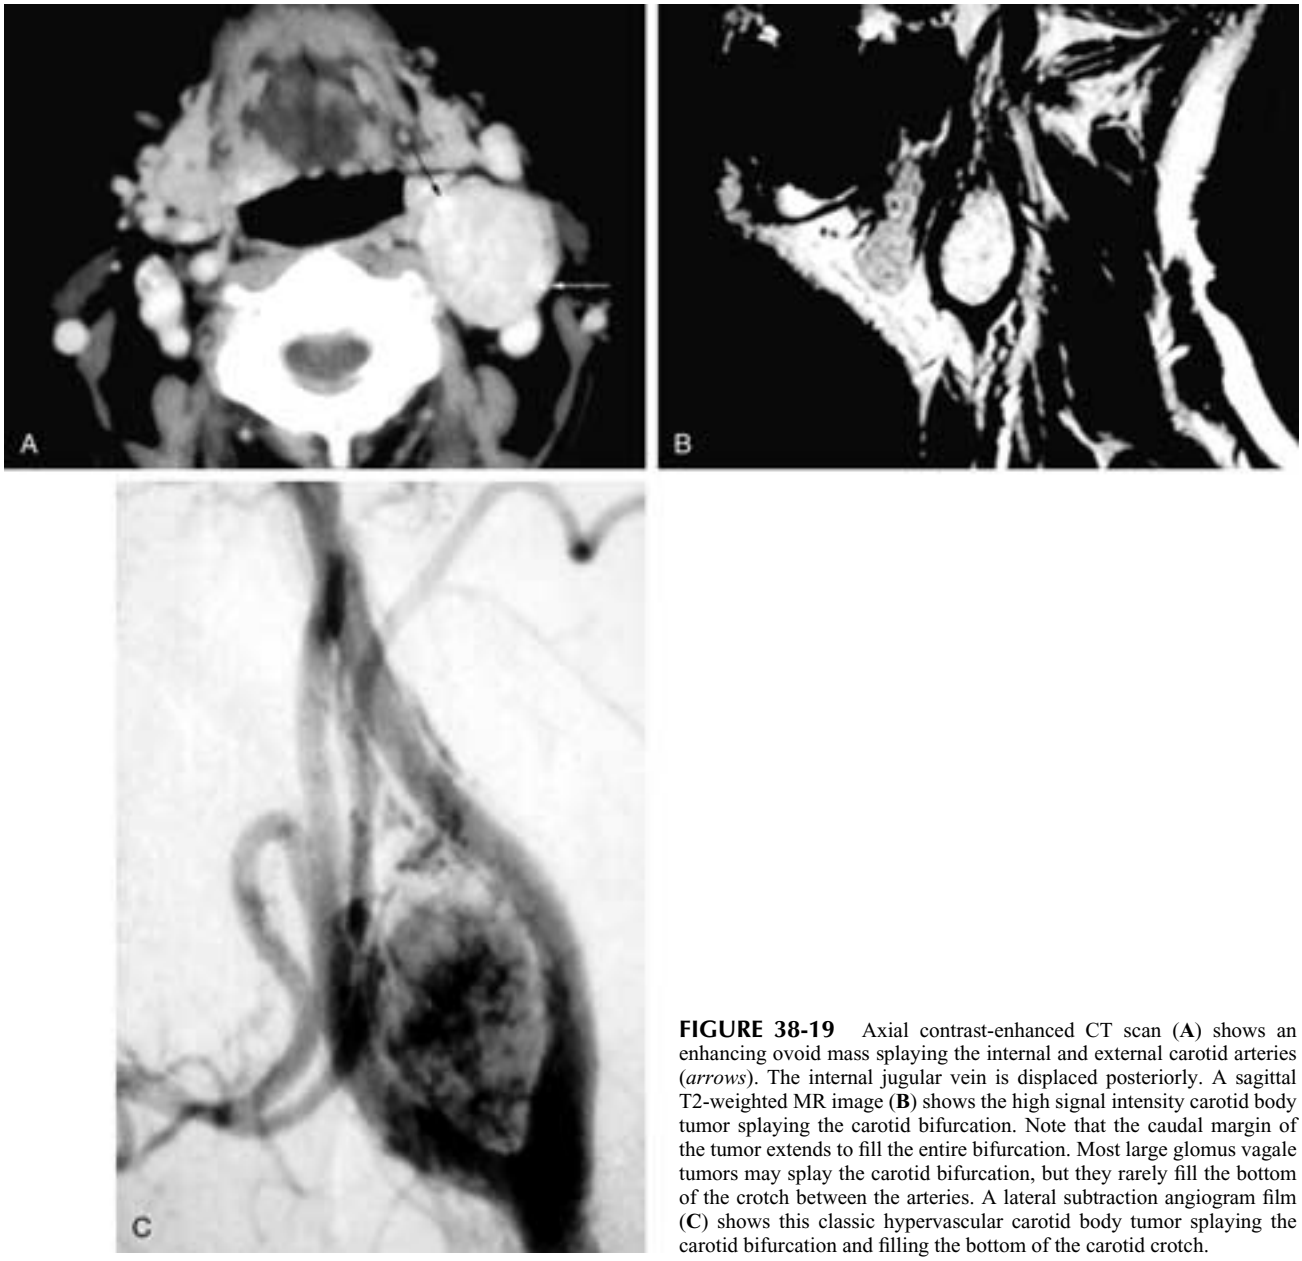

FIGURE 38-19 Axial contrast-enhanced CT scan (**A**) shows an enhancing ovoid mass splaying the internal and external carotid arteries (*arrows*). The internal jugular vein is displaced posteriorly. A sagittal T2-weighted MR image (**B**) shows the high signal intensity carotid body tumor splaying the carotid bifurcation. Note that the caudal margin of the tumor extends to fill the entire bifurcation. Most large glomus vagale tumors may splay the carotid bifurcation, but they rarely fill the bottom of the crotch between the arteries. A lateral subtraction angiogram film (**C**) shows this classic hypervascular carotid body tumor splaying the carotid bifurcation and filling the bottom of the carotid crotch.

FIGURE 38-20 Axial contrast-enhanced CT scan (**A**) shows bilateral enhancing ovoid masses that splay the carotid arteries. Axial T1-weighted MR image (**B**) shows the bilateral carotid body tumors to have virtually no vascular flow voids. A T1-weighted, fat-suppressed, contrast-enhanced MR image (**C**) shows marked enhancement of the tumors. A left anterior oblique projection of an MRA (**D**) shows the splaying of both carotid bifurcations but virtually no tumor vascularity. On a conventional arteriogram, these tumors each had dense hypervascularity.

may have identical imaging findings. In these cases, it is the history that distinguishes the two diagnoses (Fig. 38-24). Patients with abscesses in the parapharyngeal space are acutely ill, often with severe malaise. By comparison, patients with metastatic nodes usually are asymptomatic or complain of localized discomfort or pain. The imaging appearance of lymph nodes is discussed in Chapter 36.

Benign Soft-Tissue Masses and Cysts

The remaining lesions that occur in the parapharyngeal space are statistically rare. As a group, they represent 10% to 33% of all the cases, with the latter number including lymph nodes.

Teratomas involving the parapharyngeal space are rare, and most have occurred in newborns or infants. The child often presents in acute respiratory distress. On CT these lesions may have calcifications, ossifications, cystic areas, and fatty regions. Usually the margins are infiltrative, and CT has been found to be most useful in their diagnosis. Components of all three germ layers are present, and histologic examination of one patient showed the presence of a large amount of mature brain tissue, a moderate amount of collagenous fibers and smooth muscle cells, and a minute amount of cartilage and epithelial structures.[100, 101]

There have been numerous reports of various types of heterotopic tissue in the head and neck, with heterotopic cartilage, gastric tissue, thyroid tissue, and salivary gland tissue having been found in such varied locations as the tongue, gingiva, palate, nasopharynx, parapharyngeal space, and neck. Heterotopic brain tissue in the parapharyngeal space causing airway obstruction in the neonate has been described, and three cases were reported that caused significant airway and feeding difficulties.[102]

Solitary fibrous tumors and desmoplastic fibromas are uncommon spindle cell neoplasms that most often affect serosal surfaces, especially the pleura. However, recently, these tumors have been documented in a number of extrapleural sites, including the head and neck, and there has been direct involvement of the parapharyngeal space (see Chapter 41). The rare location of these uncommon lesions gives rise to difficulty in diagnosis, and the final diagnosis is not made until the excised tumor is examined by histopathology and immunohistochemistry.[103–107] As with such fibrous tumors elsewhere in the body, the MR signal

Copyright © 2003, Mosby, Inc. All rights reserved.

intensities tend to be intermediate to low on T1-weighted and low on T2-weighted images.

Nodular fasciitis is a benign lesion composed of fibrous tissue. It most commonly affects the upper extremity, which accounts for half of all cases. From 10% to 20% of the lesions occur in the head and neck area, most of which are subcutaneous (see Chapter 41). One case of nodular fasciitis presented as an unusually large submucosal tumor of the pharynx. The tumor extended from the retropharyngeal to the parapharyngeal space and measured $8 \times 4 \times 3$ cm. Since nodular fasciitis is known for its tendency to spontaneous regression, this tumor was transorally debulked by the use of YAG laser.[108]

Branchial cysts can occur in the parapharyngeal space and are of either a first or second arch derivation. Currently, most authors refer to them as second branchial arch cysts; they are probably of branchial pouch origin.[109] This conclusion is related to the observation that although second branchial apparatus problems usually occur along the anterior border of the sternocleidomastoid muscle, the tract of this arch courses between the internal and external carotid arteries in the parapharyngeal space, heading toward the palatine tonsil. In addition, the second branchial pouch contributes to the tonsillar fossa, and these parapharyngeal space cysts are usually deep to this fossa.[110] These cysts most often are located in the medial aspect of the parapharyngeal space, adjacent to the retropharyngeal space, and anteromedial to the carotid sheath (Fig. 38-25). Less often, the cysts occur laterally, adjacent to or involving the deep portion of the parotid gland. All of these cysts usually are less than 2 cm, are well delineated, and are spherical or ovoid in shape. Rarely, a large cyst can fill the entire parapharyngeal space, extending down to the level of the submandibular gland. In one case, the mass effect of the cyst caused cranial nerve palsies.[111]

On CT, the cysts usually have a homogeneous low-attenuation (10 to 20 HU) central region with a thin, uniformly smooth wall. On MR imaging, they usually appear as homogeneous masses with a low or intermediate T1-weighted and a high T2-weighted signal intensity. The signal intensities of the cyst's contents reflect the protein content of the cyst fluid. Their cystic nature may not be evident on noncontrast images. After contrast injection the cyst wall enhances, verifying the cystic nature of the mass (Fig. 38-25).[109–113]

When a cyst becomes infected, its protein content increases, and this is seen on CT as an increase in attenuation. In addition, the cyst wall thickens and enhances, and the surrounding soft-tissue planes become effaced due to cellulitis. On MR imaging, the findings are probably best appreciated on T2-weighted images and on T1-weighted, fat-suppressed, contrast-enhanced images. Such an infected cyst is, in effect, an abscess, and its imaging appearance is similar to that of an abscess. Two points may aid in the distinction between an abscess and an infected parapharyngeal space cyst: (1) The abscess usually arises secondary to an infection of the soft tissues surrounding the parapharyngeal space, with the seeding source often being in the palatine tonsil or teeth. A tonsillar abscess or evidence of a pharyngitis is usually seen on the images. (2) With an

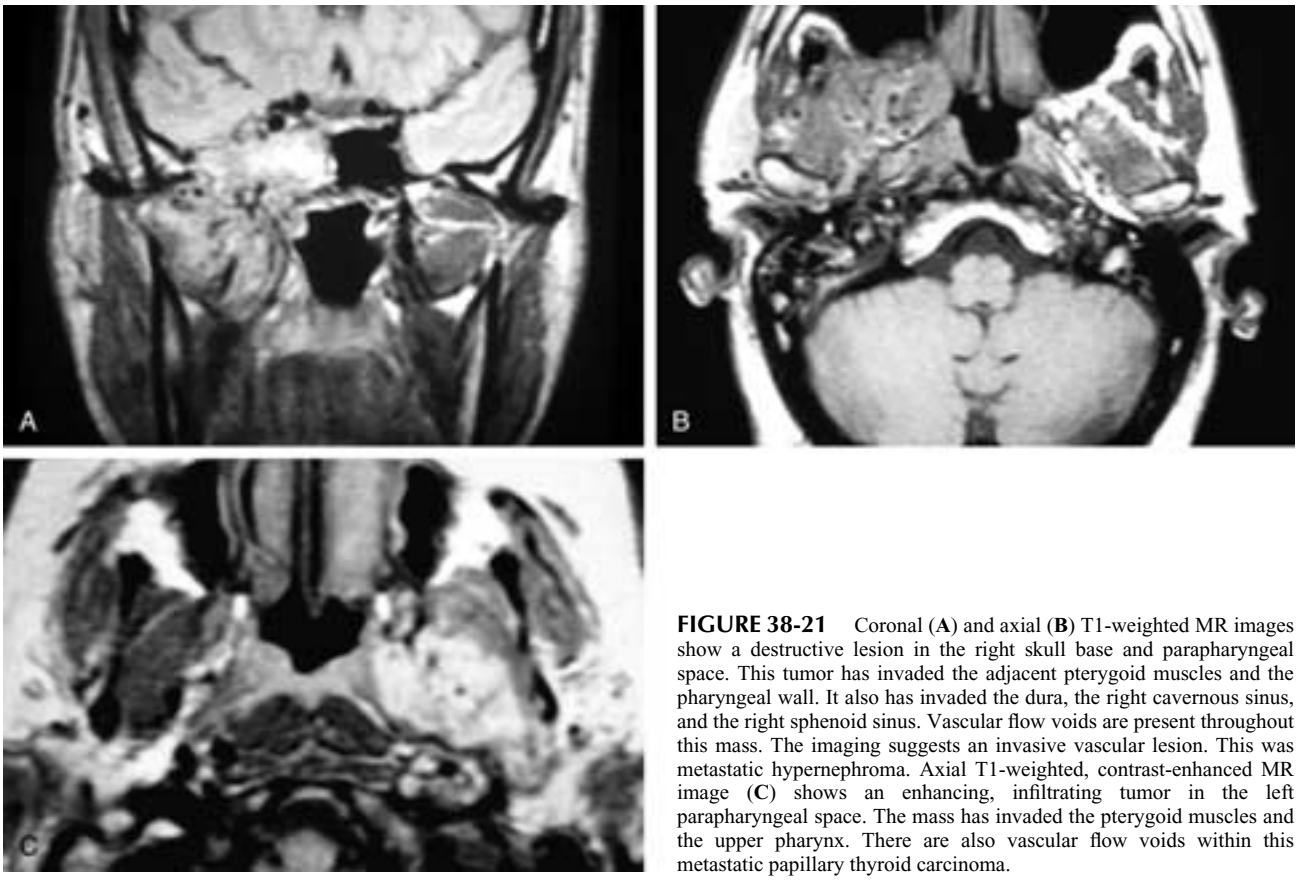

FIGURE 38-21 Coronal (**A**) and axial (**B**) T1-weighted MR images show a destructive lesion in the right skull base and parapharyngeal space. This tumor has invaded the adjacent pterygoid muscles and the pharyngeal wall. It also has invaded the dura, the right cavernous sinus, and the right sphenoid sinus. Vascular flow voids are present throughout this mass. The imaging suggests an invasive vascular lesion. This was metastatic hypernephroma. Axial T1-weighted, contrast-enhanced MR image (**C**) shows an enhancing, infiltrating tumor in the left parapharyngeal space. The mass has invaded the pterygoid muscles and the upper pharynx. There are also vascular flow voids within this metastatic papillary thyroid carcinoma.

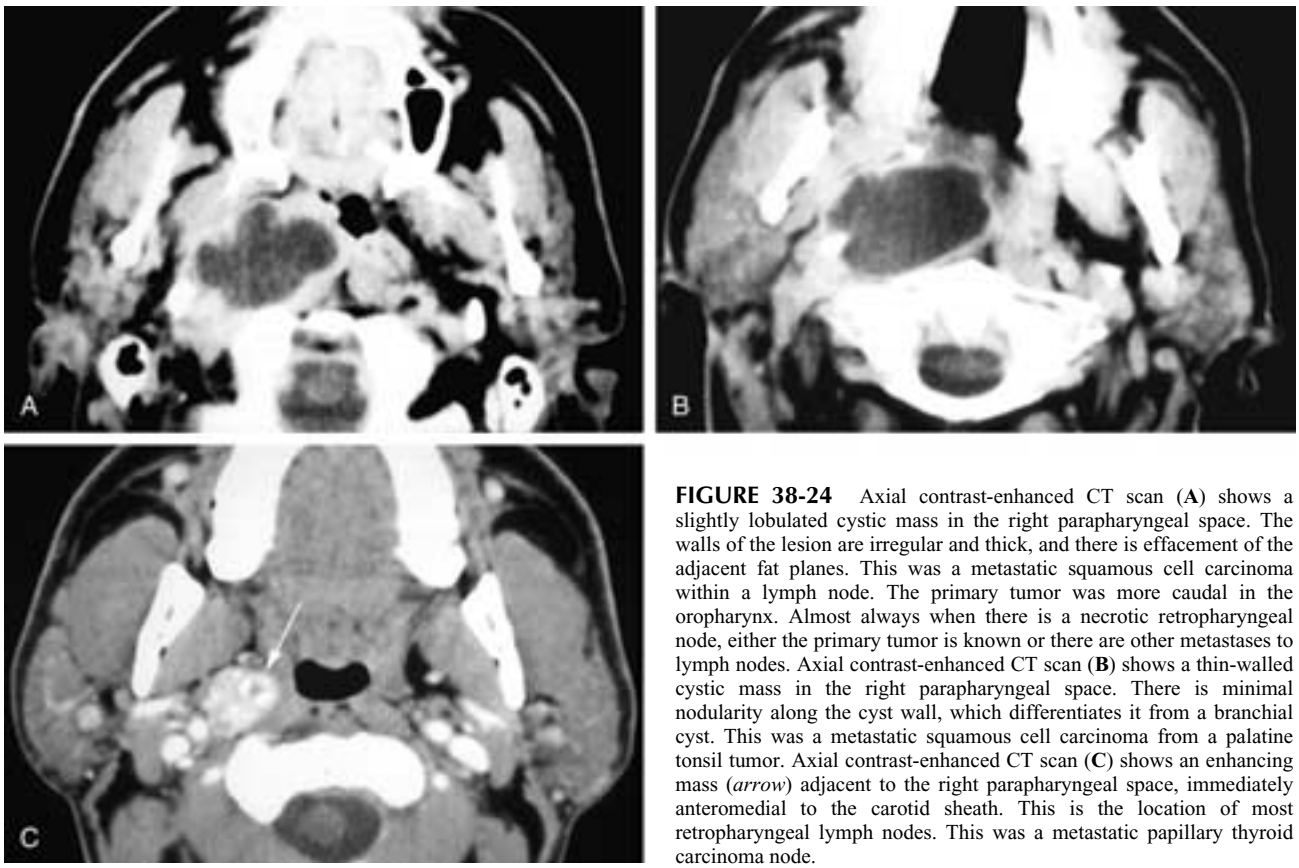
FIGURE 38-23 Axial T1-weighted MR image shows slightly increased fat in the right parapharyngeal space. The feature differentiating a benign lipoma (see Fig. 38-28) from this liposarcoma is the infiltration of the right medial pterygoid muscle (*arrow*).

abscess, multiple enlarged lymph nodes usually are present in the adjacent neck. By comparison, with an infected branchial cyst there rarely are adjacent lymph nodes. As mentioned earlier, the primary role of the radiologist in such cases is to differentiate between cellulitis and abscess.

Cystic lymphangiomas or cystic hygromas are rarely found in adults, with 90% of the cases being discovered by age 2 years. When the parapharyngeal space is involved, there usually are multicystic extensions of a posterior triangle mass. Less commonly, there may be an anterior triangle mass with extension into the parapharyngeal space; rarely, large cystic hygromas can involve the entire parapharyngeal space and floor of the mouth. The cyst walls are normally so thin that they are not clearly identified as a rim on sectional imaging. However, if infection has occurred, the cyst wall thickens and enhances, and the normally sharp contours of noninfected cysts become blurred and effaced. During surgery on large lymphangiomas, intraoperative neurologic monitoring has been suggested so that cranial nerves hidden or encased in the lesion are not damaged.[114]

On CT, cystic hygromas usually are composed of multiple conglomerate cysts with well-delineated borders (Fig. 38-26). Increased attenuation within the cyst's contents usually reflects either infection or hemorrhage, and a fluid-fluid level may be seen. The individual cysts are usually better seen on MR imaging, and the cyst's contents usually have a low to intermediate T1-weighted and a high T2-weighted signal intensity (Fig. 38-27).[115–118] If the cyst is infected, both the T1-weighted and T2-weighted signal intensities are usually high. If hemorrhage has occurred, intracystic fluid-fluid levels are seen. These actually represent the separation of fluids with different specific gravities, as the blood does not clot within the cysts. Such hemorrhage can occur with or without an antecedent history of trauma. The classic MR appearance is that of multiple cysts, each with a fluid-fluid level.



VIEW IMAGE

FIGURE 38-24 Axial contrast-enhanced CT scan (**A**) shows a slightly lobulated cystic mass in the right parapharyngeal space. The walls of the lesion are irregular and thick, and there is effacement of the adjacent fat planes. This was a metastatic squamous cell carcinoma within a lymph node. The primary tumor was more caudal in the oropharynx. Almost always when there is a necrotic retropharyngeal node, either the primary tumor is known or there are other metastases to lymph nodes. Axial contrast-enhanced CT scan (**B**) shows a thin-walled cystic mass in the right parapharyngeal space. There is minimal nodularity along the cyst wall, which differentiates it from a branchial cyst. This was a metastatic squamous cell carcinoma from a palatine tonsil tumor. Axial contrast-enhanced CT scan (**C**) shows an enhancing mass (*arrow*) adjacent to the right parapharyngeal space, immediately anteromedial to the carotid sheath. This is the location of most retropharyngeal lymph nodes. This was a metastatic papillary thyroid carcinoma node.

Lipomas and fatty neurofibromas involving the parapharyngeal space may have similar appearances on CT and MR imaging (Fig. 38-28). The MR findings of these fat-dominated lesions are those of high T1-weighted and intermediate T2-weighted signal intensities. However, occasionally a lipoma contains hemorrhage. This can cause the CT attenuation to approach that of muscle and can cause the MR T1-weighted and T2-weighted signal intensities to be high. In such cases, the imaging diagnosis can be quite difficult.[119–124]

Angiolymphoid hyperplasia with eosinophilia (ALHE) is an uncommon benign condition characterized by cutaneous nodules with a predilection for the head and neck region. Extracutaneous involvement is rare. A 44-year-old woman has been reported with a large submucosal ALHE tumor in the parapharyngeal space, diagnosed at pathology.[125]

Two cases of eumycotic mycetomas in the head and neck region were reported, one localized to the soft tissue of the neck. It was completely excised, and the patient needed no further treatment. In the second case, the lesion extensively

involved the structures in the parapharyngeal space, submandibular space, and carotid sheath, extending to the skull base. The patient was treated by a combination of wide excision with a radial forearm flap and antifungal agents.[126]

Vascular and Neurologically Related Abnormalities

A partially or totally occluded vessel may occasionally present a diagnostic problem on sectional imaging. If internal jugular vein thrombosis is present, it is most often iatrogenic, either the result of a catheter, a needle, or prior surgery or irradiation. ICA occlusions usually are secondary to atherosclerotic disease or surgical trauma. Although on a single axial image a thrombosed internal jugular vein or an occluded carotid artery may simulate a cystic mass, the tubular configuration of the vessel is easily identified once all of the scans are examined serially (Fig. 38-29). On MR imaging, with the use of gradient-echo and short flip angle techniques, slow flow through a partially occluded vessel can be identified, and the high signal intensity of the clotted

FIGURE 38-26 Axial contrast-enhanced CT scan shows a multiloculated cystic mass in the right parapharyngeal space. Although no cyst wall is clearly identified, this cystic lymphangioma (hygroma) remains clearly differentiated from the adjacent soft tissues.

or slowly flowing blood can be helpful in diagnosing these lesions.

Aneurysms tend to occur at the carotid bifurcation and often are the result of either atherosclerotic disease or trauma. When an aneurysm is present, there often is peripheral rim calcification, which distinguishes it from a pleomorphic adenoma, a schwannoma, or another rare tumor in which any dystrophic calcifications occur within the lesion's matrix. Calcifications may also be seen within the parapharyngeal space lymph nodes, most often secondary to metastatic papillary thyroid carcinoma. The topic of nodal disease is discussed in Chapter 36.

On imaging, an aneurysm also obliterates the silhouette of the involved artery. Thus, whenever a mass is seen, especially with peripheral calcification, and the ICA adjacent to the mass cannot be identified, the diagnosis of an aneurysm should be made. Further studies such as CTA, MRA, or conventional angiography should be performed to confirm this diagnosis (Fig. 38-30).[127–129]

Of all the masses that occur in the parapharyngeal space, the aneurysm is most immediately life-threatening. In addition, if surgery is performed on the parapharyngeal space and the surgeon is not preoperatively aware of the diagnosis of an aneurysm, catastrophic complications may result. Thus, the imager must always be prepared to ensure that the diagnosis of an aneurysm can either be established or excluded.

Dissection of the ICA is recognized as a common cause of ischemic stroke in young adults and occurs in approximately 10% to 20% of these patients.[130] Although the most common clinical presentation is headache, patients may also present with focal neurologic deficits. In the majority of patients, the dissection involves the extracranial portion of the ICA and only infrequently extends intracranially or involves the intracranial segment alone. The etiology of spontaneous dissection of the ICA is broad and includes minor trauma, fibromuscular dysplasia, Marfan's syndrome, cystic medial necrosis, idiopathic regressing arteriopathy, type IV Ehlers Danlos syndrome, hypertension, ICA redundancy, and alpha 1-antitrypsin deficiency.[130] The presumption that there is preexisting arterial disease that

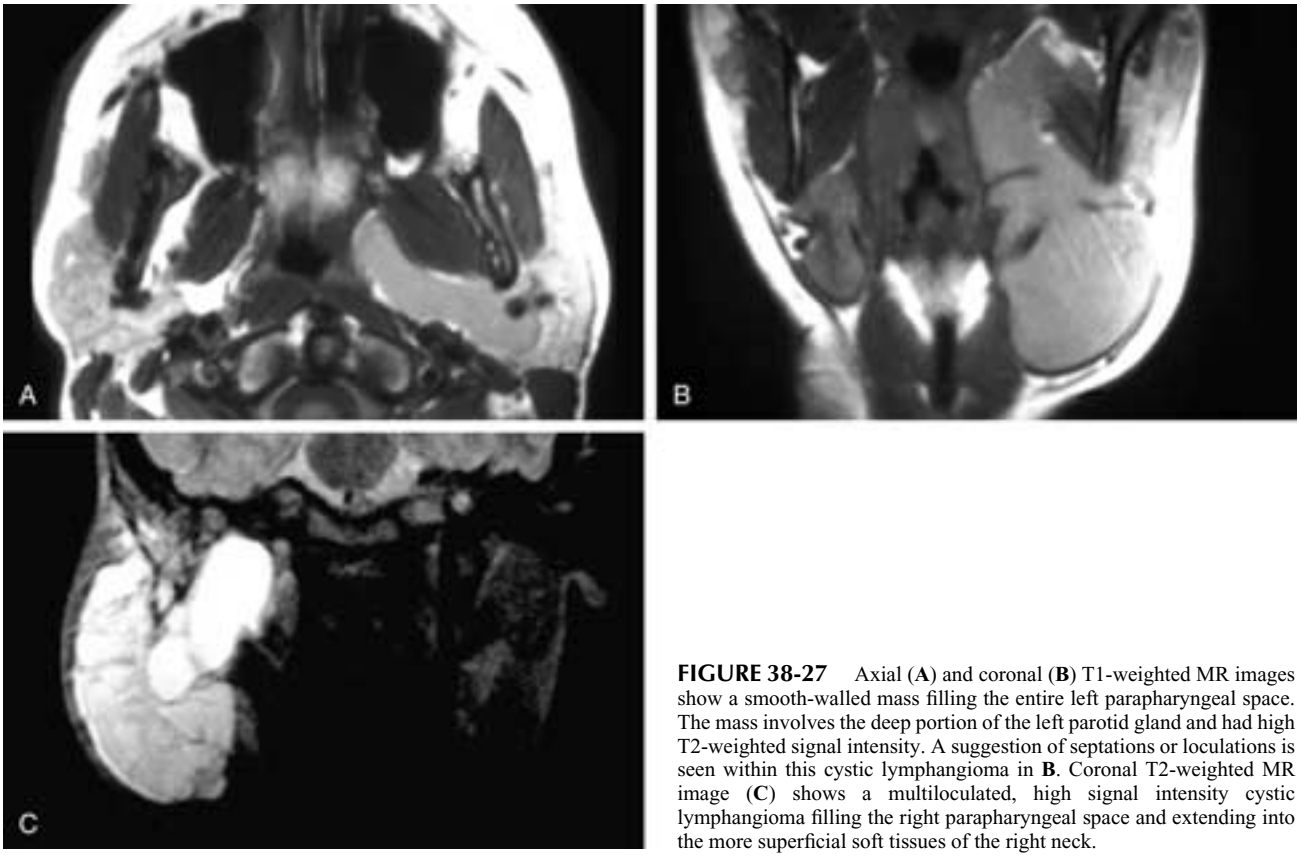

FIGURE 38-27 Axial (**A**) and coronal (**B**) T1-weighted MR images show a smooth-walled mass filling the entire left parapharyngeal space. The mass involves the deep portion of the left parotid gland and had high T2-weighted signal intensity. A suggestion of septations or loculations is seen within this cystic lymphangioma in **B**. Coronal T2-weighted MR image (**C**) shows a multiloculated, high signal intensity cystic lymphangioma filling the right parapharyngeal space and extending into the more superficial soft tissues of the right neck.

predisposes cervical arteries to dissection is supported by reports of intracranial aneurysms associated with spontaneous cervical artery dissection, a familial association of intracranial aneurysms and cervical artery dissection, a familial occurrence of cervical artery dissections, and the occurrence of multivessel dissections.

Mokri et al. reported that cranial nerve palsy was present in 12% of 190 adults diagnosed with spontaneous dissection of the extracranial ICA.[131] Of these patients with cranial nerve findings, 65% presented with isolated cranial nerve palsy. The most common isolated cranial nerve to be involved in this series was cranial nerve V. There are also two distinct syndromes of cranial nerve palsies that are recognized in association with dissection of the ICA: a syndrome of ocular motor palsies (III, IV, VI) and a syndrome of lower cranial nerve palsies (IX, X, XI, XII). These lower cranial nerves can be affected in multiple combinations; however, cranial nerve XII is almost always involved, and frequently there is an associated ipsilateral headache. When the dissection involves the cavernous portion of the ICA, ocular motor palsy is seen.[131] Isolated vagal neuropathy has also been reported.[130]

The traditional method of imaging cervical cephalic arterial dissection has been catheter angiography, in which findings may include smooth or slightly irregular luminal narrowing, pseudoaneurysm, an intimal flap, or distal branch occlusions secondary to embolization. CT and MR imaging provide a noninvasive means of diagnosing arterial dissection, and findings on each of these studies include an eccentric rim of mural thickening surrounding a narrowed lumen. On CT, the intramural hemorrhage usually is hypodense to muscle, and a thin rim of enhancement may be seen around the hematoma, presumably representing enhancement of the vasa vasorum. On MR imaging, typically the eccentric or circumferential periarterial rim of the intramural hematoma demonstrates hyperintense signal on T1-weighted and T2-weighted images (Fig. 38-30). The utility of MRA in the diagnosis of dissection is limited, and probably the most useful MR imaging sequence is fat-suppressed, axial T1-weighted images with inferior saturation pulses.[130] Other authors prefer a non-fat-suppressed, noncontrast sequence to best identify the bright signal of the dissection with a ring around it. Duplex sonography is less reliable than angiography and MR imaging, primarily because the dissection is usually distal to the region that can be well visualized on ultrasound. Findings on ultrasound may include an echogenic intimal flap or an echogenic thrombus, and Doppler waveforms may show a highly resistive, obstructive pattern.

Variations in the course of the ICA are reported to occur, with an incidence of 15% to 40%. They are mainly the result of degenerative atherosclerosis, with elongation, slight coiling, and kinking of the vessel. In addition, a sigmoid-shaped tortuosity represents an occasional congenital anomaly.[132] Commonly, the tortuous ICA causes an impression on the pharyngeal wall, and this may be an uncommon cause of a retropharyngeal or parapharyngeal ''mass.'' Such a fullness has also been related to minor globus syndromes. The ICA can also come into direct contact with the tonsillar fossa, creating a significant surgical risk during tonsil surgery.[132, 133] This abnormal positioning of the artery is well seen on contrast CT and MR images, and it is extremely important that the

clinician be notified of this vascular aberration so that an ill-fated biopsy is not attempted (Fig. 38-31) (also see Chapters 28 and 41).

An intense vasovagal reaction characterizes those reflex cardiovascular syncopes in which the glossopharyngeal nerve constitutes the main afferent nerve pathway. In these syndromes, afferent fibers of the glossopharyngeal nerve project from the baroreceptor area to the medullary cardiac, and vasomotor centers and efferent fibers then descend to the vagus nerve. The most common reflex cardiovascular syndromes linked to cranial nerve IX are carotid sinus syndrome (CSS) and the glossopharyngeal neuralgia-asystole syndrome (GNS). Most patients are males, with a mean age of 65.4 years. The episodes are characterized by weakness, general malaise, pallor, sudation (sweating), very low (40 to 60 mmHg) systolic pressure, mental disorientation, and/or syncope. Often the admission diagnosis in these patients is CSS, but the clinical picture differs in that a triggering factor is not present, the vasovagal episodes are longer, syncope is more frequent and severe, and cranial nerve pacing is ineffective. In all of these patients, imaging shows either a malignant or a benign mass compressing the parapharyngeal space. The pathogenesis of syncope may be similar to that occurring in GNS, except for the absence of neuralgia. Surgical carotid sinus denervation or atrioventricular (A-V) sequential (DDD) pacing is ineffective in completely controlling symptoms, and intracranial sectioning of cranial nerve IX appears to be the most effective mechanism for controlling the syndrome.[134, 135]

Copyright © 2003, Mosby, Inc. All rights reserved.

Trauma

Many different types of trauma can involve the parapharyngeal space, either accidentally or intentionally. The trauma can vary from the unusual explosion of a bottle in a child's mouth, to pellets or bullets, to sharp foreign objects often accidentally placed in food, to knives. In particular, lateral oropharyngeal injuries raise increased concern regarding potential neurovascular impairment via extension into the parapharyngeal space. Unfortunately, neither the mechanism of injury nor the degree of injury correlates well with the potential for neurovascular sequelae, which may not become clinically apparent until days or weeks after the incident.[136–141]

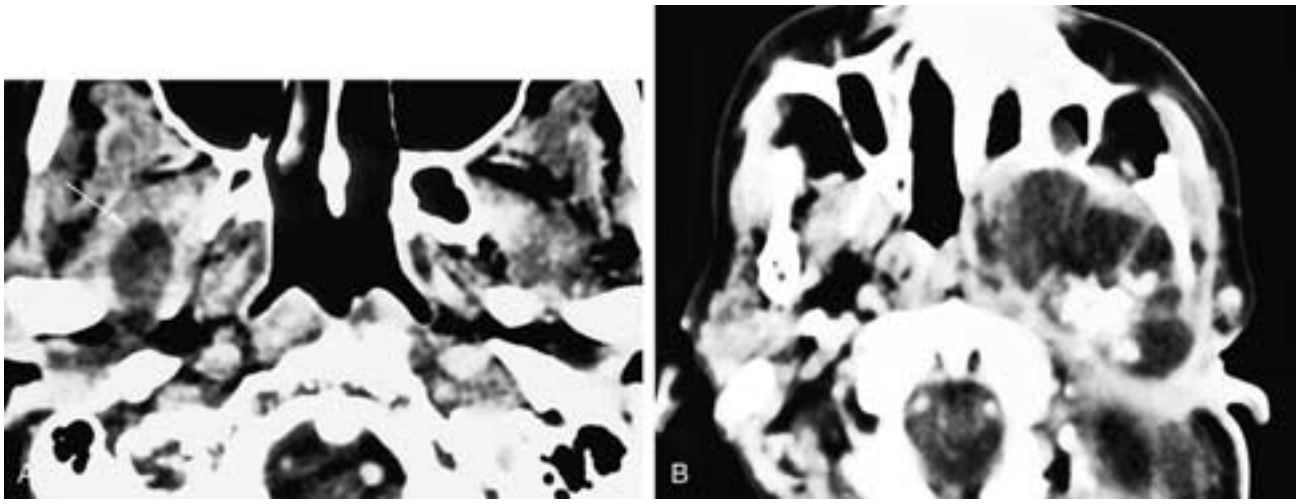
Diseases and Tumors Arising in the Skull Base

Osseous and cartilaginous lesions of the skull base, cervical vertebrae, and mandible are uncommon. These tumors can extend, usually via a stalk-like extension, into the parapharyngeal space. Osteomas (exostoses), osteogenic sarcomas, chondromas, chondrosarcomas, osteochondromas, chordomas, and fibroosseous lesions have all been reported.[124, 142–144] These patients present with signs and symptoms related to the mass effect in the parapharyngeal region. Malignant degeneration of a benign osteocartilaginous exostosis into osteosarcoma and chondrosarcoma has also been reported, and it has been suggested that the differentiation of these benign and malignant osteocartilaginous tumors is best accomplished by examining the imaging features of the cartilage cap.[142] Because of either an osseous matrix or calcifications, these lesions are usually better diagnosed on CT. Often, the final diagnosis is made only by pathologic examination (Fig. 38-32).

Chordomas usually arise in the clivus. Those tumors that arise in the petrous apex are now referred to as chondrosarcomas. Rarely, they may extend caudally into the parapharyngeal space. About 35% of all chordomas occur in the bones of the skull, and the usual natural history is that of relentless local recurrences. However, recent skull base surgery has shown promise of improving this prognosis. About 7% of skull base chordomas can metastasize, usually to the lungs, other bones, skin, lymph nodes, and liver. On CT, most tumors have a nonhomogeneous enhancing appearance, with multiple scattered areas of ''calcification'' that presumably represent residual skull base fragments. On MR imaging, these tumors have a variable nonhomogeneous signal intensity on all imaging sequences, depending upon the histologic makeup of the tumor.[9] In general, because of their bony matrix and the presence of scattered calcifications, some authors believe that these tumors are more easily diagnosed on CT than on MR imaging studies.[124, 142, 143]

Diseases and Tumors Arising Intracranially

Intracranial masses rarely extend through the skull base to project into the parapharyngeal space, and only a few such cases have been reported. Meningiomas represent 13% to 18% of all primary intracranial tumors, and they are the most common of the intracranial neoplasms to extend into the parapharyngeal space. They exit the intracranial compartment either by extending through the jugular fossa or other neurovascular canals or by invading the skull base bone itself.[145] The involved bone can be permeated but otherwise intact, or there can be erosion or some remodeling. Hyperostotic thickening of the bone is a common finding.[7–9, 146] Once the meningioma extends below the skull base, it can grow rapidly, becoming a bulky mass that most often causes the patient to seek medical attention. Meningiomas are enhancing, homogeneous tumors that may have calcifications either in a localized portion of the lesion or scattered throughout the tumor (Fig. 38-33). On MR imaging, they usually have signal intensities similar to those



VIEW IMAGE

FIGURE 38-32 Axial contrast-enhanced CT scan (**A**) shows a fairly low-attenuation, sausage-shaped mass (*arrow*) extending from the skull base down into the parapharyngeal and masticator spaces. This was a chondroma. Axial contrast-enhanced CT scan (**B**) shows an overall low-attenuation mass in the left masticator and parapharyngeal spaces, with destruction of the posterior left maxilla. Within the mass are large tumoral calcifications. Note the difference in the appearance of the calcifications in this chondrosarcoma from those in aneurysms (see Figs. 38-14B and 38-27).

VIEW IMAGE

FIGURE 38-33 Axial (**A**) and coronal (**B**) contrast-enhanced CT scans show a homogeneously enhancing mass in the right parapharyngeal space, the right skull base (which is thickened and sclerotic), and the right posterior fossa. This is a fairly typical imaging appearance for a meningioma. Coronal CT scan (**C**) shows a heavily calcified meningioma extending from the left posterior fossa down into the left parapharyngeal space via the jugular fossa. Coronal T1-weighted MR image (**D**) shows a nonhomogeneous giant aneurysm in the left middle cranial fossa (*black arrow*) that extends down into the left parapharyngeal space (*white arrow*).

of brain. Most of these tumors are in the posterior fossa and extend down through the petrous apex, jugular fossa, and central skull base. Despite their vascularity on angiography, vascular flow voids are rarely seen on MR imaging.

Rarely, a giant aneurysm can erode through the skull base and present as a mass in the parapharyngeal space. These long-standing aneurysms usually have wall calcifications that are best seen on CT. On MR imaging, peripheral signal voids reflect hemosiderin, fibrosis, and/or calcification in the aneurysm (Fig. 38-33). There are also rare reports of glial tumors that extend below the skull base.[147]

There is a case report of a newborn with an extracerebral, intracranial mass that extended from the right middle cranial fossa through the base of the skull to the parapharyngeal space. The mass was composed predominantly of immature brain tissue, and it was enclosed by its own leptomeninges and dura. It was classified as a glioneural hamartoma.[148]

MASTICATOR SPACE ANATOMY

Throughout the literature, there has been relatively little ambiguity about the description of the fascial boundaries of the masticator space, which contains the muscles of mastication: the temporalis, masseter, lateral pterygoid, and medial pterygoid muscles. This space was first described by Juvara in 1870 and was first referred to as the masticator space by Coller and Yglesias in 1935.[3, 5, 6, 149–151]

The anatomy of the masticator space is discussed in detail in Chapter 34. In summary, the fascia that forms the borders of the masticator space is well-defined fibrous tissue that is more on the order of an aponeurosis (Fig. 38-34). The fascia surrounds the muscles of mastication, with the lateral pterygoid muscle lying freely within the space, while the other muscles contribute to the surrounding fascia.[3, 5, 6, 149–153] Most of the medial boundary is the strong interpterygoid fascia, which sweeps cranially from the mandible to the skull base, attaching along a line that extends from the root of the medial pterygoid plate to the sphenoid spine, just medial to the foramen ovale. When viewed in a coronal plane, this fascia runs obliquely downward and laterally from the skull base. Immediately deep (medial) to this fascia is the fat within the prestyloid compartment of the parapharyngeal space. This fat provides an excellent imaging boundary by which to determine whether pathology has grossly violated the medial fascial boundary of the masticator space.[7, 9, 20, 23, 25–27, 30, 32, 42, 151, 153–156] The lateral fascia extends from the bottom of the mandible upward to

Copyright © 2003, Mosby, Inc. All rights reserved.

encase the zygomatic arch. The fascia then continues cranially to the temporal ridge of the calvarium. The fascia also attaches to the lateral orbital margin of the temporal fossa, encasing the temporalis muscle. The medial and lateral fasciae join both anteriorly and posteriorly around the mandibular ramus, closing this space. The parotid gland lies immediately dorsal to the masticator space, and the buccal fat pad is either along the ventral border of this space or within the space.

The differential diagnosis of masses that occur within the masticator space is summarized in Table 38-3.

The Masticator Muscles and Mastication

With regard to the muscles of mastication, opening the mouth is accomplished on either side by the lateral pterygoid muscle (whose medial [upper] head attaches to the temporomandibular articular disc and whose lateral head [lower] attaches to the neck of the mandible) pulling the mandibular condyle forward in a gliding motion. Mouth opening is also assisted, to a small degree, by the superficial portions of the masseter muscle and the medial pterygoid muscle, while the chin is pulled downward and backward by the digastric muscles. If the hyoid bone is fixed in place by contraction of the infrahyoid muscles (strap muscles), and there is some contraction of the temporalis muscles, then contraction of both bellies of the digastric muscles also can open the mouth. Closing the mouth requires relaxation of the lateral pterygoid muscles and digastric muscles, while the temporalis (posterior or horizontal fibers), medial pterygoid, and masseter muscles pull the mandible upward.

Chewing, which is a slewing or grinding motion, is accomplished by both anteroposterior and lateral excursions of the mandible. The anteroposterior motion is produced on either side by alternating actions of the lateral pterygoid muscle and the posterior fibers of the temporalis muscle. The lateral excursion is caused by the medial pterygoid muscle, which on either side pulls the angle of the mandible upward, forward, and medially.[157]

In anatomic summary, the ramus of the mandible lies almost centrally within the masticator space. It is surrounded by the masticator muscles, which, in turn, are contained by firm fascial boundaries.

Table 38-3
MASTICATOR SPACE MASSES

Arising Within Muscle
Hemangioma: usually within masseter muscle
Lymphangioma
Benign masticator muscle hypertrophy
Denervation of masticator muscles (disease or surgery to V_3)
Rhabdomyosarcoma
Rhabdomyoma
Leiomyoma
Lymphoma (non-Hodgkin's)
Metastasis
Arising Within Mandible
Osteomyelitis (usually secondary to odontogenic infection)
Radiation necrosis
Osteoblastoma
Osteosarcoma
Chondrosarcoma
Odontogenic
Dentigerous cyst
Keratocyst
Ameloblastoma
Metastasis
Arising Within Nerve
Schwannoma
Neurofibroma
Neurosarcoma
Spread From:
Acute sialadenitis: either parotid gland or accessory parotid tissue
Salivary gland malignancy
Mucoepidermoid carcinoma
Squamous cell carcinoma
Adenocarcinoma not otherwise specified
Retromolar trigone squamous cell carcinoma
Oropharyngeal squamous cell carcinoma

VIEW IMAGE

FIGURE 38-34 Drawing of the facial region as seen from the left anterior oblique view. A coronal slice has been made through the left masticator space showing the masseter and temporalis muscles laterally and the medial pterygoid muscle medially. The lateral pterygoid muscle lies freely within the masticator space.

CLINICAL PRESENTATION OF MASTICATOR SPACE MASSES

Symptoms referable to the masticator space are pain and trismus. The third division of the trigeminal nerve, the mandibular nerve, exits the skull base at the foramen ovale, descends in the masticator space to the inner aspect of the ramus of the mandible, and then enters the mandible through

Copyright © 2003, Mosby, Inc. All rights reserved.

the mandibular canal as the inferior alveolar nerve, supplying sensation to the teeth. Thus the mandibular nerve contains both motor fibers (for the muscles of mastication) and sensory fibers. The sensory fibers supply the skin of the temporal region, auricle, external auditory meatus, mastoid air cells, cheek, lower face, lower lip, mucous membrane of the cheek, tongue, lower teeth and gums, mandible, temporomandibular joint, and some of the dura. However, through the first and second divisions of the trigeminal nerve, pain of masticator space origin can present as referred pain to the upper face and orbit. Thus, a patient may complain of numbness in the lower teeth, temporomandibular joint pain, ear pain, midfacial pain, pain over the temporal fossa region, temporal headache, or pain in the orbit or forehead. Tumors involving the masticator space often extend in a retrograde manner along the mandibular nerve, through the foramen ovale, into the lateral margin of the cavernous sinus, and occasionally back to the Gasserian ganglion. Tumor spread can also extend into the cavernous sinus proper.

An additional important branch of the mandibular nerve is the auricular temporal nerve, which arises near the middle meningeal artery at the foramen spinosum. This nerve runs laterally deep to the external (or lateral) pterygoid muscle, along the medial side of the mandible, and then turns upward with the superficial temporal artery, under the cover of the parotid gland. The peripheral branches then communicate with the facial nerve, in the substance of the parotid gland, and connect to the otic ganglion. It is this auricular temporal nerve that may act as a pathway for a parotid tumor to extend in a retrograde manner not only along the facial nerve, but along the mandibular nerve. The topic of neural tumor spread is discussed in Chapter 13.

Infections are more common in the masticator space than are tumors, and most of these infections are odontogenic in origin. Often, the offending source is related to a recent tooth extraction, especially a mandibular molar tooth. Less commonly, chronic caries with severe gingivitis and even osteomyelitis of the mandible are the offending sites. Rarely, a traumatic extraction of a maxillary molar tooth may lead to a masticator space infection. Other infectious sources include parotid (and less often submandibular) gland sialadenitis, extension of a severe retropharyngeal space infection or a pharyngitis, and extension of a palatine tonsillar abscess.[158–165]

Noninfectious pathology that affects the masticator space can arise from components within it, can be extensions of processes that arise in proximity to it, or can be metastases to it. Lesions that have been reported to arise within the space include schwannomas, fibrous dysplasia, ossifying fibroma, osteomas, dentigerous cysts, odontogenic keratocysts, ameloblastomas, pigmented vilonodular synovitis, synovial chondromatosis, hemangiomas, lymphangiomas, lipomas, masticator hypertrophy, and a variety of sarcomas including osteosarcoma, chondrosarcoma, fibrosarcoma, rhabdomyosarcoma, hemangiosarcoma, hemangiopericytoma, ameloblastic sarcoma, Ewing's sarcoma, juxtacortical osteosarcoma, myxosarcoma, malignant fibrous histiocytoma, and large cell lymphoma. Metastases to this space from a variety of primary tumors have been reported including adenocarcinoma of the breast, prostate, colon, and stomach; urinary bladder, renal cell, hepatocellular, and follicular thyroid carcinomas; squamous cell carcinoma of the lip; and metastases from chordomas and meningiomas. There can also be extension of carcinomas arising in the nasopharynx, retromolar trigone, buccal region, and parotid and submandibular glands. Cases of recurrent maxillary ameloblastomas have also been reported, with tumor extension from the maxilla into the infratemporal fossa, infraorbital fissure, masticator space, and left ethmoid sinus. A postbiopsy traumatic aneurysm of the buccal artery has also been reported.[166–190]

THE BUCCAL FAT

There is a well-encapsulated collection of fat that lies superficial to the posterior aspect of the buccinator muscle and along the anterior edge of the masseter muscle. This fat pad is clearly separated from the superficial layer of the deep cervical fascia as it covers the masseter muscle and from the buccopharyngeal fascia (middle layer of the deep cervical fascia) as it covers the buccinator muscle. This fat pad fills the groove between these muscles and in the adult is called the buccal fat pad. In the newborn, this same fat pad is referred to as the suctorial pad, as it is alleged to help prevent indrawing of the cheeks during sucking. Extensions from this fat pad are thought, by some, to reach between the masseter and temporalis muscles and to extend deeply into the infratemporal fossa, separating the external pterygoid and temporalis muscles from the maxilla. Stenson's duct from the parotid gland lies over the buccal fat pad before penetrating the buccinator muscle at the level of the second upper molar tooth.

Also in this buccal region are the facial artery and vein, which lie adjacent to the superior and middle pharyngeal constrictors and deep to the platysma, risorius, and zygomaticus muscles. The facial artery is especially tortuous and ends as the angular artery, rising along the side of the nose and ending near the medial orbital commissure. The buccal region is often affected by disease arising in the masticator space, the parotid gland, the buccal oral cavity margin, and the retromolar trigone.

IMAGING PATHOLOGY AFFECTING THE MASTICATOR SPACE

Inflammatory Diseases

The classic imaging manifestation of inflammation is cellulitis, which is seen as a swelling of the fat planes in the involved region, with a rete pattern of soft-tissue stands that represent dilated venules and lymphatics. This ''dirty'' fat appearance is a nonspecific finding that reflects any type of inflammation, whether from infection, trauma, or irradiation. On CT, the attenuation of the fat is greater than that of normal fat, while on MR imaging, the fat may have a lower than normal T1-weighted signal intensity and a high T2-weighted signal intensity, reflecting the increased fluid within it.

When the masticator muscles become inflamed they enlarge, and on CT they usually have a lower attenuation

Copyright © 2003, Mosby, Inc. All rights reserved.

than normal muscle. On MR imaging, the inflamed muscle has a higher T2-weighted signal intensity than normal muscle, and on both CT and MR imaging, the muscle enhances and is usually nonhomogeneously affected (Figs. 38-6 and 38-35).[158] Clinically, the patient has an acute history, with pain in the masticator region, swelling and redness of the overlying facial area, and often trismus.

The ramus, angle, and posterior body of the mandible are within the masticator space, and they are the least likely of the masticator space structures to be affected by routine infections. It is only the unusual case of osteomyelitis spreading from the alveolar region of the mandible or an infected radiation osteitis that affects the masticator space portions of the mandible. Early changes of osteomyelitis are not commonly seen on CT, while on MR imaging there is loss of the normal fatty marrow high T1-weighted signal intensity as inflammatory cells invade the bone. On CT, there may be focal areas of cortical deossification and some loss of the bony medullary septae. In more advanced osteomyelitis, sequestra, a periosteal reaction, and gross demineralization of the bone are present, again changes better seen on CT than on MR imaging (Fig. 38-36). Extension outside of bone can distort the soft tissues, and a ''cloaca'' may be seen as a defect in the cortex.

The most critical imaging steps in treatment planning of a masticator space infection are identifying the presence of an abscess, mapping the boundaries of the disease, and identifying a carious tooth as the potential source of the problem. An abscess, as elsewhere in the body, is seen as a localized area of low-attenuation, nonenhancing pus surrounded by an irregular, enhancing, often fairly thick capsule. Not only is the distinction between the central pus and the abscess rim best seen after contrast administration on both CT and MR imaging, identification of the abscess wall may be missed on noncontrast images. On MR imaging, the pus has a low to intermediate T1-weighted and

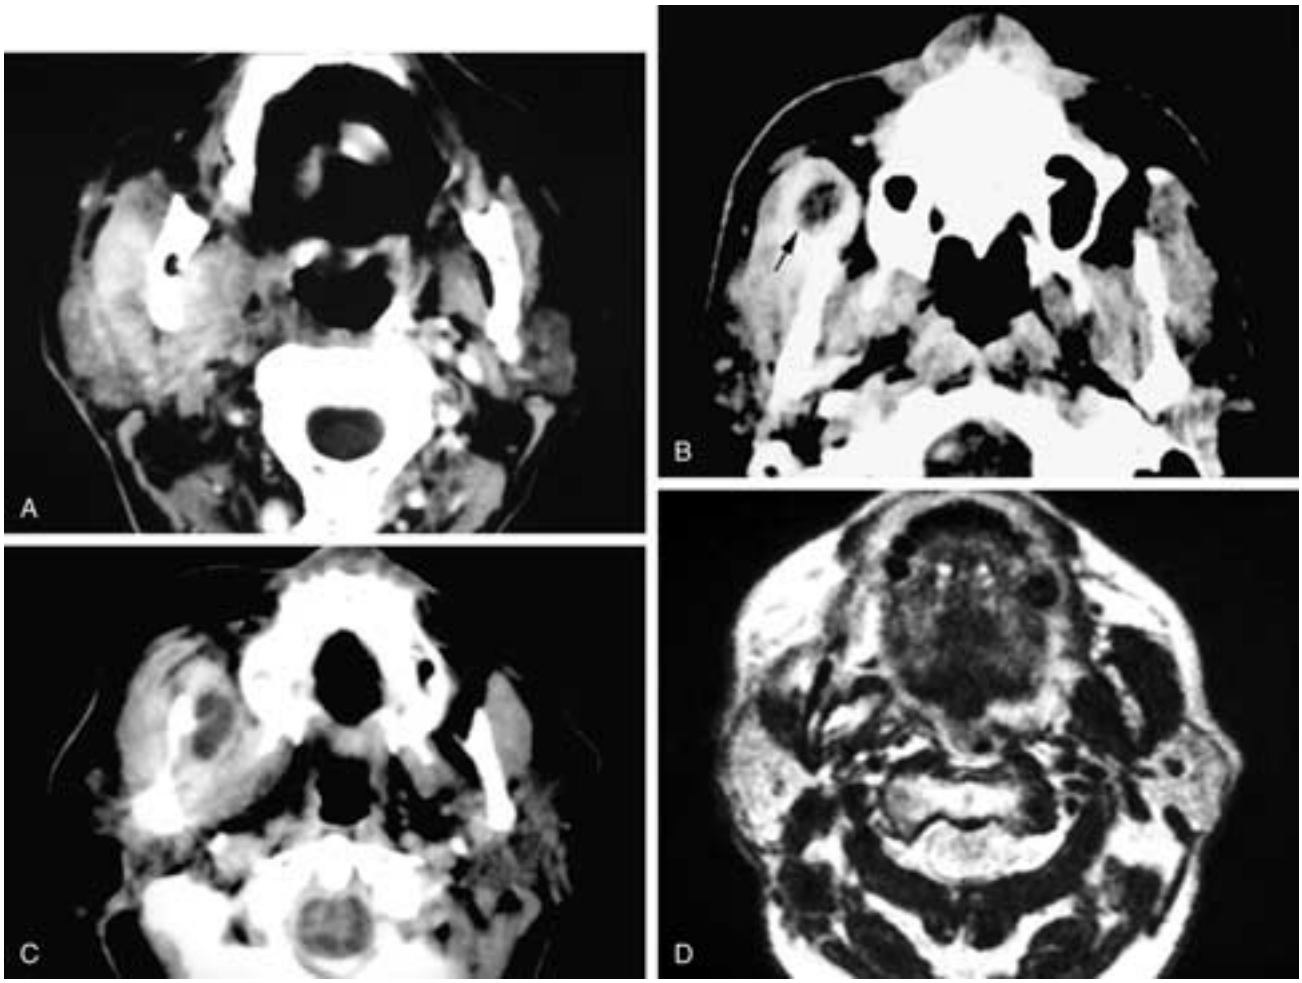

FIGURE 38-35 Axial contrast-enhanced CT scans show (**A**) enlargement and enhancement of the right masticator space muscles, with effacement of the adjacent fat planes including the fat in the right prestyloid compartment of the parapharyngeal space. There is also enhancement of the right parotid gland representing a secondary parotitis. This was an acute cellulitis of the masticator space. In **B**, there is swelling and enhancement of the right masseter muscle, with a low-attenuation abscess (*arrow*) anteriorly within the muscle. There is also enhancement of the medial pterygoid muscle in this patient with a masticator cellulitis and abscess. There is virtually no effacement of the adjacent fat planes. In **C**, there is a right masticator space cellulitis and abscess, with virtually no effacement of the adjacent fat planes. In **D**, an axial T2-weighted MR image shows the right masticator space muscle to have high signal intensity (compared to that of the normal left masticator muscles). This patient had a right masticator space cellulitis.

VIEW IMAGE

FIGURE 38-36 Axial CT scan viewed at wide window settings shows interruption of the cortices of both mandibular rami. There is loss of some of the medullary septations and there are areas of sclerosis. There is a non-displaced fracture of the anterior left ramus. Similar changes are also present in the zygomas. This patient had radiation osteitis after RT treatment and surgery for a right medial wall maxillary sinus carcinoma. The surgical defect is seen as is the partial resection of the right pterygoid plates.

a high T2-weighted signal intensity. Due to beam hardening artifact from the mandible and/or dental amalgams, a small abscess along the dorsal aspect of the ramus of the mandible may be difficult to identify in some patients. Angled CT scans or sagittal or oblique MR images may occasionally be necessary in these cases. It is important to identify an abscess, as this usually indicates the need for immediate surgical intervention in association with intravenous antibiotic therapy. Without an abscess, antibiotic therapy alone usually causes the infection to resolve within a few days.

Mapping the infection is also important in treatment planning, as the disease may have spread to the masticator space from adjacent areas such as the submandibular space, the parapharyngeal space, or the parotid gland.[191] Parotid gland involvement is identified by enlargement of the gland, increased attenuation on CT, and a higher T2-weighted signal intensity than normal (compared to the uninvolved side) (Fig. 38-35A). Spread of the infection into the parapharyngeal space is noted as a ''dirty'' appearance of the prestyloid compartment fat and a blurring of the normally sharp interface between the medial masticator space and the parapharyngeal space. Similarly, if the infection has spread to the submandibular space, the fat planes are blurred and the digastric muscles and muscles of the floor of the mouth may be enlarged, as occurs with the muscles in the masticator space. In virtually all cases, there is cellulitis of the overlying face, as noted by thickening of the subcutaneous fat, a ''dirty'' fat appearance, and possible thickening of the skin.

Denervation Atrophy

The imaging changes of inflammation should not be confused with denervation atrophy of the masticator muscles.[191–198] Patients with denervation of the masticator muscles usually have a prior history of trauma or surgery involving the mandibular nerve (also see Chapter 41). There may be bite weakness and flattening of the side of the face; pain is rarely present. Occasionally, clinically unexpected early denervation may be observed on imaging studies. When this is seen, attention should be directed to the foramen ovale and along the course of the mandibular nerve, as the denervation may signal the presence of an otherwise clinically silent tumor. Neural and perineural tumor spread is discussed in detail in Chapter 13.

If there is masticator muscle denervation, within the first 4 weeks there usually is mild muscle enlargement, and there may be some muscle enhancement and increased T2-weighted signal intensity. During the next 20 months after denervation, the muscle volume starts to decrease as muscle fibers progressively undergo fatty replacement, which is seen as progressive low attenuation on CT and as high T1-weighted signal intensity on MR imaging. There is also muscle enhancement and an increase in T2-weighted signal intensity. With long-standing denervation, there is progressive fatty replacement of the muscle, decrease in muscle size, loss of muscle enhancement, and loss of the high T2-weighted signal intensity (Fig. 38-37).[193]

Masticator Muscle Hypertrophy

Masticator muscle hypertrophy can affect all the muscles of mastication, several muscles, or just one muscle (also see Chapter 41). It can occur either bilaterally or unilaterally, and most commonly the masseter muscles alone are affected.[199–201] The involved muscles, which are variably enlarged and can be up to three times the normal size, are otherwise normal on all imaging studies. Flaring of the mandibular angle on the involved side can also occur.[202] The process usually starts in adolescence or early adulthood, and there is a history of slowly progressive muscle growth. The facial fullness is located anterior to the usual location of a parotid lesion, and the mass enlarges when the patient's teeth are clenched. The mass feels like muscle on palpation and is not tender or painful. The etiology is unclear but may be related to bruxism and gum chewing. Plain films may show an exostosis of the lateral aspect of the angle of the mandible at the line of attachment of the masseter muscle. A sialogram demonstrates lateral bowing of Stensen's duct around the enlarged masseter muscle, and CT and MR imaging show an enlarged, otherwise normal muscle (Fig. 38-38). Surgery is performed only for cosmesis, and microscopic examination of resected muscle demonstrates either normal muscle or muscle with true work hypertrophy.

Muscle hypertrophy can also occur as a compensatory mechanism; this has been reported in cases of hemifacial microsomia with unilateral condylar hypoplasia. CT has shown the ipsilateral medial pterygoid muscle to be larger. This was considered likely to be a compensatory adjustment to help keep the mandible centered.[203]

There is sparse quantitative information on the normal size range of the masticatory muscles, and such data may be needed for the successful treatment of facial asymmetry. In one study, the muscles were scanned from their origins to their insertions, and the maximum cross-sectional area (MCSA) and its location relative to the mandibular foramen were noted. The MCSA of the masseter muscle was centered 8 mm above the mandibular foramen, while that of the medial pterygoid muscle was centered at the level of the

Copyright © 2003, Mosby, Inc. All rights reserved.

foramen. It was noted that the MCSA of both muscles was highly correlated with their volumes, suggesting that this parameter might serve as an indicator of their volume.[204] In this article, the mean MCSA of the masseter muscle in males was 535.9 mm^2 and in females it was 434.9 mm^2. The mean MCSA for the medial pterygoid muscle was 363.7 mm^2 in males and 310.6 mm^2 in females.

Tumors and Nonneoplastic Masses

Three helpful imaging criteria are used to determine the presence of an invasive malignancy in the masticator space: (1) erosion of the mandible, (2) invasion of the muscles, and (3) violation of the surrounding fascial planes.

Erosion of the mandible by a malignancy can occur as a tumor from outside the masticator space spreads into this space, first involving the masticator space fascia, then the muscles, and finally the mandible. This may be noted especially in tumors involving the retromolar trigone and the anterior tonsillar pillar regions. Alternatively, tumor may extend from the oral cavity, erode into the mandibular alveolus, and spread into the posterior body and ramus of the mandible. In this circumstance, initially the surrounding muscles and fascia may be uninvolved or only minimally affected.

Because most tumors, especially squamous cell carcinomas, arise adjacent to the masticator space and extend toward the bone, there often is erosion of the cortex only at the point of tumor entry. With more extensive disease, the bone is eroded and often fragmented, and there are infiltrative rather than sharp borders of the uninvolved bone. On MR imaging, the fatty marrow is replaced with tumor that has an intermediate T1-weighted and a slightly higher T2-weighted signal intensity. The tumor usually enhances to a moderate degree (Fig. 38-39).

Fragmentation of the bone may occur as a result of radiation osteitis. In these circumstances, the bone is sclerotic in areas, there are sequestra, and there are regions of demineralization. Often there are also mild inflammatory changes in the masticator muscles and the adjacent soft tissues (Fig. 38-40). Osteoradionecrosis is not a true necrosis of bone, but rather a particularly severe osteitis that evolves in bone and is related to compromise of the bone's vascularity. It may occur from 1 to 20 years after irradiation and is directly related to the total dose, the dosing rate, the presence of local infection or trauma, and the concurrent administration of chemotherapy.[205–207]

Bone production is also associated with tumors such as osteosarcomas, Ewing's sarcomas, plasmacytomas, metastatic meningioma, and keratocysts (Fig. 38-41). In addition, bone production or thickened bone can be seen with fibrous dysplasia, ossifying fibroma, and Paget's disease. These diseases are discussed in detail in Chapters 6 and 17. Multiple calcifications or ossifications about the ramus of the mandible can also be seen with osteosarcoma, chondrosarcoma, osteochondroma, hemangioma, and temporomandibular diseases such as synovial chondromatosis and chondrocalcinosis. These latter diseases are discussed in Chapter 18.

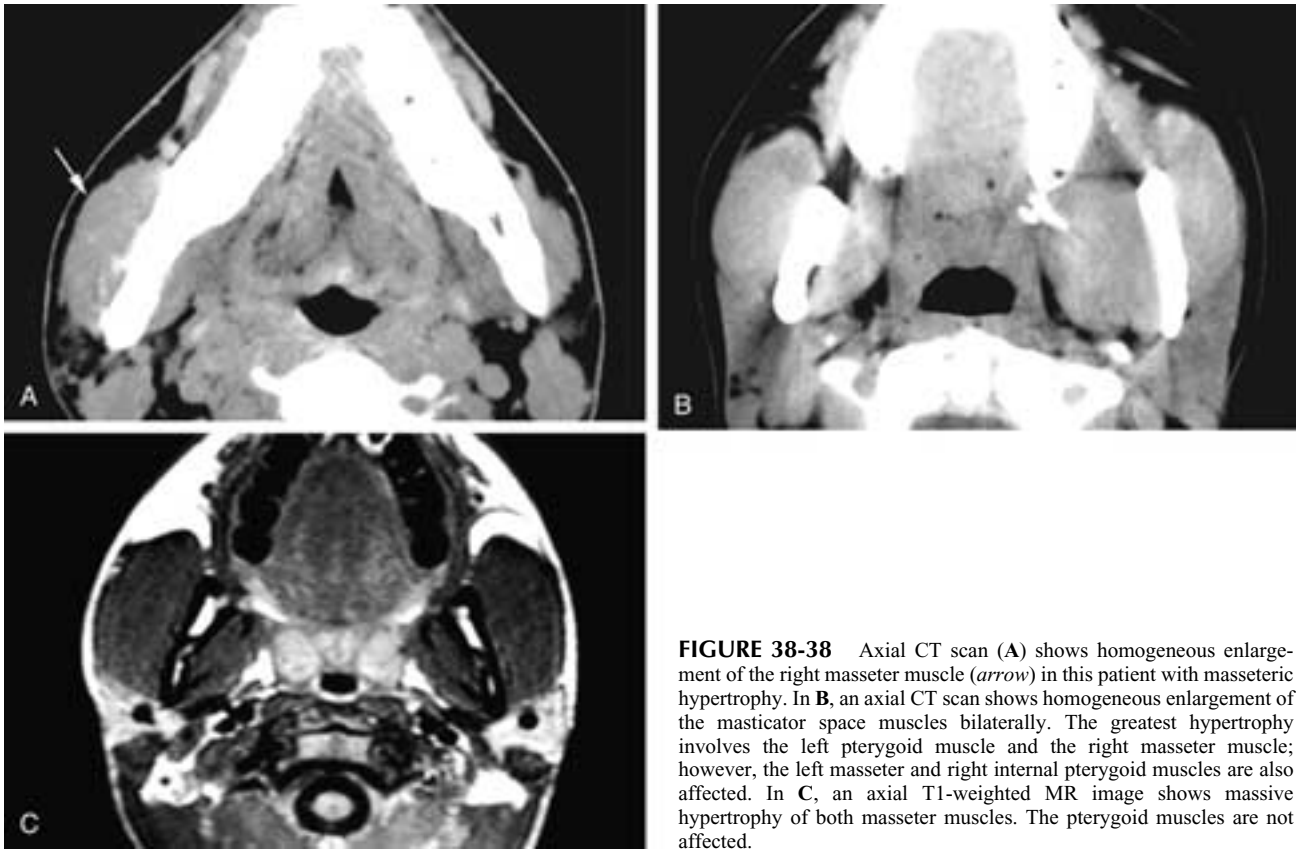

FIGURE 38-38 Axial CT scan (**A**) shows homogeneous enlargement of the right masseter muscle (*arrow*) in this patient with masseteric hypertrophy. In **B**, an axial CT scan shows homogeneous enlargement of the masticator space muscles bilaterally. The greatest hypertrophy involves the left pterygoid muscle and the right masseter muscle; however, the left masseter and right internal pterygoid muscles are also affected. In **C**, an axial T1-weighted MR image shows massive hypertrophy of both masseter muscles. The pterygoid muscles are not affected.

VIEW IMAGE

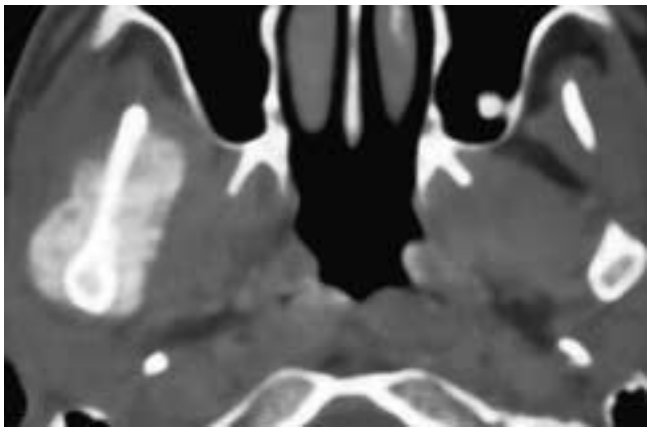
FIGURE 38-40 Coronal CT scan shows irregular areas of sclerosis, erosion, and fracture on both sides of the mandible in this patient with the typical imaging findings of radiation necrosis.

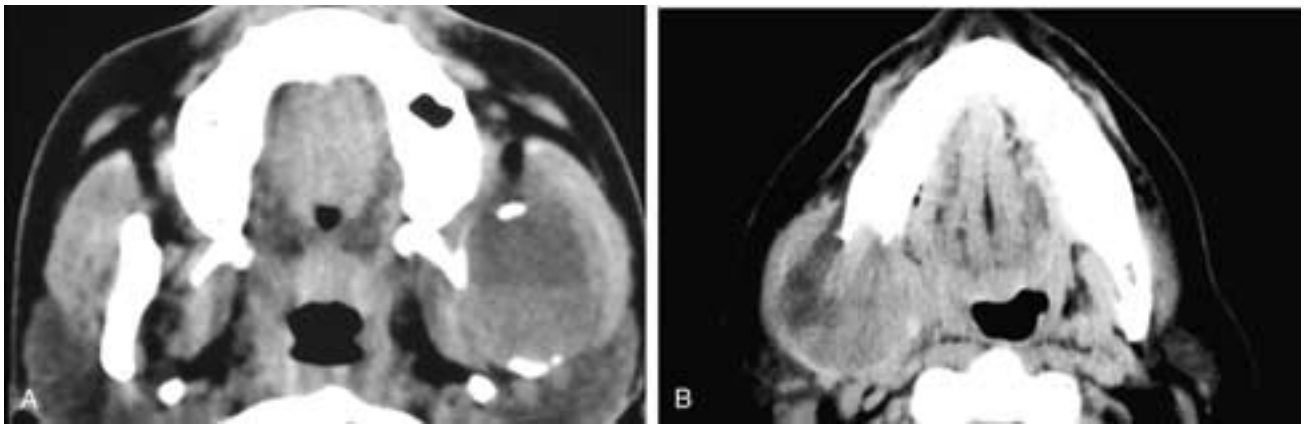
With regard to the de novo or postradiation mandibular osteosarcomas, nearly half of the cases are osteoblastic and occasionally a periosteal reaction is present. Tumor matrix mineralization occurs in more than 75% of the cases, and osteoid matrix calcification is frequent, even though most tumors are chondroblastic. Soft-tissue extension of tumor is present in all cases, and it contains calcifications in more than half of the cases. CT provides excellent detection of any tumor calcification, cortical involvement, and, in most instances, soft-tissue and intramedullary extension. However, MR imaging is even more effective in demonstrating the intramedullary and extraosseous tumor components on both T1-weighted and T2-weighted images. However, CT and plain films are superior to MR in detecting the matrix calcifications and bone destruction or reaction (Fig. 38-41). There can be dense sclerosis, an aggressive periosteal reaction, or multiple ossifications or calcifications.[142, 208–211]

Cystic expansion of the ramus may be seen with large dentigerous cysts, cherubism, aneurysmal bone cysts, keratocysts, and rare metastases (Fig. 38-42). The identifica-



VIEW IMAGE

FIGURE 38-41 Axial CT scan shows thickening and sclerosis of the right mandibular ramus, with an exuberant periosteal bone reaction along both the buccal and lingual cortices. There was a minimal adjacent soft-tissue mass effect in this patient with an osteosarcoma of the mandible.



VIEW IMAGE

FIGURE 38-42 Axial CT scan (**A**) shows an expansile cyst arising in the left mandibular ramus. Only a small region of cortex remains along the anterior and posterior edges of the ramus. The masticator space muscles are displaced away from the ramus but are otherwise normal. There is a fluid-fluid level in this benign bone cyst with hemorrhage. Axial CT scan (**B**) shows an area of cystic expansion of the right posterior body of the mandible, with erosion of the cortex around the mass. The masticator muscles are poorly seen as they are stretched around the lesion. This was a rare metastatic meningioma.

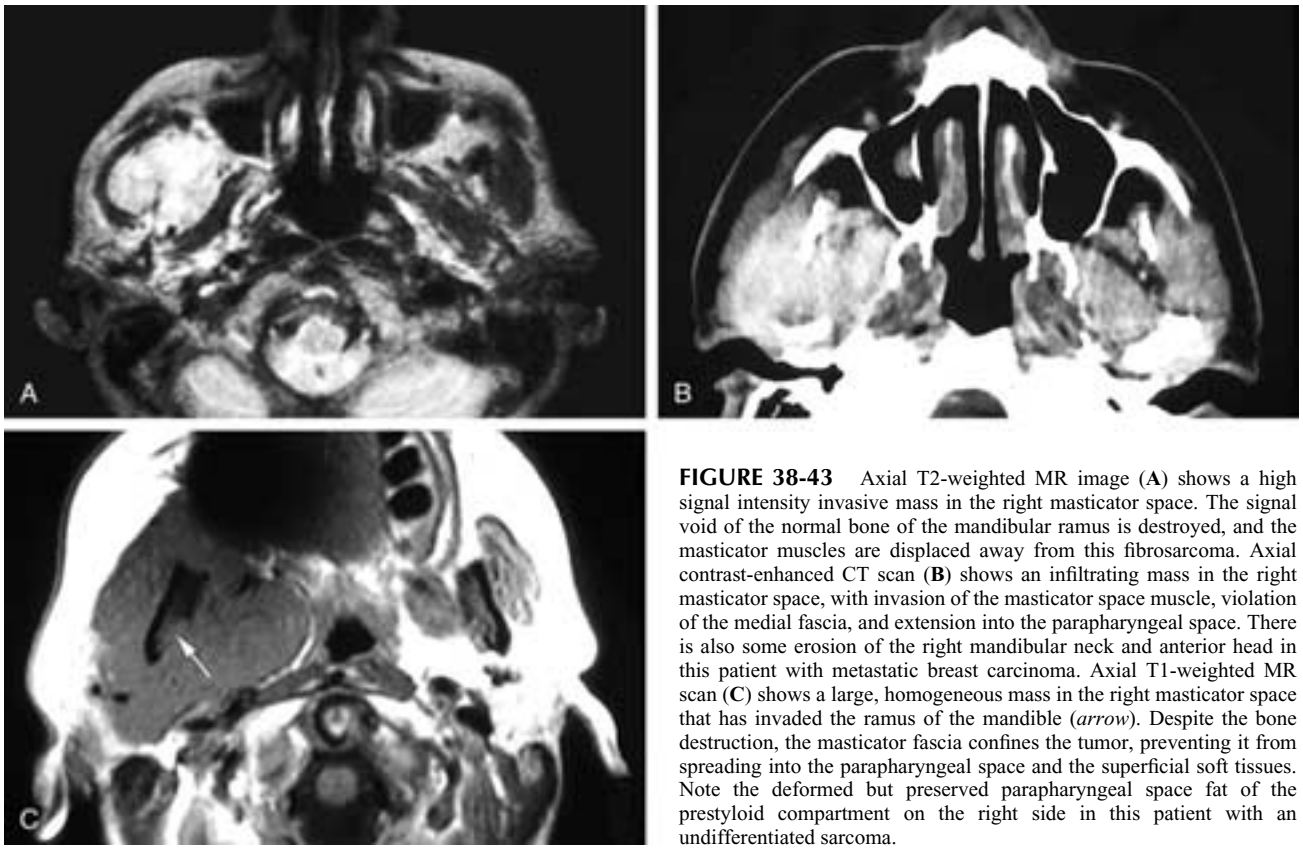

FIGURE 38-43 Axial T2-weighted MR image (**A**) shows a high signal intensity invasive mass in the right masticator space. The signal void of the normal bone of the mandibular ramus is destroyed, and the masticator muscles are displaced away from this fibrosarcoma. Axial contrast-enhanced CT scan (**B**) shows an infiltrating mass in the right masticator space, with invasion of the masticator space muscle, violation of the medial fascia, and extension into the parapharyngeal space. There is also some erosion of the right mandibular neck and anterior head in this patient with metastatic breast carcinoma. Axial T1-weighted MR scan (**C**) shows a large, homogeneous mass in the right masticator space that has invaded the ramus of the mandible (*arrow*). Despite the bone destruction, the masticator fascia confines the tumor, preventing it from spreading into the parapharyngeal space and the superficial soft tissues. Note the deformed but preserved parapharyngeal space fat of the prestyloid compartment on the right side in this patient with an undifferentiated sarcoma.

VIEW IMAGE

tion of a tooth within the cyst is diagnostic of the dentigerous cyst. These odonogenic lesions are discussed in Chapters 6 and 17.

Muscle invasion by tumor is better seen on MR imaging than on CT, as most cellular tumors have an attenuation similar to that of muscle. On MR imaging, the tumor has an intermediate T1-weighted and a slightly higher T2-weighted signal intensity, usually enhances to a moderate degree, and has infiltrative, unsharp margins. Thus, on MR imaging, the tumor is usually well seen silhouetted against the normal low T2-weighted signal intensity of muscle. The affected muscle is usually enlarged, and either a localized portion or the entire muscle may be infiltrated (Figs. 38-43 and 38-44).

Fascial invasion at first appears to be a very reliable sign of malignancy extending either into or out of the masticator space. This is, in fact, true when tumor extends into the masticator space, since the neoplasm must cross these strong fascial layers in order to gain entrance to this space. However, this is not always true when the tumor arises within the masticator space, and often, despite erosion of the mandible and involvement of the muscles, the outer masticator space fascia remains intact. In fact, high-grade malignancies can arise within the masticator space without evidence of either bone destruction or fascial invasion.[177] More commonly than tumor, infections cross the fascia, mimicking a tumor on CT and MR imaging. However, the history distinguishes inflammatory disease from neoplasm in almost all cases. Although both may present with trismus, tumors usually are painless, with a nontender or slightly tender mass. Infections produce pain, tenderness, and an associated elevated white blood cell count with a shift to the left.

Importantly with regard to tumors in the masticator space, it should be remembered that high-grade malignancies can be present without evidence of either bone erosion or fascial violation. When such a mass is seen within this space, especially in a patient less than 30 years of age, biopsy should be performed without delay (Fig. 38-44).[177]

Anatomically, after exiting the skull base via the foramen ovale, the third division of the trigeminal nerve lies along the medial margin of the lateral pterygoid muscle. Thus, schwannomas of this nerve may smoothly expand the foramen ovale and then present as a well-defined mass in the masticator space, with imaging characteristics similar to those of the neurogenic tumors described in the section on Diseases and Tumors Arising in the Parapharyngeal Space. (Fig. 38-45). Retrograde tumor extension along the third division of the trigeminal is discussed in detail in Chapter 13.

VIEW IMAGE

FIGURE 38-44 Axial T1-weighted MR image (**A**) shows an enhancing mass in the right masticator space. This periosteal osteosarcoma causes the medial masticator space fascia to bulge medially, but there is no invasion of the parapharyngeal space. Axial T1-weighted MR image (**B**) shows a left masticator space mass that has invaded the pterygoid muscles and is limited to the medial portion of the masticator space. This undifferentiated sarcoma is contained by the medial masticator fascia, and there is no extension into the parapharyngeal space. Axial T2-weighted MR image (**C**) shows a left masticator space sarcoma with high signal intensity that has invaded the masticator muscles but remains contained by the masticator space fascia. Axial contrast-enhanced CT scan (**D**) shows a destructive left masticator space mass that has eroded the anterior left mandibular head (*large arrow*). Despite its aggressive nature, the masticator fascia prevents this sarcoma from spreading outside the masticator space except in the most anterior medial margin of this space (*small arrow*).

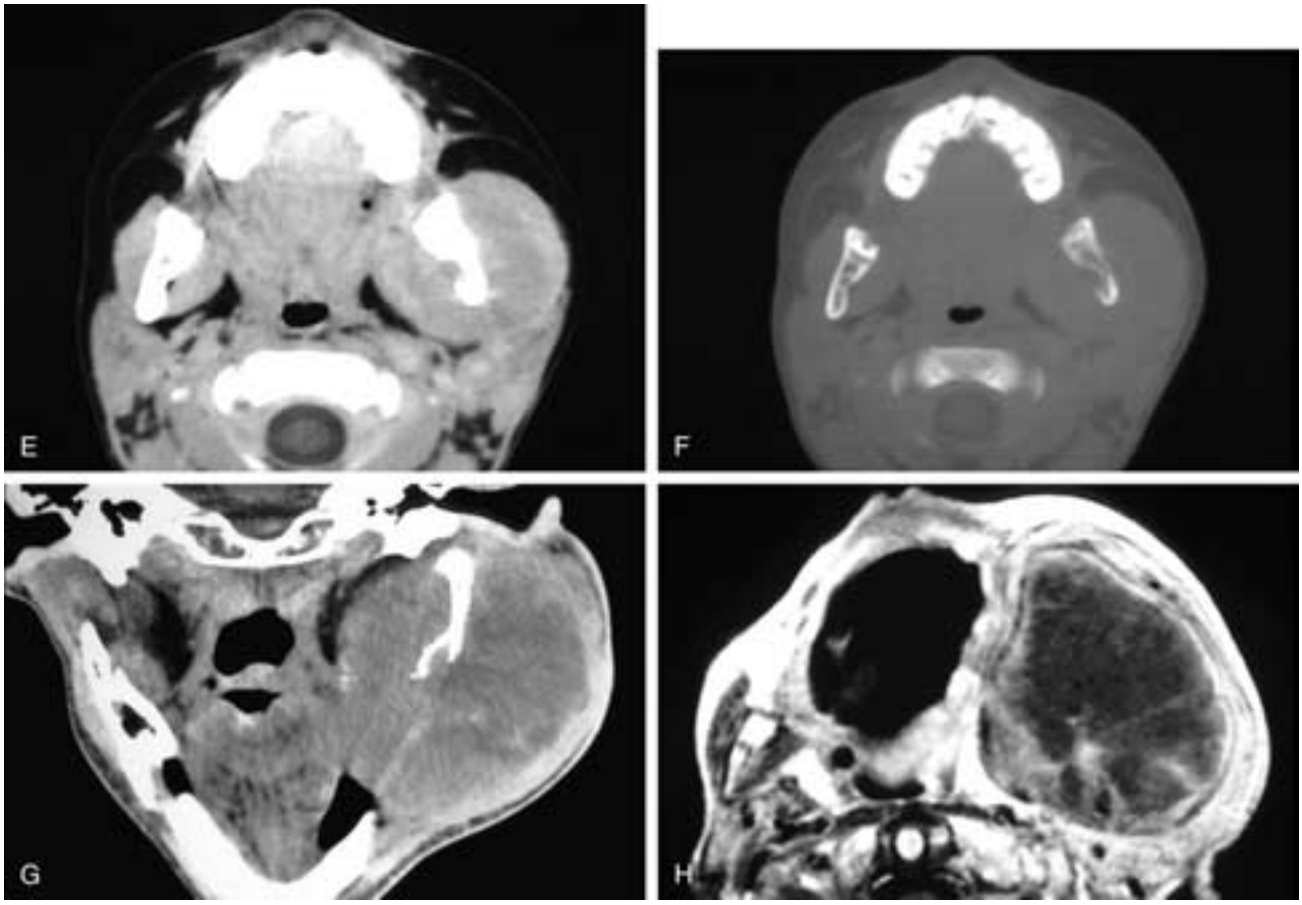

FIGURE 38-44 *Continued.* Axial CT scans viewed at narrow soft-tissue window settings (**E**) and wide bone window settings (**F**) show a rhabdomyosarcoma in the left masticator space that has permeated the mandibular ramus but is contained by the masticator space fascia. Coronal CT scan (**G**) and axial T1-weighted MR image (**H**) show a large, destructive left masticator space mass. Much of the left mandible has been destroyed by this metastatic melanoma. However, the masticator space fascia contains the tumor, and there is no extension into the parapharyngeal space or the superficial soft tissues.

VIEW IMAGE

FIGURE 38-45 Coronal T2-weighted MR image (**A**) shows a high signal intensity mass within a smoothly widened right foramen ovale. This schwannoma extends both toward the cavernous sinus and down below the skull base into the masticator space. Although on coronal images such masses appear to lie directly above the parapharyngeal space, such schwannomas extend along the third division of the trigeminal nerve into the masticator space. Coronal T1-weighted, fat-suppressed, contrast-enhanced MR image (**B**) shows a schwannoma of V_3. The tumor extends from the smoothly widened foramen ovale down into the medial mandibular ramus, displacing the pterygoid muscles medially. Sagittal T1-weighted, fat-suppressed, contrast-enhanced MR image (**C**) shows a schwannoma of V_3 extending down into the masticator space. Axial T2-weighted MR image (**D**) shows a huge schwannoma of V_3 that extends through a smoothly widened foramen ovale down into the masticator space, where it has expanded the medial aspect of this space, filled the infratemporal fossa, and remodeled the posterior right antral wall forward (*arrow*).

INTRODUCTION

The salivary tissues can be affected by a variety of pathologic processes: inflammatory, infectious, obstructive, systemic, and neoplastic. The diversity of benign and malignant salivary neoplasia is probably greater than that of any other organ system. On the other hand, the incidence of salivary neoplasia is extremely low. Salivary tumors comprise less than 3% of all head and neck tumors and cause less than 0.1% of all cancer deaths.[1] As to the relative incidence of salivary gland involvement, it is estimated that for every 100 parotid tumors, there are 10 submandibular tumors, 10 minor salivary tumors, and 1 sublingual tumor.[2]

Little data are available on the epidemiology of salivary neoplasia. Radiation is a known promoter of both benign and malignant salivary gland tumors.[3] Sun exposure may also be causally related to salivary tumorigenesis, as there is a greater than expected coincidence of skin malignancies with salivary tumors.[4] There are a few associations between viruses and salivary tumor neogenesis. Transgenic mice infected with mouse mammary tumor virus have developed acinic carcinoma-like tumors.[5] Epstein-Barr virus (EBV) has been demonstrated within the parotid counterpart of nasopharyngeal carcinoma, the undifferentiated lymphoepithelial carcinoma found in the Aleutian population, or the so-called Eskimo tumor.[6] A finding of EBV genomic clonality in these tumors is strong evidence for a causal relationship.

Concerning the mechanism of salivary tumor genesis, it was assumed for decades that there were but two potential stem cells from which the scores of different salivary tumors originated. It was generally accepted that the basal cells of the excretory duct and the intercalated duct cells acted as the reserve cells for the more differentiated cells of the salivary gland unit. It was also believed that all of the epithelial tumors arose from these reserve cells rather than from the acini.[7, 8] The basal cells of the excretory duct gave rise to the columnar and squamous cells, while the intercalated duct cells gave rise to the acinar cells, striated duct cells, and other intercalated duct cells. The myoepithelial cells function to contract ductules, moving secretions along the ductal system. It was believed that the origins of most salivary tumors could be traced back to their corresponding ductal elements. So, for instance, pleomorphic adenoma, the most common salivary tumor, arose from the intercalated cell/myoepithelial unit, while tumors such as mucoepidermoid carcinoma and squamous cell carcinoma arose from the excretory duct reserve cell. Implicit in the assumption that there were but two basic stem cells was the notion that *end-differentiated* specialized cells, (e.g., acinar and striated duct cells) were incapable of mitotic division and hence incapable of giving rise to tumors.[8] However, there is

evidence demonstrating the proliferative and regenerative ability of rat salivary tissue that is not confined to one cell type. Acinar cells, intercalated duct cells, striated duct cells, and excretory duct cells may all cycle.[9] Further, in cell cultures from human salivary glands, all differentiated cell types have now been shown to be capable of cycling.[10] Thus the pathogenesis of the salivary gland tumors appears to be far more diverse than was previously thought. The embryology of the salivary glands is discussed in Chapter 33.

Normal Anatomy

The paired parotid, submandibular, and sublingual glands are referred to as the major salivary glands; each is anatomically, histologically, and functionally unique. The minor salivary glands are submucosal clusters of salivary tissue present in the oral cavity, paranasal sinuses, pharynx, and upper respiratory tract. It has been estimated that more than 750 minor salivary gland clusters are present.

Parotid Gland

The parotid is the largest salivary gland, and the palpable superficial portion of the gland lies beneath the skin and over the mandibular ramus. The fascia that surrounds the parotid is derived from the superficial layer of the deep cervical fascia. Its thickness varies, being densest over the lateral and inferior aspects of the gland and filmy or incomplete over the medial surface of the gland. Fascial extensions into the parotid parenchyma subdivide the gland into lobules. The parotid weighs between 14 and 28 g in the adult male and measures, on average, 5.8 cm craniocaudally and 3.4 cm ventrodorsally.[8, 11] The female parotid gland tends to be slightly smaller.

Most of the gland (~80%) is superficial to the masseter muscle, ascending ramus, and angle of the mandible; it rarely extends cranially to the zygoma. The superficial parotid lies below and anterior to the external auditory canal and the mastoid tip, usually extending caudally to about the level of the angle of the mandible. The remaining deep aspect of the parotid gland (~20%) extends medially through the stylomandibular tunnel and is present between the posterior edge of the mandibular ramus and the anterior borders of the sternocleidomastoid muscle and the posterior belly of the digastric muscle (Fig. 39-1). The stylomandibular tunnel actually is formed by the skull base, the back of the mandibular ramus, and the stylomandibular ligament and styloid process (Fig. 39-2). The stylomandibular ligament also separates the parotid gland from the submandibular gland.

As a result of these anatomic relationships, the retromandibular or deep portion of the parotid gland is anterior to the styloid process (and its musculature) and the carotid sheath, which places the deep portion of the parotid gland within the prestyloid compartment of the parapharyngeal space (see Chapters 34 and 38) (Fig. 39-3).[8, 11] There are several lobulations (outward projections) or recesses (indentations) of the parotid gland related to (1) the external auditory meatus, (2) the mastoid process, (3) the anterior border of the sternocleidomastoid muscle, (4) the anterior border of the posterior belly of the digastric muscle, and (5) the styloid process and the styloid muscles. These lobulations or

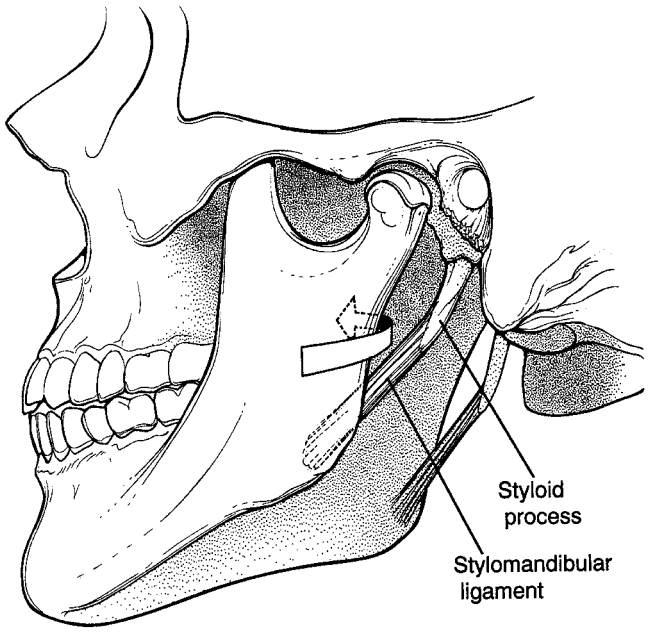

FIGURE 39-2 Left lateral drawing of the facial region shows the stylomandibular tunnel, through which passes the deep portion of the parotid gland (*arrow*).

recesses vary in size or may be nonexistent. Despite the commonly used terminology, there is actually no anatomic division into separate superficial and deep parotid lobes, a nomenclature based on the facial nerve as a reference plane within the gland. By convention, parotid tissue situated deep to this plane is referred to as the deep lobe, while parotid tissue superficial to this plane is considered to be the superficial lobe. This terminology persists despite its anatomic inaccuracy. However, anatomically correct terminology in which the mandible has become the reference point is gaining popularity. Parotid tissue external to the mandible is referred to as superficial, whereas the smaller amount of parotid tissue that resides behind and deep to the mandible is referred to as the retromandibular or deep portion of the parotid gland. Although anatomically these are different nomenclatures, either is appropriate to use. The main trunk of the facial nerve exits the skull base via the stylomastoid foramen, immediately producing three small branches: the posterior auricular, posterior digastric, and stylohyoid nerves. The facial nerve then courses laterally around the styloid process and is immediately superficial to the posterior belly of the digastric muscle. Distal to this, it pierces the posterior capsule of the parotid gland. The nerve continues within the gland lateral to the posterior facial vein (retromandibular vein) and the more medially situated external carotid artery. It then divides via variable anatomic patterns into the temporal, zygomatic, buccal, mandibular, and cervical branches (Fig. 39-4).[12]

The parotid ductal organization has an arborizing or tree-like branching pattern. As one traces proximally from the main parotid duct (Stensen's duct) toward the terminal acini, the ducts become progressively smaller, with more numerous branches (Fig. 39-5). Histologically, the main excretory ducts can be seen to lead into the striated ducts (columnar, oncocytic epithelium), the intercalated ducts (cuboidal epithelium surrounded by myoepithelial cells),

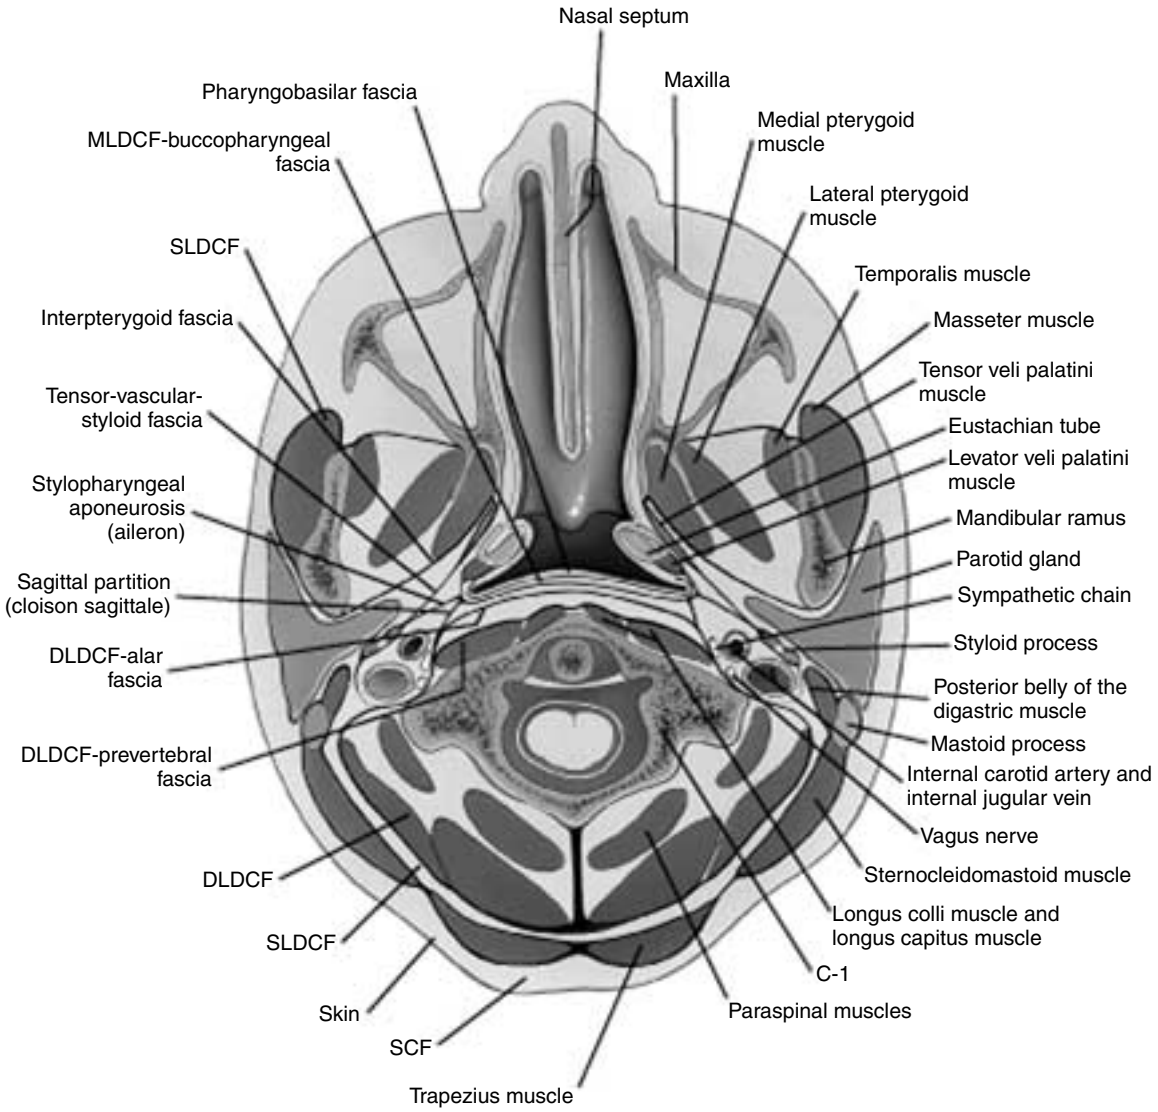

FIGURE 39-3 Diagram of the fascia at the level of C1. Note that the parotid gland is dorsal to the masticator space structures and that the deep portion of the parotid gland lies in the prestyloid compartment of the parapharyngeal space, anterior to the internal carotid artery.

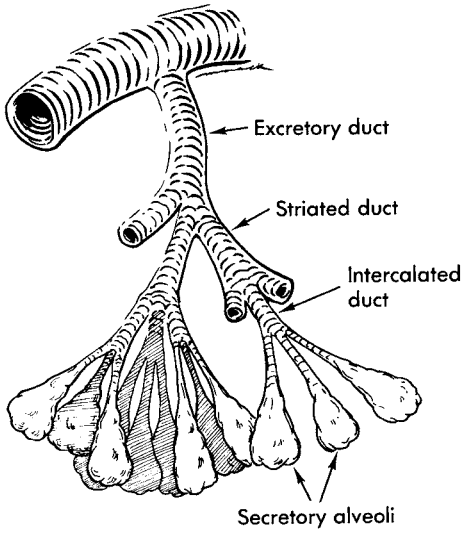
FIGURE 39-4 Variations of facial nerve branching in the parotid gland. (From Davis PA, Anson BJ, Budinger JM, et al. Surgical Anatomy of the Facial Nerve and Parotid Gland Based upon a Study of 350 Cervicofacial Halves. Surg Gynecol Obstet 1956;102: 385–412.)

and the terminal acini. In the adult, the parotid acini are purely serous; it is only in the neonatal period that some mucous cells are found.[8, 11] Sebaceous elements may be uncommonly found in the parotid gland and are thought to explain the sebaceous differentiation that may be seen in some salivary tumors. The parotid parenchyma has abundant adipose tissue, with a ratio of adipose to glandular tissue of 1:1. The parotid intercalated ducts are long and thin compared to the submandibular gland. The sublingual gland has the shortest and widest intercalated ducts. These variations in intercalated duct morphology may be related to the types of secretions in each of these glands.

Stensen's duct is about 7 cm long; after emerging from the anterior parotid gland, it courses over the masseter muscle and buccal fat pad, and then abruptly courses medially to pierce the buccinator muscle, forming a nearly 90° angle with this muscle. It then courses obliquely and inferiorly for a short distance between the buccinator muscle and the oral mucosa, terminating in a papilla of the buccal mucosa, opposite the second upper molar tooth (see Fig. 39-1). An accessory parotid duct may join Stensen's duct as the latter passes over the masseter muscle.[13]



VIEW IMAGE

FIGURE 39-5 Diagram of the major salivary gland ductal system. (From Batsakis JG. Tumors of the Head and Neck: Clinical and Pathological Considerations. 2nd ed. Baltimore: Williams & Wilkins, 1979.)

Accessory parotid tissue is present in about 20% of the population, usually about 6 mm anterior to the main parotid gland, adjacent to Stensen's duct as it passes over the masseter muscle. This accessory tissue is usually cranial to Stensen's duct, with only one excretory duct entering Stensen's duct. There may be multiple accessory glands, each with its own primary drainage into Stensen's duct.

The parotid gland contains 3 to 32 (average, 20) intraglandular lymph nodes interconnected by a plexus of lymphatics that drain the ipsilateral upper and midfacial skin. The palatine tonsil also drains into the parotid lymph nodes. The parotid lymph nodes drain primarily into the internal jugular chain (level IIA) and also into the upper spinal accessory chain (level IIB).

The parotid is innervated from the sympathetic plexus on the carotid artery, while the parasympathetic parotid innervation is derived from the auriculotemporal nerve of the mandibular division of the trigeminal nerve via the glossopharyngeal nerve; parasympathetic fibers may also be contributed via the facial nerve through the otic ganglion. The sympathetic nerves regulate chiefly vasoconstriction, while the parasympathetic nerves regulate secretion.[13]

Proper surgical planning requires that the surgeon be informed as to whether a parotid mass is limited to the superficial gland or extends to the deep portion of the gland. If a parotid mass extends into the parapharyngeal space, its size is important, as such a mass will require one of several modifications of the standard surgical parotidectomy for successful extirpation without violation of the tumor capsule. The surgical modifications vary, depending on tumor size, from simple anterior dislocation of the temporomandibular joint (TMJ), to an angle mandibulotomy, to a midline mandibular split with dislocation of the TMJ. If the deep neck mass can be shown not to be of parotid gland origin, a lateral neck or submandibular approach is used.

VIEW IMAGE

FIGURE 39-6 Drawing of a lateral view of the anatomy of the left submandibular and sublingual glands in the floor of the mouth. Note that the sublingual gland is lateral to Wharton's duct and that the submandibular gland wraps around the back edge of the mylohyoid muscle.

Thus it is important for the radiologist not only to map the lesion, but also to measure its size accurately.

Submandibular Gland

The submandibular gland is the second largest salivary gland, weighing between 10 and 15 g, or about one half the size of the parotid gland. It occupies most of the submandibular triangle of the neck; actually, the gland is folded around the dorsal free edge of the mylohyoid muscle. Despite the fact that there are no separate lobes to the gland, by convention it is also often referred to as being divided into superficial and deep lobes. The larger superficial lobe lies in the submandibular triangle superficial to the mylohyoid muscle. This portion of the gland is bounded anteriorly and inferiorly by the anterior belly of the digastric muscle, posteriorly by the posterior belly of the digastric and stylohyoid muscles, and laterally by the lower border of the mandible and the medial pterygoid muscle (Fig. 39-6). Posteriorly, it is separated from the parotid gland by the stylomandibular ligament. The floor or deep surface of the submandibular triangle is formed by the mylohyoid and hyoglossus muscles. The superficial portion of the submandibular gland is covered by the superficial layer of the deep cervical fascia, the platysma muscle, and the anterior facial vein, and the marginal mandibular nerve runs adjacent to the gland. The facial artery runs upward on the gland's posterior aspect, then turns downward and forward between the submandibular gland and the mandible. The anterior facial vein has been suggested as a useful imaging landmark to help determine if a mass arises within or adjacent to the submandibular gland. A lesion arising within the gland will never be separated from the gland by this vein. If the vein separates the mass and the gland, the lesion may have originated from submandibular lymph nodes (level IB) or the adjacent soft tissues.[14]

The deep portion of the submandibular gland lies deep (or cranial) to the mylohyoid muscle and contains the hilum of the gland. The lingual nerve and submandibular ganglion are superficial (lateral) to the submandibular gland, and the hypoglossal nerve with its accompanying vein lie deep to it. Wharton's duct is the main duct of the submandibular gland and is about 5 cm long, with thinner walls than Stensen's duct. The duct exits the gland anteriorly, occasionally making a sharp turn at the posterior edge of the mylohyoid muscle, and then extending anteriorly and superiorly, medial to the sublingual gland and lateral to the genioglossus muscle. Along this course, the duct is angled at approximately 45° to both the sagittal and axial planes. It terminates within the sublingual papilla in the anterior floor of the mouth. As the duct courses upward, the lingual nerve winds around it, first laterally, then inferiorly, and finally medially (Fig. 39-7).

Histologically, the submandibular gland is composed predominantly of serous acini (90%), with a mucinous acinar component (10%). Adipose tissue is not a significant component of the glandular parenchyma, as it is in the parotid. The arterial supply is derived from branches of the external maxillary and lingual arteries. Its sympathetic innervation comes from the carotid plexus, while its parasympathetic innervation is derived from the facial nerve and possibly the glossopharyngeal nerves via the chorda tympani nerve and the submandibular ganglion.[13] The glandular lymphatic drainage is into the submandibular nodes (level I).

Sublingual Gland

The sublingual gland is the smallest of the major salivary glands, about half the size of the submandibular gland, weighing only about 2 g, measuring about 2.5 cm, and shaped like a flattened almond (see Figs. 39-6 and 39-7). It

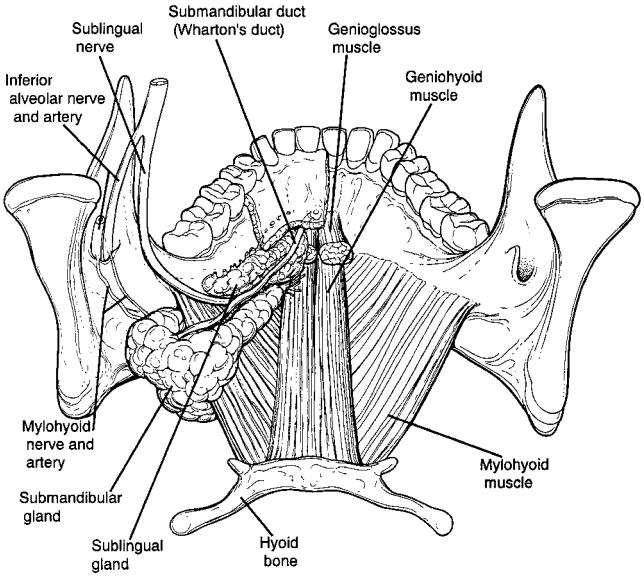

FIGURE 39-7 Drawing of a dissected view of the mandible seen from above and behind shows the muscles of the floor of the mouth, the sublingual and submandibular glands, and the branches of the lingual nerve. Note that in the floor of the mouth, the nerve and Wharton's duct lie medial to the sublingual gland and lateral to the genioglossus and geniohyoid muscles.

VIEW IMAGE

lies submucosally against the sublingual depression of the lingual mandibular surface, adjacent to the symphysis, and rests on the mylohyoid muscle. The lingual nerve and Wharton's duct separate the medial sublingual gland contour from the genioglossus muscle. There is no well-defined capsule, and histologically the gland is composed entirely of mucinous acini. There are about 20 individual small ducts (the ducts of Rivinus), most of which open independently into the floor of the mouth along the sublingual papilla and fold. Occasionally some of these ducts fuse to form Bartholin's duct, which in turn opens into Wharton's duct.[11, 13] The sublingual innervation is identical to that of the submandibular gland. The gland's lymph drains into the submental and submandibular lymph nodes (level I).

Minor Salivary Glands

The minor salivary glands (MSG) lie within the submucosa of the oral cavity, palate, paranasal sinuses, pharynx, larynx, trachea, and bronchi. They are particularly concentrated in the buccal, labial, palatal, and lingual regions. The gingivae, anterior hard palate, and true vocal cords have relatively sparse concentrations of MSG. The concentration of MSG within the nasal cavity has been estimated at 7 to 10 glands /mm^2, which is less than that of the palate but greater than that of the paranasal sinuses.[15] Histologically, the MSG acini are either entirely mucinous (e.g., hard palate) or mixed seromucous glands (e.g., sinonasal, oral). The acinar clusters lead to intercalated ducts, striated ducts, and excretory ducts that terminate as mucosal pores. The autonomic secretory function of the upper aerodigestive tract MSG is controlled by the following ganglia: the sphenopalatine (pterygopalatine) ganglia, located near the sphenopalatine foramina of the medial pterygopalatine fossae, innervate the paranasal sinuses, nasal cavity, portions of the palate, and the uppermost pharynx; the otic ganglia, located along the medial aspect of the mandibular nerves below the skull base, innervate the buccal mucosa; the submandibular ganglia, adjacent to the submandibular gland hili at the posterior border of the mylohyoid muscle and the lingual nerve, innervate the floor of the mouth and the anterior tongue; and finally, the pharyngeal plexus innervates the pharynx.[16, 17]

Developmental Anomalies

Developmental salivary gland aplasia, atresia, or agenesis are rare occurrences usually associated with other facial abnormalities (Fig. 39-8). They may be either unilateral or bilateral, and these anomalies of the salivary glands are associated with xerostomia, sialoadenitis, and dental caries. Parotid gland agenesis has been reported with hemifacial microstomia, mandibulofacial dysostosis, cleft palate, and anophthalmia. Agenesis of the parotid duct has been reported, and unilateral aplasia of the parotid gland can occur.[18] Atresia of one or more major salivary gland ducts is very rare. This condition usually occurs in the sublingual and submandibular ducts and may be associated with a cyst.[11, 19] Congenitally imperforate submandibular ducts and duplications of the submandibular gland and duct have also been reported.[20]

FIGURE 39-8 Axial contrast-enhanced CT scan shows a normal left parotid gland (*arrow*). In the right parotid bed, there is only fat and some interstitial stranding. This patient had a congenital absence of the right parotid gland. Incidentally noted is a retention cyst in the right maxillary sinus.

VIEW IMAGE

Hypoplasia of the parotid gland has been reported in the Melkersson-Rosenthal syndrome: an episodic condition of unknown etiology characterized by the triad of orofacial swelling, facial nerve palsy, and lingual plicata (furrowed tongue). Congenital fistulas of the parotid ductal system have been associated with branchial cleft abnormalities, accessory parotid ducts, and diverticula.[11]

A salivary choristoma is ectopic, histologically mature salivary tissue at abnormal sites. Such heterotopic salivary tissue has been reported in a large number of locations including the middle ear cleft associated with ossicular abnormalities, the external auditory canal, the lower neck near the sternoclavicular joints, the upper neck, the hypopharynx, the inner posterior mandible (Stafne cyst), the anterior mandible, the thyroglossal duct, the pituitary (pars nervosa), and the cerebellopontine angle.[7, 11, 21]

Congenital intraglandular cysts occur in a variety of forms and are discussed in the section on ''Congenital Cysts'' later in this chapter. Accessory salivary gland tissue is uncommon and usually occurs in relationship to the parotid gland. A congenital fistula to the cheek from an ectopic accessory parotid gland located lateral to the masseter muscle was demonstrated by CT sialography and CT fistulography.[22]

With regard to salivary abnormalities associated with syndromes or generalized diseases, in the familial form of amyloidosis (an autosomal dominant condition with high penetrance) there is an association with Sjogren's syndrome. Cystic fibrosis (an autosomal recessive disease mapped to chromosome 7, q21–31) is associated with pneumoparotitis

Copyright © 2003, Mosby, Inc. All rights reserved.

and sialolithiasis. The lacrimo-auriculo-dento-digital syndrome (autosomal dominant) is a rare malformation complex consisting of lacrimal, aural, digital, and dental anomalies and is also associated with salivary gland hypoplasia.[23, 24] The hypoglossia-hypodactylia syndrome (sporadic, no sex predilection) is a complex of variable tongue hypoplasia, micrognathia, and abnormalities of the upper extremities. It can be associated with sublingual and submandibular glandular hypertrophy. The spectrum of oculo-auriculo-vertebral abnormalities includes Goldenhar syndrome, Goldenhar-Gorlin syndrome, facio-auriculo-vertebral sequence, hemifacial microsomia, first and second arch syndrome, lateral facial dysplasia, and unilateral craniofacial microsomia. These syndromes are usually sporadic but occasionally are transmitted in an autosomal dominant fashion. They are associated with parotid aplasia and ectopic salivary gland tissue. The Treacher Collins (TCS) syndrome is an autosomal dominant disorder with an incidence of approximately 1 in 50,000 live births that is caused by mutations in the *TCOF1* gene mapped to chromosome 5q32–33.1. TCS is characterized by bilaterally symmetric midfacial hypoplasia, downward-slanting palpebral fissures, cleft palate, colobomata of the lower lids, microtia, and other ear deformities often leading to conductive hearing loss. Parotid aplasia can be associated with TCS.[25]

Physiology

Salivation is physiologically controlled almost entirely by the autonomic nervous system. Either parasympathetic or sympathetic stimulation will produce secretions; parotid or submandibular secretions probably never occur without autonomic input. Parasympathetic stimulation predominates, and parasympathetic denervation results in glandular atrophy. Conversely, sympathetic denervation causes little, if any, effect.[26]

Normal saliva is composed predominantly of water (99.5%) with a specific gravity of 1.002 to 1.012. Between 1 and 1.5 liters of saliva are produced daily, usually during meals. The parotids contribute about 45% (450 to 675 ml) of the total secretions, the submandibular glands about 45% (450 to 675 ml), the sublingual glands 5% (50 to 75 ml), and the minor salivary glands 5% (50 to 75 ml).[27] The basal secretory rate is low (parotid gland = 0.04/ml/minute/gland and submandibular gland = 0.05ml/minute/gland). During sleep, the flow rate is virtually nil.

Saliva is formed in the acini (Fig. 39-9). The secretion of electrolytes into saliva is under parasympathetic control via acinar cholinergic receptors. Their stimulation activates cytoplasmic guanylate cyclase and the conversion of GTP to GMP, necessary for the transport of sodium. Sodium enters along the basal cell membrane following an electrochemical gradient, which is the result of acetylcholine-induced enhanced permeability of the basal cell membrane to potassium and sodium. The result of this process is the formation of an isotonic, high-sodium, low-potassium fluid. The saliva becomes hypotonic as sodium is reabsorbed and potassium is excreted in the striated ducts, which are histologically, ultrastructurally, and functionally similar to the renal distal convoluted tubules. This sodium reabsorption is influenced by aldosterone.[11, 28]

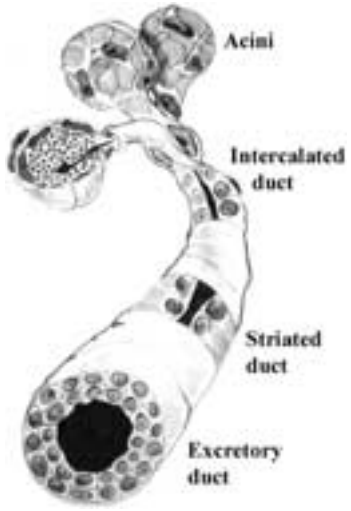

FIGURE 39-9 Schematic representation of the ducto-acinar salivary apparatus.

VIEW IMAGE

Saliva is multifunctional: it protects mucosa from the harmful effects of microbial toxins, noxious stimuli, and minor trauma. The salivary mucins are glycoproteins, which act as lubricants. Although the minor salivary and sublingual glands produce 10% of the total saliva volume, they secrete the majority the of mucinous components of saliva, and functional compromise of these glands (e.g., by autoimmune disease or irradiation) results in xerostomia.[11, 27] The antibacterial activity of saliva is accomplished by secretory IgA, plus enzymes such as lysozyme, peroxidase, alpha-amylase, and lactoferrin and ions such as thiocyanate and hydrogen. Normal salivary pH ranges from 5.6 to 7.0 (average, 6.7).[11, 27] The pH varies directly with the blood pH (CO_2 content).[25]

IMAGING

An Overall Imaging Approach

Salivary imaging has shifted from predominantly utilizing plain films and sialograms to nearly complete reliance upon computed tomography (CT), magnetic resonance (MR) imaging, and ultrasound. After two decades of debate, some consensus has been achieved regarding recommendations as to which imaging modality is indicated for a specific clinical situation. CT is the modality of choice for patients with a clinical history and findings suggestive of inflammatory disease, such as acute, painful, diffuse parotid or submandibular swelling. Similarly, recurrent, subacute episodes of mildly painful and tender parotid or submandibular swelling indicate an inflammatory related process, either infectious or noninfectious. As the imaging identification of calcifications (sialoliths) is important in the diagnosis of these inflammatory processes, either CT or ultrasound is the preferred modality.[29–35]

MR imaging is the primary modality of choice when a mass is palpated, whether or not it is tender, solitary or

Copyright © 2003, Mosby, Inc. All rights reserved.

multiple, or discrete or diffuse.[20, 36–50] Although MR imaging best delineates the morphology of the mass, CT can be an acceptable alternative; ultrasound is generally utilized as a complementary study. It should be noted that some clinicians and radiologists believe that children and adolescents with inflammatory and superficially located disease should be approached primarily by ultrasound, while MR imaging should be utilized for deeply positioned masses.[29]

When imaging minor salivary gland tumors, either CT with contrast or MR imaging (usually with contrast) is recommended as the initial examination. Imaging of these lesions is discussed in the chapters on the sinonasal cavities, oral cavity, pharynx, and larynx (respectively Chapters 6, 27, 28, and 30).

With CT, major salivary gland tumors require intravenous contrast agents, whenever possible, to enhance tumor conspicuity. However, the use of contrast agents with MR imaging below the skull base is less well established, as contrast may enhance tumor visualization for some cases and obfuscate lesion conspicuity in others. For the majority of such MR imaging studies, the addition of contrast yields little diagnostic information. In addition, most radiologists use fat suppression pulses to improve lesion conspicuity. However, this may also add artifact to the images. The additional required examination time, the added cost of the contrast agent, and the relatively low positive yield has led many radiologists not to employ contrast routinely. A notable exception to this is the detection of perineural tumor spread, as contrast-enhanced MR imaging is more sensitive than contrast-enhanced CT.[48] Sectional imaging with contrast-enhanced MR imaging is indicated, for instance, for patients with the diagnosis of adenoid cystic carcinoma of the parotid gland. The topic of perineural tumor spread is discussed in Chapter 13.

Plain Films

Plain films are rarely used today for the imaging evaluation of the major salivary glands. They are best for grossly detecting radiopaque sialolithiasis, dystrophic calcifications, or adjacent mandibular bone and dental disease. Although plain film studies can be obtained quickly and relatively inexpensively, they are of limited clinical value since they only identify moderately large, fairly dense calcifications (Figs. 39-10 and 39-11). Thus, a negative plain film may miss a clinically significant small sialolith or soft-tissue calcification that is easily identified by either ultrasound or CT. In fact, CT has about a 10-fold increased sensitivity compared to plain films for detecting soft-tissue calcifications, and one of the primary strengths of ultrasound is its ability to identify small, solid soft-tissue densities.

Even if calcifications are identified on plain films, further imaging is indicated to detect other possible and clinically important calcifications, findings that can potentially alter the treatment plan. For instance, a sialolith may be localized to a subsegment of the gland or a contralateral sialolith may be identified. Thus, either noncontrast CT or ultrasound is the current standard for investigation of soft-tissue calcifications. If plain films are to be obtained for the parotid region, the survey examination should consist of an extended-chin, open-mouth lateral film with both posteroanterior views (with or without the cheeks blown out for detection of Stensen's duct stones or other calcifications) and oblique views (Fig. 39-10).

For the submandibular gland, an extended-chin, open-mouth lateral view with the patient's finger depressing the tongue, an intraoral occlusal film, and oblique views are routinely obtained (Fig. 39-11). Fluoroscopy may also help the radiologist to detect a small calculus by allowing visualization of the stone's motion and/or by providing a means to optimize the patient's position in order to demonstrate the calculus.[51]

Sialography

Sialography is rarely employed today due to the continual improvements in CT and MR imaging, as well as changes in the clinical management of major salivary gland nonneoplastic disease. Sialography is an imaging examination that uses a positive contrast medium to demonstrate radiographically the ductal anatomy of either the parotid gland or the submandibular gland. This examination remains the only imaging study for examining the fine anatomy of the salivary ductal system. The sublingual and MSG are not studied by this technique, as MSG cannot be cannulated and the sublingual gland ducts can rarely be cannulated.

On routine CT and MR imaging, gross pathologic ductal dilatation or stenosis can be imaged, but small to moderate degrees of functional and anatomic alteration cannot be

seen. Because the quality of MR sialography continues to improve (see the section on MR Sialography), in the few remaining clinical situations that require analysis of ductal morphology, many of these patients can be sufficiently studied by MR sialography (which allows visualization of Stensen's or Wharton's ducts and the major and secondary intraglandular ducts). If even finer detail is needed, a situation rarely necessary for clinical decision making, sialography remains the examination of choice.

In the past, sialography was important in differentiating between certain cases of subacute and chronic sialoadenitis, autoimmune disease and sialosis, as neither the clinical presentation nor conventional sectional imaging can confidently distinguish among these entities.[52, 53] However, serology (general autoimmune antibodies, plus those specific for Sjogren's sydrome: SS-A and SS-B) now aids in the diagnosis of autoimmune sialoadenitis. In addition, improved understanding of the pathophysiology of these diseases and advances in surgical techniques have limited the need for conventional sialography despite its diagnostic specificity.

Sialography is an invasive procedure in which radiopaque contrast material is injected retrograde into the gland's ductal system via the intraoral opening of either Wharton's or Stensen's duct. The procedure is contraindicated for clinically active infection, as it will often spread the infection retrograde into the gland. Additionally, as acute sialoadenitis is already painful, the patient will not tolerate the additional discomfort of the retrograde pressure injection required for an adequate sialogram; thus a technically adequate study is usually not feasible.

In the event that a patient is recovering from a recent acute sialoadenitis, although the gland may have returned to an apparently normal clinical state, a sialogram can reactivate a clinically quiescent infection. Prophylactic administration of oral antibiotics after a sialogram is indicated in such cases to avoid reinfection. A sialogram is also contraindicated for patient with a history of allergic sensitivity to iodine compounds (contrast materials).

Indications to perform a sialogram include (1) the detection or confirmation of small parotid or submandibular gland sialoliths or foreign bodies (either calcified or noncalcified); (2) the evaluation of the extent of irreversible ductal damage present as a result of infection; (3) the differentiation of diseases such as chronic sialoadenitis, Sjogren's syndrome, and sialosis; (4) the evaluation of fistulas, strictures, diverticula, communicating cysts, and ductal trauma; and (5), rarely, as a dilating procedure for mild ductal stenosis.[54]

The original sialographic contrast agents, such as Lipiodol or Pantopaque, were lipid soluble and viscid, had high iodine concentrations, and produced sharp boundaries with the salivary secretions. These agents, however, were reported to cause foreign body reactions following ductal perforation during sialography. When water-soluble agents became available, they did not initially have as high an iodine content, they were too watery to remain within the ductal system long enough to produce a good study, and their boundary with saliva was unsharp. When Ethiodol was introduced, it became the agent of choice because it had all the benefits of the lipid-soluble media and a very low reported incidence of foreign body reactions. The few reported reactions secondary to Ethiodol were autopsy studies of subclinical reactions.[55]

Recently, the water-soluble agents have been further improved, but they remain generally less viscid and more miscible with saliva than the fat-soluble agents. Water-soluble Sinografin has an iodine content (38%) similar to that of Ethiodol (37%) and its viscosity facilitates injection, but it is not so watery as to empty rapidly from the main

Copyright © 2003, Mosby, Inc. All rights reserved.

ductal system. Additionally, there have been no reported foreign body reactions subsequent to perforation. If the sialographic radiographs are taken quickly, before Sinografin mixes with saliva, the study demonstrates clear, sharp ductal anatomy, equivalent to that seen on an Ethiodol study. Therefore, water-soluble agents such as Sinografin have replaced the fat-soluble agents as the sialographic contrast materials of choice.

The equipment used to perform a sialogram varies with the examiner's preferences. However, a general list includes the following:

1. Sialographic cannulas. The most commonly employed are the Rabinov-type cannulas with tips ranging from 0.012 to 0.033 inch (Fig. 39-12).[56] Variations such as the Manashil modification of the Rabinov cannula and cannulas designed by Lowman and Belleza are also commercially available. Modifications of butterfly needles also can be used for parotid cannulazations.[57] In general, the larger-diameter cannulas are used for the parotid gland and the smaller ones for the submandibular gland. Although cannulas without a polyethylene connecting tube can be used, if such a flexible connecting tube is employed, the examiner can work outside of the patient's mouth and therefore have greater mobility during the procedure.
2. A set of lacrimal dilators ranging from 0000 through 0 caliber.
3. A 5-ml or 10-ml syringe.
4. 4 × 4 inch gauze sponge pads.
5. Sinografin (or an equivalent contrast agent).
6. Secretogogue such as fresh lemon, lemon extract, or lemon concentrate.
7. Adequately focused lighting, usually a head-light unit.
8. High-powered magnifying glasses.

Once the salivary duct is cannulated, the injection is usually made with hand pressure.[55] The patient may complain of local pressure or mild pain during the injection; however, a slow, constant injection technique usually can accomplish complete ductal filling without much patient discomfort. This can be done when monitored by fluoroscopy. The patient's sensation of glandular fullness and pressure usually abates within minutes after the study. The patient should be alerted that there should be no residual discomfort by 24 hours after the examination. If local pain increases and becomes more intense 24 to 36 hours after the study, a postsialogram infection is probably present and antibiotic therapy should be started immediately.

Parotid Gland Study

The intraoral opening of Stensen's duct is opposite the second upper molar tooth. In some patients this opening is easily seen; however, in others, it may be very difficult to identify, especially in individuals who have a dry, obstructed gland or a mucosal bite ridge across the region. After drying of the mucosa with gauze, milking of the gland and Stensen's duct may produce a drop of saliva that allows identification of the duct opening. In this regard, the use of a secretogogue (lemon) may also be helpful. Once the opening is identified, the dilators can be used to widen the opening for easier cannula placement. Slight abduction of the cheek with the thumb and index finger often provides better exposure and a better angle for cannula insertion. The cannula is then gently inserted and 0.5 to 1.5 ml of contrast material is slowly injected. The injection is often best made under fluoroscopic control so that optimal ductal filling without excessive acinar filling can be achieved. Optimal gland positioning can also be achieved, and spot filming is best used to document the examination.

Stensen's duct is approximately 6–7 cm long and has a small C-shaped curve anteriorly as it bends around the buccal fat pad and pierces the buccinator muscle to open opposite the second upper molar tooth. The duct's normal luminal caliber is only 1 to 2 mm, and on a direct conventional posteroanterior film, the duct should lie within 15 to 18 mm of the lateral mandibular cortex (Figs. 39-13 and 39-14). If the duct is more laterally placed, there is either hypertrophy of the masseter muscle or a mass in or near the masseter muscle (better seen on CT or MR imaging).

There is no specific parotid ductal branching pattern, and variation is noted from side to side within the same person as well as among different individuals.[58, 59] Usually there are main upper and lower hilar-intraglandular ducts, and it is from these that the glandular arborization pattern takes form. The overall appearance is that of a leafless tree, and no area of the gland should be devoid of peripheral ducts. As the ducts arch behind the ramus of the mandible, they may appear slightly stretched on frontal films. This appearance should not be confused with a mass lesion; on lateral films, no mass effect will be seen (Figs. 39-13 and 39-14). Normally, the ducts do not lie parallel to one another in any plane. If this appearance is seen, it usually indicates that a mass is present displacing some of the ducts away from their normal arborization configuration and causing them to appear parallel to one another.

Acinar filling can be accomplished in most patients and is a normal effect of slight overfilling of the ductal system.[59] It can be a useful technique to help identify small masses;

FIGURE 39-13 Lateral view of a normal parotid sialogram. Anteriorly, Stensen's duct enters the mouth by piercing the buccinator muscle near the second upper molar tooth; then the duct bends around the buccal fat pad and overlies the masseter muscle. Within the gland there is a ductal ''arborization'' pattern, with no area of the gland devoid of ducts.

however, the acinar filling should be carefully limited so that it does not obscure the ductal anatomy (Fig. 39-15).

The evacuation film should reveal complete, rapid ductal emptying. In some patients, more complete evacuation can be achieved if a secretogogue is given. Any delayed ductal emptying or trapping of the contrast material indicates the presence of a functional obstruction.[60] By comparison, if

VIEW IMAGE

FIGURE 39-14 Frontal view of a normal parotid sialogram. The hilum of the gland (*arrow*) is within 15 to18 mm of the lateral cortex of the mandible on a standard 40-inch TSD film. The posterior deep ducts often appear stretched or splayed as they arch behind the mandible. A lateral view, however, will show no splaying, confirming that no mass is present.

FIGURE 39-15 Lateral view of a normal parotid sialogram showing acinar filling throughout the gland, with many of the major ducts still being clearly identified. This technique made it easier to identify a mass by noting the abscence of acinarization at the site of the mass.

VIEW IMAGE

any acinar filling occurred during the sialogram, the water-soluble contrast will remain until its absorption occurs. Thus the presence of a persistent (usually less than 1 hour) acinar ''stain'' does not indicate the presence of an obstruction.

Multiple or solitary accessory parotid glands may be present and are usually situated above Stensen's duct, anterior to the main parotid gland.[60] These accessory glands are routinely filled in a retrograde manner as the contrast material courses through Stensen's duct. These accessory glands have a normal branching ductal pattern similar to that seen within the main parotid gland.

Submandibular Gland Study

The orifice of Wharton's duct lies in the floor of the mouth on or near the sublingual papilla. The opening is smaller than that of Stensen's duct, and thus it is usually more difficult to cannulate than is Stensen's duct. To best visualize the orifice of Wharton's duct, the area should be dried with gauze and the tongue pushed upward and backward to put some tension on the papilla. Milking the gland or using a secretogogue can aid in identifying the orifice by producing a drop of saliva.[37] Once the duct is cannulated, care must be taken to advance the cannula gently because painless perforation into the floor of the mouth can easily occur. Only 0.2 to 0.5 ml of contrast material should be injected. This volume reflects the facts that the submandibular gland is smaller than the parotid gland and that the ductal walls of the submandibular gland are more easily perforated than are those of the parotid gland. If

Copyright © 2003, Mosby, Inc. All rights reserved.

extensive perforation or acinarization occurs due to administration of too much contrast material, ductal detail can be completely obscured, rendering the examination virtually useless. Care must be taken not to obscure the ductal anatomy (Fig. 39-16).

Wharton's duct is seen to run downward and laterally at about a 45° angle to both the sagittal and horizontal planes.[60, 61] It is about 5 cm long and has a luminal caliber of 1 to 3 mm. Just before the duct enters the submandibular gland, it may curve caudally over the back edge of the mylohyoid muscle. The intraglandular ducts are shorter and taper more abruptly than those in the parotid gland (Fig. 39-16).

Occasionally, Bartholin's duct will be filled, extending from Wharton's duct (Fig. 39-16). In some cases the sublingual gland may be visualized, resembling an accessory gland with a normal branching ductal pattern. The most common causes of sialogram failure or of a poor sialogram are (1) failure to locate and cannulate the salivary duct, (2) perforation of the duct into either the cheek or the floor of the mouth, (3) suboptimal filling of the ductal system so that areas of the gland are not visualized, and (4) complete acinarization of the gland so that all ductal detail is obscured. The last problem is especially prone to occur in the submandibular gland and can best be avoided by fluoroscopically monitoring the injection volume.

If there has been previous surgery in the floor of the mouth, the scarring and altered anatomy probably account for more failures to cannulate Wharton's duct than any other single reason. A ''dry'' duct may be caused by prior surgery, scarring, irradiation, or obstruction by either a stone or a tumor, and the absence of saliva is the major cause of failure to identify the openings of either Stensen's or Wharton's duct.[60]

Computed Sectional Imaging

General Considerations

The inability of MR imaging to visualize small, potentially clinically significant calcifications detracts from its usefulness in imaging suspected inflammatory diseases. However, the final choice between CT and MR imaging may depend on the clinical presentation of the case and the expected differential diagnosis. Quite often the preferred examination is recognized only in retrospect.

In general, CT is the examination of choice for inflammatory related diseases. The study can identify the presence and number of sialoliths, differentiate between cellulitis and cellulitis with an abscess, map the extension of disease, and differentiate between clinically confused parotid and masticator space disease. CT can also distinguish between submandibular gland sialadenitis and adjacent reactive lymphadenitis.

If a mass is palpated, CT and MR imaging can confirm the presence of a clinically palpable mass or identify the presence of a clinically silent mass either in the same gland or in the opposite gland; map the location of a lesion within the gland and, in the case of the parotid gland, identify its position relative to the facial nerve; determine whether the mass has smooth or infiltrating margins; show if the mass is solid or cystic; and demonstrate if the mass is confined to the gland or if it has extended outside the gland capsule into the

FIGURE 39-16 Lateral view (**A**) and frontal view (**B**) of a normal submandibular sialogram demonstrates some acinar filling with shorter, more tapered ducts than those seen in the parotid gland. The bend in the course of Wharton's duct is at the point at which this duct arches around the dorsal free edge of the myohyoid muscle. There is also partial filling of a Bartholin's duct (*arrow*). In **B**, the usual 45° downward and outward angulation of Wharton's duct is seen.

upper neck and skull base. In general, a salivary mass is better seen on MR imaging than on CT, and in most cases MR imaging is the preferred modality when a mass is palpated or clinically suspected. Thus, each modality offers some benefits over the other.

CT has a reported overall sensitivity that approaches 100% in the detection of salivary tumors.[62] Since the literature also suggests that MR imaging is even more sensitive than CT in identifying such a mass, it is evident that either modality is excellent for localizing and mapping a clinically evident or occult lesion. When these nearly perfect figures are compared to the 85% sensitivity of sialography (even in the hands of an experienced sialographer) in detecting a salivary tumor, it is clear why CT and MR imaging have replaced sialography as the modalities of choice.[63–65]

The distinction between benign and malignant lesions frequently cannot be made on the basis of the morphology, as demonstrated by sectional imaging. However, by utilizing the radiologic and clinical findings, this distinction can be made in almost 90% of the cases.[40] The difficulties on sectional imaging arise because most benign salivary lesions (i.e., cysts, nodes, and tumors) have a capsule, and thus are smoothly contoured and sharply delineated from the adjacent salivary tissues. However, some of the most common low-grade malignancies (i.e., low-grade mucoepidermoid carcinomas, acinic cell carcinomas, and some adenoid cystic carcinomas) develop pseudocapsules that cause them to appear on sectional imaging as smoothly outlined, benign-appearing lesions.

By comparison, high-grade malignancies (i.e., high-grade mucoepidermoid carcinomas, adenocarcinomas, undifferentiated carcinomas, and squamous cell carcinomas) have irregular, infiltrating, indistinct margins with the adjacent salivary tissue. However, rarely, a benign mass is surrounded by inflammation and/or hemorrhage (possibly from vigorous palpation) that can present an aggressive appearance on sectional imaging.

Sectional imaging of a tumor's architecture also does not allow for a confident distinction between benign and malignant salivary tumors. However, on MR imaging, highly cellular tumors (usually high-grade malignancies) tend to have low to intermediate signal intensities on all imaging sequences, while the less cellular, better-differentiated masses (benign tumors and low-grade malignancies) tend to have low T1-weighted and high T2-weighted signal intensities. These signal intensities reflect the fact that the benign tumors and low-grade malignancies are sufficiently differentiated to produce secretory serous and mucous products, and these secretions have a high water content. In addition, there is a fairly high cytoplasmic/nuclear ratio so that there is a relatively high intracellular water content. As a result, these tumors have MR signal intensities that reflect this water.

On the other hand, the high-grade, aggressive tumors are poorly differentiated, are very cellular with a high nuclear/cytoplasmic ratio, and have little tendency to produce secretory products. These factors yield a net low water content, which is reflected in the lower T2-weighted signal intensities of these lesions.[66] However, such a relatively low T2-weighted signal intensity is not specific for an aggressive tumor, and other lesions including fibrosis, granulomas, and, rarely, some benign tumors can have similar signal intensities (Fig. 39-17). Thus, a lower T2-weighted signal intensity should only serve to alert the radiologist to the possibility that a high-grade malignancy may be present.

Clinically, benign tumors tend to be slow growing, painless, nontender, mobile, and firm but not rock hard. Facial nerve paralysis usually does not occur. Benign cysts usually develop rapidly over several days and are nontender unless infected, in which case they are tender and painful. These cysts are moderately firm to palpation, and patients often have a history of prior recurrent clinical episodes. By comparison, malignant tumors tend to enlarge fairly rapidly over several weeks or months, and they are either not painful (more insidious growth) or are slightly painful and minimally tender. In general, the faster these malignancies grow, the more symptomatic they are. When palpated, these malignancies are usually rock hard, and they may be fixed in position. There may be an associated facial nerve paralysis. In fact, the overall incidence of facial nerve paralysis with a parotid malignancy is 12% to 14%.[26] Often, such high-grade tumors are estimated to be larger on palpation than they are seen to be on CT and MR imaging. This discrepancy is the result of the presence of a zone of early microscopic infiltration extending from the mass into the adjacent tissues.

CT and MR Imaging

Parotid Gland: CT

In the adult, the parotid gland normally is a relatively fatty structure with numerous thin interstitial strands interlacing throughout it, as well as through the branches of the facial nerve and the ductal system. The gland produces serous secretions. The resulting usual CT attenuation of the gland (15 to 25 HU) is lower than that of muscle but greater than that of fat.[62] In children and some adults, a clinically normal parotid gland can have an attenuation similar to that of muscle. Presumably, such a CT appearance reflects a lower glandular fat content and is of no clinical significance. However, in such a ''dense'' gland it is more difficult to identify a small mass. Additionally, CT does not allow for the distinction between a dense normal gland and one that has been infiltrated with cells due to a variety of causes.

The fine anatomy of the intraglandular ducts is not normally visualized on CT, and Stensen's duct is seen only if abnormally dilated. The external carotid artery and the posterior facial (retromandibular) vein are seen situated posterior to the ramus of the mandible (Fig. 39-18). The vein extends caudally to drain into the external jugular vein, while the external carotid artery courses superiorly to become the superficial temporal artery. Some variable but normal glandular lobulations can also be seen primarily in relationship to the sternocleidomastoid muscle and the mastoid tip.

On axial CT scans, an area of high attenuation is routinely visualized near the caudal root or the attachment of the pinna of the ear. This musculotendinous region may mimic a small mass in the upper pole of the parotid gland; however, coronal images and clinical correlation almost always resolve any such imaging question.

The facial nerve normally cannot be seen on CT scans. However, the course of the nerve can be traced on the scans. The nerve exits the skull base via the stylomastoid foramen,

Axial T1-weighted (**B**), T2-weighted (**C**), and T1-weighted, fat-suppressed, contrast-enhanced (**D**) MR images show the mass to have low signal intensity on the T1- and T2-weighted images and to enhance. This was a scar at the site of a biopsy performed many years prior to this study.

bends lateral to the styloid process, extends down along the lateral surface of the posterior belly of the digastric muscle, pierces the posterior gland capsule, and runs lateral to the posterior facial vein and external carotid artery. With these landmarks, an accurate estimate can be made in most cases as to whether a mass is medial or lateral to the facial nerve. More direct visualization of the nerve may be possible with the use of high-resolution, three-dimensional Fourier transform MR imaging.[67]

Artifacts from adjacent metallic dental restorations often badly degrade axial CT images through the parotid gland. In these cases, exaggerated inferior orbitomeatal (IOM) angled scans or modified coronal scans can be obtained. Although these images distort the axial anatomy, they are superior to the routine axial studies for avoiding these artifacts. In many such cases, less image distortion may be seen on MR imaging; however, even here, significant image degradation may occur.

Normal Parotid Gland: MR Imaging

On MR imaging, it is primarily the fat content of the parotid gland that accounts for its signal intensities, namely, an overall intermediate to high T1-weighted and a low to intermediate T2-weighted signal intensity.[37, 41, 68, 69] The T1-weighted signal intensity of the gland is nonhomogeneous, with multiple irregular areas of lower signal intensity that represent interstitial tissues, salivary ducts, and possibly branches of the facial nerve. The major vessels are identified by their flow voids.

The facial nerve and the intraparotid ducts can be identified on MR imaging.[70] One such technique employs high-resolution T1-weighted images of the parotid gland, acquired with a prototype three-dimensional Fourier transform gradient-echo sequence that permits a very short echo time (4.2 msec) coupled with a modified phase-encoded, time-reduced acquisition scheme. The sequences were obtained at 1.5 T with a head and neck coil. Postprocessed multiplanar, curved, and volumetric images were obtained. Using this technique, the most clinically useful images were acquired at parameters of 40/4.2 (TR/TEeff), a flip of 30°, a field of view of 18 to 20 cm, a matrix of 512×288 or 512×256, an axial plane, 60 images, no gaps, and a section thickness of 1.5 mm.[71] The resulting image contrast obtained was similar to that of a standard spin-echo, T1-weighted image. That is, the parotid gland showed intermediate signal intensity and the fat spaces showed high signal intensity. The vessels had variable signal intensity, depending on the saturation. The nerves, muscles, ducts, and saliva had lower signal intensity. In all patients, the facial nerve could be seen from the brain stem to the parotid gland. In addition, the parotid duct could be seen from the mouth to the hilum of the gland. The proximal intraparotid facial nerve to the level of the retromandibular vein was seen in 72% of the subjects, and the main intraparotid ducts were seen in 66%.[71]

The normal parotid gland has this appearance on conventional and fast spin-echo, T1-weighted images. On spin-echo, T2-weighted scans, the overall signal intensity of the gland is low to intermediate (Fig. 39-19). However, on fast spin-echo, T2-weighted images the gland maintains an intermediate to high signal intensity reflecting both its fat

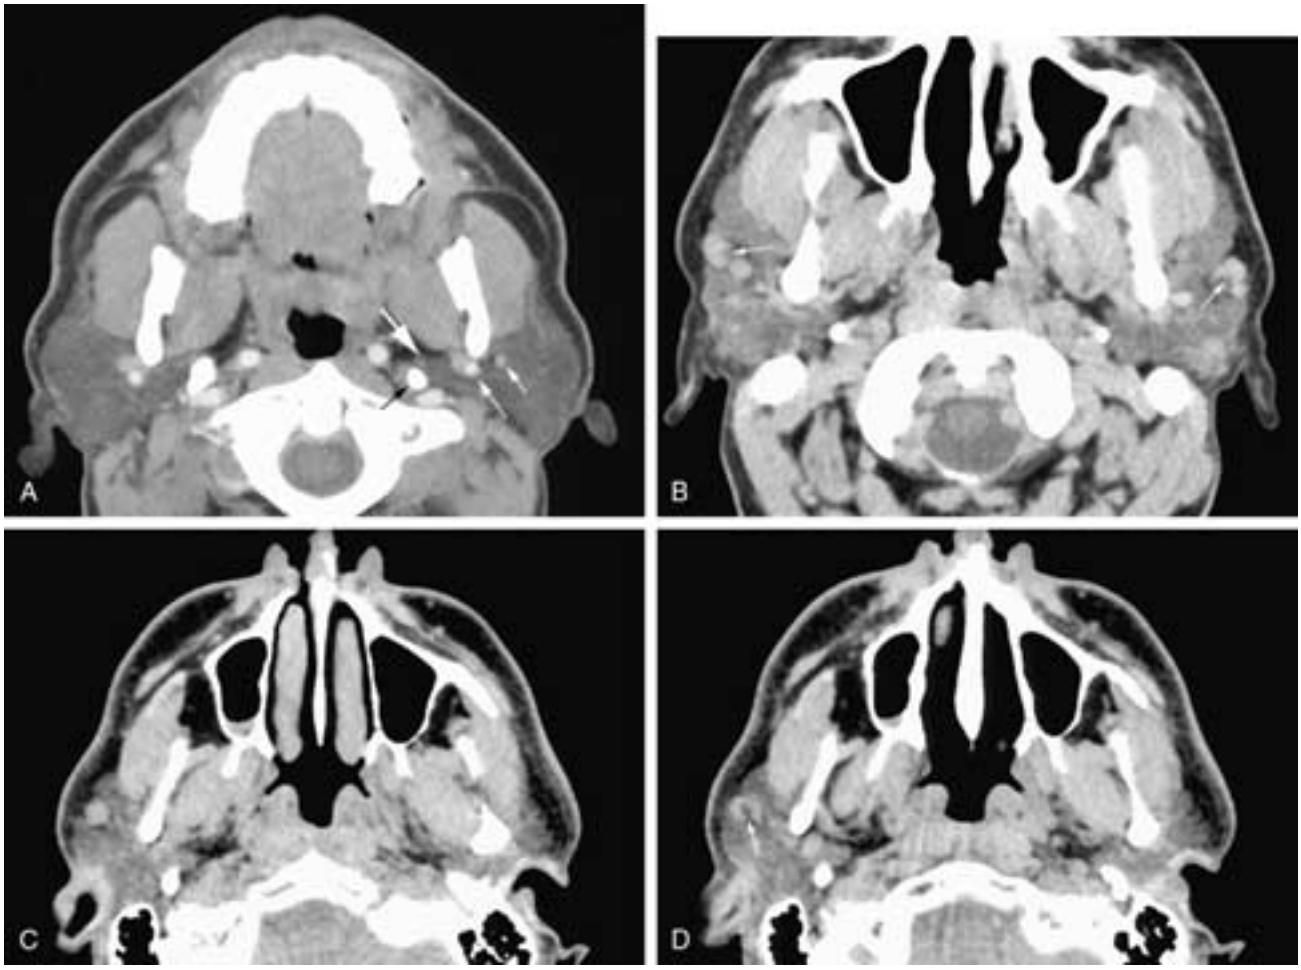

FIGURE 39-18 Axial contrast-enhanced CT scan (**A**) shows the parotid glands to be of lower attenuation than muscle but of higher attenuation than subcutaneous fat. The retromandibular vein (*long thin arrow*) and the external carotid artery (*short thin arrow*) are seen. At this level, the artery is lateral as it starts to ascend to become the superficial temporal artery. The styloid process (*black arrow*) is dorsal to the deep portion of the parotid gland (*large white arrow*) as it projects into the parapharyngeal space. Axial CT scans (**B** to **D**) show examples of parotid lymph nodes. Note the superficial location of the nodes and fat in the hilum (*arrow* in **B**).

content and the gland's water content. Inversion recovery fast spin-echo imaging and inversion recovery (STIR) images have been reported to increase lesion conspicuity over routine spin-echo images by lowering the high T1-weighted signal intensity of fat.[37, 40, 72]

Although some authors have suggested that MR contrast is routinely needed to optimize the diagnostic results of MR imaging, as mentioned, most authors believe that MR contrast is not necessary in the majority of cases.[73] In fact, the use of such contrast can decrease the lesion's conspicuity against the fatty parotid gland unless fat suppression techniques are used. Furthermore, on inversion recovery sequences, not only is there a decreased signal intensity from fat, but any high signal intensity from contrast enhancement is not seen. In general, MR contrast may be beneficial only when a clinically palpable mass is not visualized on the noncontrast-enhanced MR image. It has also been noted that T1-weighted images may be the best overall sequence to localize a mass.[74] Although this may be true in some cases, the T2-weighted scans often best show the tumor margins, and in general, both T1-weighted and T2-weighted sequences are usually obtained in order to best assess the pathology.

Normal Submandibular Glands: CT and MR Imaging

The submandibular glands have a less fatty parenchyma than the parotid glands. As a result, compared to the parotid glands, the submandibular glands are more homogeneous and have a higher attenuation on CT, and slightly lower T1-weighted and higher T2-weighted signal intensities on MR imaging (Fig. 39-20). Occasionally mucoid secretions can normally be identified in the major collecting ducts and hilum of the submandibular gland. However, such ductal visualization may indicate some element of ductal obstruction, and careful scrutiny is required to rule out an obstructing lesion. After contrast administration, both submandibular glands should enhance to the same degree. If not, one gland is functioning abnormally, usually the gland that is more enhanced.

Normal Sublingual Glands: CT and MR Imaging

In general, the sublingual glands are the least well studied of the major salivary glands. This reflects the fact that inflammatory disease and tumors in these glands are rare. The most common abnormality is the ranula, an obstructed mucocele of the gland. Each sublingual gland is located just along the lingual aspect of the anterior third of the mandible. It lies in the floor of the mouth, above the mylohyoid muscle. The gland enhances with contrast and has either a linear or slightly medial concave configuration.

On MR imaging, the T1-weighted signal intensity of the sublingual gland is lower than that of the surrounding fat but higher than that of muscle. The T2-weighted signal intensity is high (Fig. 39-20). The sublingual glands show an age-related decrease in size, with approximately 25% of the gland's thickness present in the second decade of life being lost by the seventh decade. Although the T1-weighted signal intensity of the parotid gland increases with age, the T1-weighted signal intensity of the sublingual and submandibular glands does not.[75]

MR Sialography

MR sialography is a study that is performed without injection of any intraductal contrast material, intravenous contrast, or ductal catheterization. It is thus noninvasive and painless. Several different techniques have been proposed, including a heavily T2-weighted, fast spin-echo sequence (TR 3600 msec/TE 800 msec) with a slice thickness of 30–40 mm using an 8 cm surface coil,[76–78] a T2-weighted single-shot (TSE) sequence (TR/TE 2800/1100 msec, acquisition time 7 seconds) using a quadrature head or a surface coil,[79] a heavily T2-weighted sequence (TR = 3600 msec, TE = 80 msec),[80] and a heavily T2-weighted, two-dimensional, fast spin-echo technique with a 12-cm circular surface coil. Contiguous 3-mm axial images with frequency-selective fat suppression were then acquired through the symptomatic gland.[81] In another study, after being given lemon as a secretogogue, patients had MR

Copyright © 2003, Mosby, Inc. All rights reserved.

imaging using T2-weighted, 3D, constructive interference in steady-state (CISS) imaging. In this study, MR sialography was found to be superior to ultrasound and comparable to digital sialography of the submandibular glands.[82]

In all of these sequences there was depiction of the fluid-filled parotid ducts, with the main duct, primary branches, and secondary branches being clearly seen (Fig. 39-21). In addition, both intraparotid and extraglandular duct widening and ductal strictures were well seen, and sialolithiasis in the main duct was also visualized. By comparison, conventional sialography showed all of the parotid ducts up to the tertiary branches. However, in half of the submandibular gland studies, the ductal system was not seen due to difficulty in canalizing Wharton's duct. The

submandibular gland ducts were seen in all cases of MR sialography.

Unfortunately, the MR sialographic study may be time consuming to perform and clinically useful images may be difficult to obtain. As a result, it is presently not routinely performed as a part of the MR salivary gland study.

Other Approaches

Dynamic contrast examinations have been studied as a means of furthering sectional imaging diagnosis. With regard to CT, a two-phase helical CT study was performed to characterize salivary gland tumors. After the injection of 90 ml of contrast material at a rate of 3 ml/second, helical CT scans were obtained at early and delayed phases, with scanning delays of 30 and 120 seconds, respectively. The attenuation change and enhancement patterns in the tumors were then assessed. There was an increase in attenuation in 86% of pleomorphic adenomas and a decrease in 89% of Warthin's tumors. A multinodular enhancement pattern was found in only 34% of pleomorphic adenomas. With malignant tumors, there was an increase in 55% and no change in 40% of the cases at delayed phase scanning. This study concluded that the ratio of CT numbers was

Copyright © 2003, Mosby, Inc. All rights reserved.

significantly different between Warthin's tumors and pleomorphic adenomas and between Warthin's tumors and malignant tumors.[83] Although this technique does improve diagnosis, its clinical benefits are limited and it is not commonly performed.

With regard to MR imaging, the efficiency of dynamic contrast-enhanced MR imaging for the diagnosis of salivary gland masses was studied. Both T1-weighted and T2-weighted images were obtained, dynamic studies on each mass were performed, and the enhancement patterns were correlated with pathology. Four enhancement patterns of a mass were recognized: type 1 showed marked, homogeneous enhancement; type 2 had slight, homogeneous enhancement; type 3 had marginal enhancement; and type 4 had poor enhancement. Most pleomorphic adenomas had a type 1 enhancement pattern, but two had a type 2 pattern. Warthin's tumor generally showed the type 4 pattern. Primary malignant tumors of the salivary gland all showed the type 3 pattern. One inflammatory cyst and one Warthin's tumor also showed the type 3 pattern.[84] These studies show that although there is some improvement in imaging diagnosis, at present their clinical significance seems limited. Because of this and the additional time needed for these calculations, most people do not perform these dynamic studies.

Three-Dimensional MR Imaging

Three-dimensional MR imaging has been proposed as a good communication tool when describing pathology to clinicians who have difficulty assimilating serial images to display pathology. The use of MR contrast has been proposed to improve the identification of salivary masses on such 3D images.[85] At present, few radiologists routinely use 3D MR imaging because they find it adds little to their imaging information. However, as technology advances and CT and MR data can be rapidly combined to produce a 3D image, the use of this approach may become more popular.

MR Spectroscopy

MR spectroscopy is a relatively new field as applied to clinical imaging. One study has shown that ^{31}P spectroscopy of salivary malignancies demonstrated a significant increase in the concentration of phosphomonoesters, phosphodiesters, and inorganic phosphates compared to the concentrations in normal individuals, and there was a large reduction in creatine phosphate.[86] This early work may lead the way to attainment of more pathologic and prognostic information on the MR study. At present, because of the considerable time necessary to gather sufficient data and the limited clinical application of MR spectroscopy, it is primarily an investigative tool. MR spectroscopy has also been used to study various physiologic functions of the salivary glands. One review summarized the results of studies of energy metabolism and acid-base balance [using ^{31}P and ^{14}N nuclear magnetic resonance (NMR)], electrolytes transport (^{23}Na, ^{39}K, ^{35}Cl, and ^{87}Rb NMR), and water transport (^{1}H NMR). The study noted that the three-dimensional structure of salivary glands can be observed with ca. 60-µm resolution; it is also possible to observe circulation, flow, and volume changes during secretion. The study concluded that MR spectroscopy may open up new fields in the study of exocrine secretion.[87]

CT Sialography

The CT sialogram was developed to provide better definition of major salivary gland masses than was attainable with the early low-resolution CT scanners.[88–91] The study was a combination of a sialogram and a simultaneous CT scan of the gland. Acinarization of the gland provided a background density that silhouetted virtually any mass (Fig. 39-22). However, as a result of the development of high-resolution CT scanners and MR imaging, this cumbersome double examination is no longer performed.

Noncomputed Tomographic Sialography

In a manner similar to CT sialography, conventional multidirectional tomography of the parotid gland was performed immediately after a sialogram that intentionally had acinarization. If a mass was present, it was outlined by the contrast material and was more easily identified than on the routine sialographic study. In the present era of high-resolution CT and MR imaging, this technique is no longer employed.

Ultrasound

Ultrasound has traditionally been used to differentiate solid and cystic salivary gland masses and to identify salivary calculi. More recently, it has been used to make more specific diagnoses. Autoimmune disease (Sjogren's disease) can be diagnosed by ultrasound when the disease is in its more advanced stages. However, when the disease is in its early stages, it cannot be consistently diagnosed by ultrasound (or, for that matter, by MR imaging), and the improved reliability of labial minor salivary gland biopsies, sialochemical studies, and serum studies has made the current diagnosis of Sjogren's disease less dependent on imaging than it was in prior decades. Similarly, although in some cases lymphomatous and nonlymphomatous nodes can be distinguished by ultrasound, biopsy is still necessary. The diagnosis of multiple parotid cysts in HIV-positive patients can also be made by ultrasound. It is fair to say that overall in the last decade, ultrasound has become a more useful imaging technique, particularly for the parotid and submandibular glands. Although ultrasound can differentiate some intraglandular lesions from extraglandular masses, this technique is not used frequently in this regard because of the routinely superior visualization of the deep spaces of the upper neck, skull base, and floor of mouth attainable by CT and MR imaging.[29–31, 92, 93]

It has also been suggested that color Doppler ultrasound can be used to differentiate between a peripheral parotid mass that is near the caudal tip of the gland and a soft-tissue mass in this area that is adjacent to the gland. The technique is based on identifying the origin of the feeding vessels to the mass, with those masses deriving their vascular supply from the parotid gland being of parotid origin.[94]

Usually the ultrasound examination is performed with a linear probe, high-frequency (7- to 10-MHz) transducer. This gives higher-resolution images but does not penetrate as deeply as the lower-MHz transducers. This limitation is one of the reasons that ultrasound is not utilized as frequently as CT or MR imaging to examine patients with possible deep extensions of their salivary lesions. Sono-

graphically guided biopsy of masses and lymph nodes related to the salivary glands is now commonly performed. This approach adds a degree of pretreatment diagnosis in those cases where the surgeon needs this information.[95] Many surgeons are of the opinion that a mass in a major salivary gland must be resected; in such situations, a presurgical biopsy is usually not performed.

Radionuclide Salivary Studies

The major advantage of salivary gland scintigraphy, compared to other imaging modalities, is that both parenchymal function and the excretion fraction of both parotid and submandibular glands can be quantified simultaneously with a single well-tolerated intravenous injection.[96]

The salivary glands normally concentrate ^{99m}Tc pertechnetate, and there is a generalized decreased uptake of this radionuclide associated with aging. Although masses that excessively accumulate the radionuclide can be identified, they are not as accurately localized as on CT or MR imaging studies. In addition, masses that do not accumulate excessive radionuclide are poorly seen, if they are even identified. As a result, radionuclide sialograms are not routinely used to study parotid and submandibular gland masses.

The lesions that are most often examined by radionuclide sialograms are those that are suspected of highly concentrating ^{99m}Tc. These tumors are primarily Warthin's tumors and oncocytomas.[60, 97, 98] Salivary gland function can also be assessed, and hyperfunction can be demonstrated in acute sialoadenitis, granulomatous disease, lymphoma, and sialosis. A cold area within a gland that has overall increased activity may represent an abscess in a patient with an acute purulent sialoadenitis. Decreased glandular activity is seen in Sjogren's syndrome and in most primary and metastatic tumors. A viral sialoadenitis causes a generalized decreased uptake, and ductal obstruction can be estimated by the degree of prolongation of the secretory phase of the radionuclide study. Patchy decreased uptake may indicate chronic and atrophic salivary gland disease.[60, 99–101]

In one study, dual-isotope (^{99m}Tc and ^{201}Tl) Single Proton Emission Computed Tomography (SPECT) imaging was compared to CT and MR imaging in the differentiation of various lesions of the major salivary glands. The uptake ratio and retention index for ^{99m}Tc and ^{201}Tl were calculated by drawing regions of interest on the involved and normal glands. All malignant tumors were detected by all three modalities. Warthin's tumors were specifically identified by dual-isotope SPECT imaging; however, MR imaging failed to differentiate Warthin's tumor from pleomorphic adenoma. Of 16 tumors showing a cold defect on the ^{99m}Tc images, parametric analysis with ^{201}Tl had an accuracy of 94%, whereas CT had an accuracy of 70% to 90%. MR imaging was 73% to 91% accurate in differentiating between Warthin's and malignant tumors.[102] Although one may question the clinical significance of being able to specifically identify a Warthin's tumor, this approach clearly has merit in selected cases.

Angiography

Interventional vascular studies play little role in the diagnosis and treatment of most salivary gland diseases. With the rare exception of the embolization of an unusually large hemangioma or another rare vascular lesion, angiographic studies are not used in the salivary glands.

Copyright © 2003, Mosby, Inc. All rights reserved.

Catheter Dilatation and Endoscopy

In recent years, manufacturing techniques have progressed so that smaller-diameter catheters are now available. These catheters have started to be utilized both diagnostically and therapeutically in disease involving Stensen's duct.[101] The procedure, referred to as *sialendoscopy*, allows direct inspection of the salivary ductal system by means of a microendoscope. This technique is performed under local anesthesia on an outpatient basis.[103] It is presently considered a research technique and is rarely employed in the average clinical setting.

Fine Needle Aspiration

Fine needle aspiration of salivary masses is becoming increasingly popular. It is performed with a 22-gauge needle and can be done with or without CT or MR imaging guidance.[29, 31, 104–107] Diagnostic yields are highest when a cytopathologist or a cytotechnologist is present during the procedure and can check the specimen for adequacy. With greater experience, the concurrence between the cytologic and histologic findings can be expected to rise above the present 91%.[60]

Positron Emission Tomography Scanning

Early clinical work with positron emission tomography (PET) scanning has shown that when imaging using 2-(F-18) fluoro-2-deoxy-D-glucose (FDG), tumors with increased metabolic activity are seen as areas of increased PET activity.[108] However, initial results have also indicated that although PET can identify the higher-grade malignancies, there is confusion with the common benign Warthin's tumor, which also has high metabolic activity. Because of this limitation, the high cost of this examination, and the long procedure time, PET scanning appears to have a limited future in this area.

In fact, FDG is not a very tumor-specific substance, and its accumulation in benign lesions with increased glucose metabolism may give rise to false-positive results and hence cause FDG PET to display relatively low specificity, frequently below 85%. Correct interpretation of FDG PET studies is predicated upon both detailed knowledge of morphologic abnormalities and the correlation of functional and morphologic information derived from CT or MR imaging. False-positive findings may be obtained in patients with acute inflammatory lesions or benign salivary gland tumors. It has been suggested that these problems may be alleviated by means of multitracer studies, for example, using ^{11}C-labeled aminoisobutyric acid for quantification of A-type amino acid transport. Finally both radiotherapy and chemotherapy can cause increased FDG uptake, complicating diagnosis and evaluation.[109]

In another study using CT or MR imaging, FDG PET studies were performed in 28 patients with parotid lesions. All lesions except two showed higher accumulation of FDG than the normal parotid gland. High accumulation was found in all 5 carcinomas, all 6 Warthin's tumors, and 8 of 12 pleomorphic adenomas, with standardized uptake values (SUVs) of over 3.0. The mean SUVs of carcinomas, Warthin's tumors, and pleomorphic adenomas were 5.92 ± 2.05, 7.03 ± 2.49, and 4.07 ± 1.55, respectively. On the other hand, all five inflammatory lesions demonstrated low accumulation, with a mean SUV of 1.66 ± 0.89. The authors concluded that it is difficult to differentiate malignant from benign parotid lesions by SUV on FDG PET.[110]

NONNEOPLASTIC DISORDERS

Infections

Acute parotitis has only a few etiologies; most commonly it is caused by infections. By comparison, chronic salivary inflammation may be caused by numerous processes: infectious, autoimmune, systemic, and certain neoplasms. In this clinical setting, the radiologist may play an important role in resolving some diagnostic dilemmas.

Acute Infections

As a group, bacterial and viral infections are the most common causes of salivary abnormalities. Most of the bacterial infections ascend from the oral cavity and are related to a decrease in salivary flow. In fact, maintenance of normal salivary flow is the single best deterrent to infections. Many situations can decrease saliva flow: prior infections, dehydration, trauma, surgery, irradiation, some medications, and obstructing masses such as stones or tumors.[60] Ascending infections are more common in the parotid gland than in the submandibular gland. Reasons for this include the following: the orifice of Stensen's duct is larger than that of Wharton's duct, the parotid duct orifice is more easily injured by cheek biting and by the presence of dental prostheses and other mechanical trauma, and the overall smaller caliber of Stensen's duct itself may allow easier interruption of salivary flow by epithelial tears and thickened secretions.[7, 8] In addition, parotid secretions are primarily serous, while saliva from the submandibular and sublingual glands is more mucinous. Such mucoid secretions contain antibacterial elements such as lysosomes and IgA antibodies. Mucins also contain sialic acid, which agglutinates bacteria, preventing adherence to host tissues, and specific glycoproteins that bind epithelial cells, competitively inhibiting bacterial attachment to those cells.[111]

Dehydration classically occurs in the postoperative patient, especially after major abdominal surgery. Typically, such parotitis develops 2 to 7 weeks after surgery; however, cases can develop in the immediate postoperative period after spinal anesthesia, which causes peripheral vasodilatation, hypovolemia, and dehydration. In addition, patients with debilitating conditions and immunosuppression are at risk of developing acute sialadenitis. Such conditions include diabetes mellitus, malnutrition, HIV infection, Sjogren's syndrome, renal and hepatic failure, depression, anorexia, bulimia, cystic fibrosis, Cushing's disease, hyperuricemia, hyperlipoproteinemia, and lead intoxication.[111] There are also a number of medications that can contribute to dehydration and thus predispose the patient to acute sialadenitis. These medications include diuretics, barbiturates, antitricyclics, antihypertensives, antidepressants, antihistamines, and parasympathetic drugs.[111, 112]

Eosinophil-rich mucous plugs have been associated with acute bacterial parotitis in children, especially those with a history of allergies. In addition, foreign body materials such as food, seeds, and feathers have been reported to obstruct the salivary ducts.

FIGURE 39-23 Axial contrast-enhanced CT scan shows a solitary low-attenuation area (*arrow*) in the right parotid gland. There is a thick, indistinct, enhancing rim, and the remaining gland is denser than normal. There is also thickening of the overlying skin and increased density in the subcutaneous fat. This patient had a parotid abscess with cellulitis.

There are two age groups particularly at risk of developing acute sialadenitis. Neonates can develop suppurative parotitis, usually within the first 2 weeks of life, and the elderly are prone to acute sialadenitis, usually due to debilitation.[111]

Bacterial Infections

Acute suppurative sialoadenitis is an acute, painful, diffuse disease primarily of the parotid gland. The gland is swollen and tender, and a purulent exudate can be seen in the buccal orifice of Stensen's duct. This disease usually occurs in debilitated, dehydrated patients, usually with poor oral hygiene.[112–114] The dry mouth may be caused by general debilitation, fluid restriction, irradiation, or medications that decrease salivary flow. The incidence of acute suppurative sialoadenitis varies between 0.004% and 0.74% of patients who have had a major surgical procedure.[60] Good oral hygiene and hydration have markedly reduced the incidence of this condition. The most common offending agents are *Staphylococcus aureus*, *Streptococcus viridans*, *S. pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes*, and *Escherichia coli*. Intraparotid and periparotid lymph nodes may be involved in the inflammatory reaction. The treatment of choice is antibiotic therapy.[60, 112]

Suppurative parotitis can also occur in neonates, usually affecting premature infants (35% to 40% of cases), and dehydration is the main predisposing factor.[113] The onset is usually between 7 and 14 days after delivery, and there is erythema of the skin overlying the parotid glands. The offending agents are *Staphylococcus*, *Pseudomonas Streptococcus*, *Pneumococcus*, and *Escherichia*.[60] Hydration and antibiotic therapy usually cure the infection. Patients with an undiagnosed or incompletely treated acute suppurative sialoadenitis can develop an intraglandular abscess (Figs. 39-23 and 39-24) regardless of their age. Uncommonly, the infection may progress to an abscess despite aggressive medical treatment. Small abscesses may form (Fig. 39-25) and coalesce to form a larger abscess, or a solitary abscess may develop. Patients with such abscesses have fever and malaise. The abscess may extend into the parapharyngeal space or the upper neck. Surgical drainage with adequate antibiotic therapy is the treatment of choice.

Acute suppurative sialoadenitis can also involve the submandibular gland, although the incidence is lower than that in the parotid gland. Such submandibular gland disease can occur in the absence of parotid disease. The lower incidence in the submandibular gland is related both to the protective anatomy of Wharton's duct and to the fact that the saliva of the submandibular gland is more bacteriostatic than that of the parotid gland. The submandibular glands also have a faster resting salivary flow rate, which helps prevent ascending infection from the oral cavity.[114] The presence of sialolithiasis is a major factor in the development of submandibular sialoadenitis, and a calculus is found either within the gland and/or within Wharton's duct in most cases of acute submandibular sialoadenitis.[60] The periglandular submandibular nodes are often enlarged, causing painful swelling of the gland. These enlarged nodes are a characteristic clinical presentation (Fig. 39-26).

Sialodochitis is inflammation of either Stensen's or Wharton's duct. Usually the duct is dilated secondary to a distal obstruction near the mouth. The enlarged duct can have a fusiform shape or appear as a ''string of sausages'' resulting from multiple areas of ductal stenosis (Figs. 39-27 and 39-28).

Because of the acute, painful nature of these inflammatory diseases and their usually short duration, sialography is rarely performed. In fact, it is contraindicated in these patients, as retrograde injection of contrast may drive the infection back into the gland and cause either exacerbation or recurrence of a clinically quiescent infection. If a sialogram is performed on a patient with acute sialoadenitis, the study shows peripheral tapering of the ducts, giving a

VIEW IMAGE

FIGURE 39-25 Left lateral views (**A**, **B**) of parotid sialograms on two different patients. In **A**, there are multiple collections of varying size of contrast material primarily located in the posterior portion of the gland. These were old abscesses in a clinically normal patient. In **B**, the patient had a vaguely palpable mass (superiorly, just below the mandible, where there is an absence of filled ducts). There are also scattered collections of contrast material in the upper and lower poles of the gland. This patient had tuberculous abscesses.

pruned appearance to the ductal system. This appearance results from periductal cellular infiltration of acute inflammatory cells, which is confined by the gland capsule and thus exerts pressure on the ductal system. Focal areas of major ductal dilatation can occur secondary to areas of ectasia, and narrowing at the ductal branch points due to functional spasm may also be seen.[113–115]

On CT scans obtained very early in an acute infection, the central ducts are dilated and the walls of the central ducts and of Stensen's duct may enhance (Figs. 39-29 and 39-30). The gland itself is variably enlarged and has an increased attenuation on noncontrast scans reflecting the cellular infiltration.[114] There may be diffuse enhancement of the gland on postcontrast studies, reflecting the associated increased vascularity (Fig. 39-30). Calcified sialolithiasis can be clearly identified on CT and may be located within the ductal system of the gland and/or within Stensen's duct (Figs. 39-31 to 39-35). Occasionally, even a noncalcified stone can be identified in Stensen's duct. It may appear as a low-attenuation area within a dilated, obstructed, saliva-filled duct (Fig. 39-36). If Stensen's duct is dilated and has thickened, enhancing walls (Figs. 39-28 to 39-30), sialodochitis is present.

On MR imaging, the parotid gland is variably enlarged, and the usual interstitial and ductal components are poorly seen compared to those of a normal gland. The gland can have either higher or lower than normal signal intensity on T2-weighted scans, depending on whether edema or cellular infiltration predominates.

In cases of acute sialoadenitis, the submandibular gland is enlarged and it enhances. Submandibular adenopathy is usually present. As in the parotid gland, calcified sialolithiasis may be present within the gland and/or in Wharton's duct (Figs. 39-26, 39-37 to 39-42).

Viral Infections

By far the most common cause of viral parotitis is mumps, which is caused by an RNA virus of the paramyxovirus group. Mumps is the most common of all salivary gland diseases.[12] It primarily involves the parotid glands but can occur in the submandibular and sublingual glands. The disease is most reliably diagnosed during epidemics, and the diagnosis can be confirmed by measuring serum antibody titers.[8] The incubation period is between 2 and 3 weeks, and parotid involvement is clinically unilateral in about 20% to 33.3% of the cases. The patient may experience a prodromal period of general malaise. During this period, there may be redness at the orifices of Stensen's or Wharton's ducts. The disease is then characterized by an acute, painful swelling of the involved gland that may persist for 1 or more weeks. Ingestion of sour liquids at this stage will result in an acute exacerbation of the discomfort. During the acute phase, the saliva is clear but contains virus. Mumps can be subclinical, and this type of infection may account for some misdiagnosed or apparently idiopathic cases of parotid gland enlargement. It may also account for adults who have no history of mumps but have a positive complement-fixation test for the virus (serum antibodies to mumps S and

Copyright © 2003, Mosby, Inc. All rights reserved.

V antigens). One episode of mumps provides immunity. Although about 75% of patients have an uncomplicated course, mumps can cause epididymo-orchitis, meningoencephalitis, pancreatitis, and thyroiditis. It may also be responsible for some cases of unilateral neurosensory hearing loss.

Other viral agents can cause parotitis, including coxsackie viruses, parainfluenza viruses (types I and III), influenza virus type A, herpes virus, echo virus, and choriomeningitis virus.[8, 60, 112, 116, 117] EBV may remain latent within the ductal epithelium and is a potential source (along with latently infected pharyngeal mucosa) of secreted virus in the saliva of patients. Cytomegalovirus (CMV) may also infect salivary tissue. HIV has not, to date, been shown to infect the salivary glands directly, although it does interact with and potentiate the effects of CMV and EBV.[118–120]

The imaging findings are nonspecific. The gland is usually enlarged and has a slightly greater CT attenuation than normal. On MR imaging, the gland tends to have a slightly higher T2-weighted signal intensity than normal.

Chronic Inflammations

The chronic inflammatory diseases of the major salivary glands may be due to recurrent bacterial infection or infection with other agents, as discussed below. Noninfectious conditions such as prior irradiation, autoimmune disease, or idiopathic causes may also lead to chronic inflammation.

Clinically, these chronic conditions have one of three general presentations. The first is that of repeated episodes of acute sialoadenitis with associated painful swelling of the involved gland. There are intervening intervals characterized by lack of symptoms and decreased gland size. The second presentation is that of a slowly progressive enlargement of the gland with periodic episodes of acute sialoadenitis. The third presentation is that of a slowly

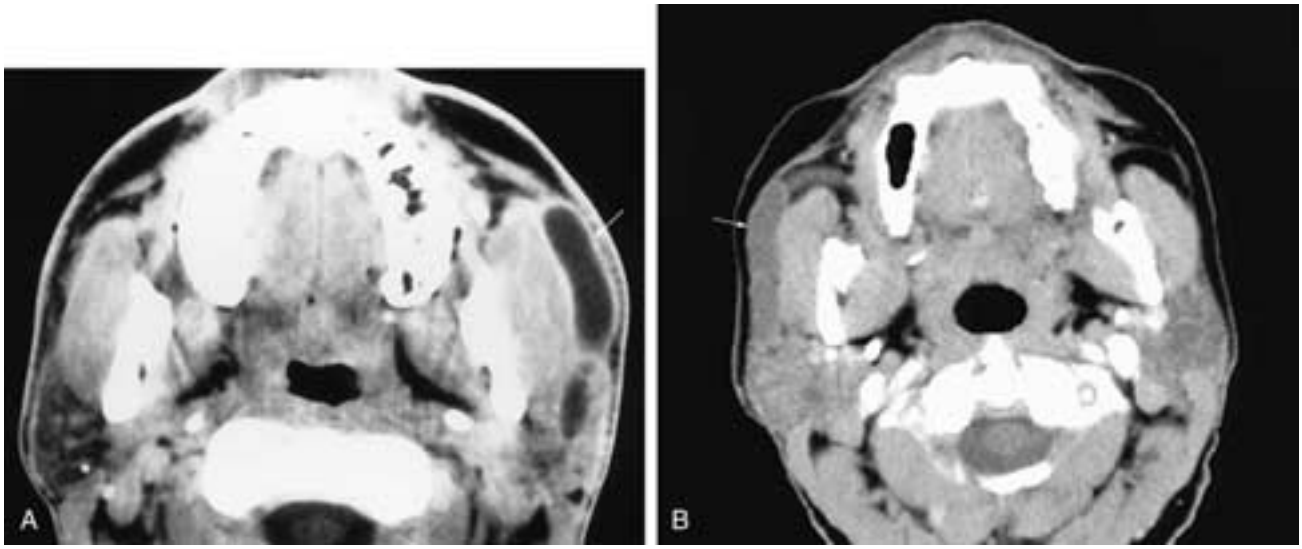
FIGURE 39-27 Frontal oblique view of a left parotid sialogram (**A**) shows dilatation of the entire Stensen's duct and some central dilatation of the glandular ducts. The peripheral ducts are not visualized. This patient had sialodochitis secondary to obstruction at the buccal orifice. Lateral view of a parotid sialogram (**B**) on a different patient shows dilatation of Stensen's duct and of the central parotid ducts. The peripheral ducts are not visualized. Strictures along Stensen's duct create a ''string of sausage'' appearance. This patient had sialodochitis and severe sialadenitis. A parotidectomy was necessary.

progressive, painless enlargement of the salivary glands. This last group of patients may be confused clinically with those who have neoplasms.

An attempt should be made to differentiate the obstructive and nonobstructive diseases, since their treatment and prognosis often vary considerably. The chronic nonobstructive diseases involve the parotid glands more frequently than they do the submandibular glands. Conversely, the obstructive disorders are more common in the submandibular glands.



VIEW IMAGE

FIGURE 39-29 Axial contrast-enhanced CT scans (**A**, **B**) show minimal dilatation of the intraglandular ducts (*arrows*) within a slightly enlarged right parotid gland. This patient had very early right acute sialadenitis. Axial contrast-enhanced CT scans (**C**, **D**) show the early changes of a left sialadenitis. The left parotid gland parenchyma is denser than the normal right side secondary to edematous fluid and cellular infiltration. There is enhancement of the walls of the dilated intraglandular central parotid ducts.

The following discussion will focus on other infectious agents that can also affect the intraparotid or juxtaglandular lymph nodes, either as an ascending infection from the oral cavity or as part of a systemic process: tuberculosis, atypical mycobacterial infections, syphilis, cat-scratch fever, toxoplasmosis, actinomycosis, and sarcoidosis.[60, 121]

Mycobacteria

Primary tuberculous involvement of the salivary glands is rare. However, with the recent increase in the reported number of patients with tuberculosis (TB) in the United States, more of these cases are likely to be encountered in the next decade. Extrapulmonary TB is an uncommon event. In a review of patients with TB from Boston City Hospital during the years 1968 to 1977, it was estimated that 4.5% of all cases (over 1500 in total) had extrapulmonary TB.[122] Head and neck involvement in TB is an even rarer event. The authors had collected 136 cases of extrapulmonary TB; 16 (12%) patients had head and neck involvement: 13 patients had TB lymphadenitis of cervical, supraclavicular, or submental nodes; 1 patient had TB gingivitis; 1 had TB otitis; and 1 had TB laryngitis. For cases that do affect the salivary glands, 70% involve the parotid glands, 27% involve the submandibular glands, and only 3% involve the sublingual glands.[60] Most often the salivary disease arises from a focus in the tonsils or teeth and spreads to the gland via the regional lymph nodes. Sialadenitis occurs as the infection extends from the nodes into the gland proper. The clinical presentation may either be that of an acute tuberculous sialadenitis, which can mimic other acute infections, or a more indolent disease that may mimic a tumor.[112] In cases of chronic disease, the overlying skin may become inflamed and develop a fistulous tract. Secondary salivary TB occurs in cases of generalized TB and tends to affect the submandibular glands.[8]

The sialographic findings are primarily those of bacterial sialoadenitis, and focal abscesses tend to develop within the gland (Fig. 39-25). Adjacent tuberculous cervical adenitis may have an appearance similar to that of benign hyperplastic adenopathy or may have more extensive findings, which are described in Chapter 36.

Atypical mycobacterial infections of the salivary glands similarly tend to represent extensions from cervical adenopathy and are radiographically indistinguishable from tuberculous disease. This disease is most often found in immunosuppressed patients. Granulomatous reactions are

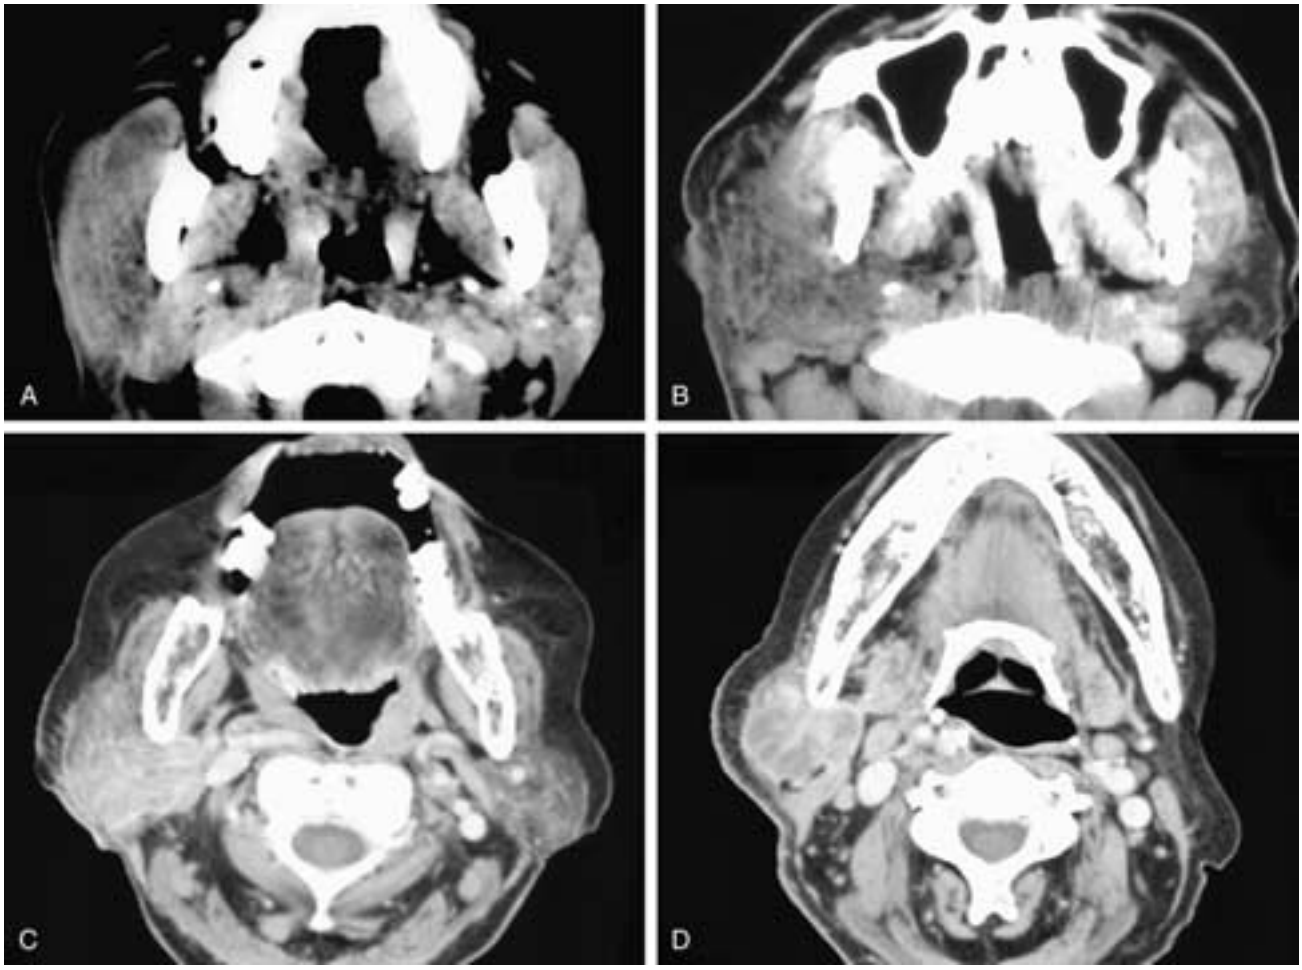
Copyright © 2003, Mosby, Inc. All rights reserved.

lacking in mycobacterial infections in the immunosuppressed population because of defects in cell-mediated immunity. Atypical mycobacterial infections are usually seen as diffuse infiltrates of foamy macrophages with abundant acid-fast bacilli.

The imaging findings are nonspecific and are generally those of a slightly enlarged, dense, congested gland, which may have microabscesses scattered irregularly throughout the gland.

Syphilis

Syphilis is a sexually transmitted bacterial infection caused by *Treponema pallidum* (*treponema*—Greek: turning thread, *pallidum*—Latin: pale), a long (5 to 20 μm), slender spirochete that rotates along its long axis in fluid and may ''creep'' and ''crawl'' along solid surfaces. Primary and secondary syphilis has a propensity to affect skin and mucosal surfaces. A chancre forms at the site of the primary infection. Cutaneous chancres are painless, hard, raised lesions with shallow ulcerations and sharp, raised borders. Mucosal primary chancres may appear as silvery gray erosions, granulation tissue, or nonspecific ulcers. Head and neck manifestations of secondary syphilis include condyloma lata, hyperplastic wart-like lesions that may occur in the larynx, ears, and nasolabial folds; ''mucous patches,'' oral raised and flattened, macerated lesions with a thin, grayish membranous covering; and a generalized maculopapular rash that may also occur intraorally. Tertiary syphilis tends to affect the central nervous system and the cardiovascular system. In the head and neck, tertiary syphilis is manifested as *gummas*, large necrotizing lesions with a proclivity for membranous bones. Gummas most commonly affect the palate; however, the nose, larynx, temporal bones, and ossicles may also be involved. Sinonasal gummas may present clinically with chronic sinusitis and drainage, as well as radiologic evidence of a destructive inflammatory mass that may easily mimic Wegener's granulomatosis or



VIEW IMAGE

FIGURE 39-30 Axial contrast-enhanced CT scans on four different patients, all with acute sialadenitis. In **A**, there is enlargement of the right parotid gland, with blurring of the gland's margins. The adjacent masseter muscle is also enlarged, and there is involvement of the overlying subcutaneous tissues and skin. Thickening of the central parotid duct can be identified. The left parotid gland is dense, and there are small calcifications in the peripheral ducts. These are changes of chronic sialadenitis. In **B**, there is diffuse enlargement of the right parotid gland with a myositis of the right masseter and internal pterygoid muscles and an associated cellulitis. In **C**, there is enlargement and enhancement of the right parotid gland with adjacent cellulitis. There is minimal involvement of the right masseter muscle. In **D**, the right parotid gland is swollen, and the dilated glandular lobules can be identified. There is also evidence of cellulitis.

sinonasal fungal disease. Another manifestation of tertiary syphilis is atropic glossitis resulting from obliterative vasculitis. Syphilis rarely affects the parotid glands. When this does occur, it is reported to have a distribution and an appearance similar to those of TB, and its imaging findings are similar to those of sarcoidosis.[8]

Cat-Scratch Disease

Cat-scratch disease (CSD), first described in France in 1950, is an infection caused by a rickettsia-like gram-negative bacterium introduced through a skin break and resulting in regional lymphadenitis. Children and young adults are most often affected. Patients present with lymphadenopathy following a cat scratch or bite. An erythematous lesion develops at the site of the scratch or bite, which resolves spontaneously within 1 to 3 weeks. CSD comes to medical attention when regional lymph nodes become painfully enlarged within weeks of development of the primary lesion. This nodal enlargement may be accompanied by fever, headache, myalgias, and rash. An atypical presentation is seen in up to 25% of cases, manifesting as ocular involvement, encephalopathy, granu-

This patient had noncalcified sialolithiasis with sialodochitis and sialadenitis.

lomatous hepatitis, hepatosplenic infection, endocarditis, and osteomyelitis. The parotid lymph nodes may be involved with the lymphadenopathy, thus mimicking primary salivary gland disease.[8, 60] The imaging findings are nonspecific and are generally those of enlarged intraparotid lymph nodes. As such, the imaging findings can resemble either those of sarcoidosis or those of TB; therefore, CSD may be indistinguishable from these diseases.

The exact cause of CSD was uncertain until the 1990s. Initially, *Afipia felis* was thought to be the cause; however,

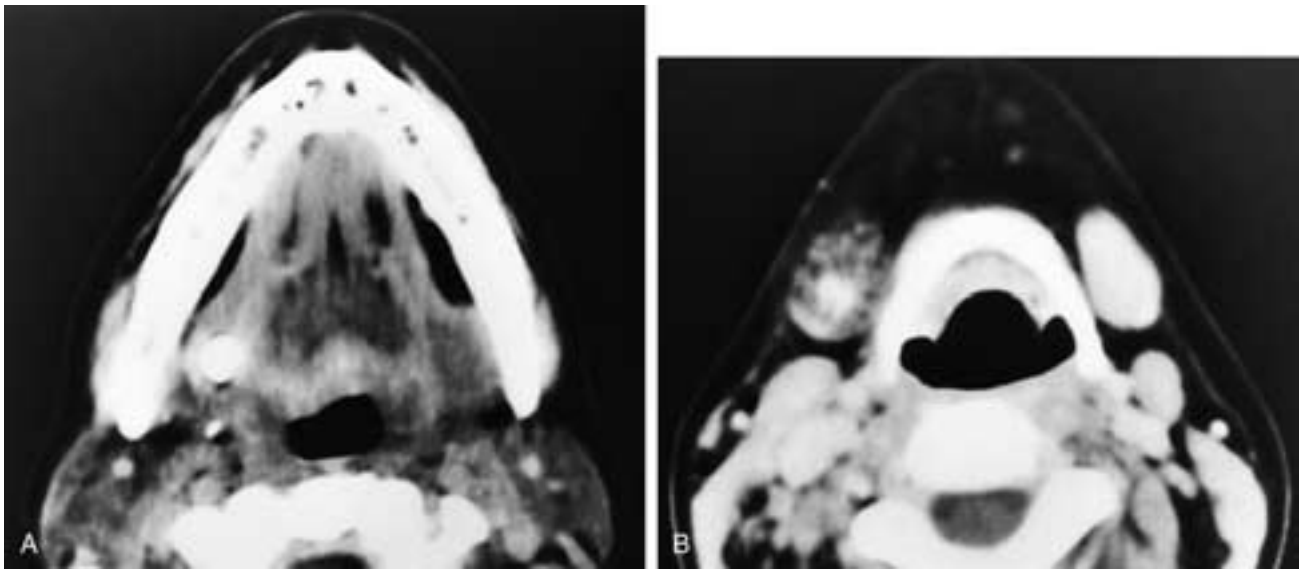

FIGURE 39-37 Axial contrast-enhanced CT scans (**A**, **B**) show a calculus near the hilum of the right submandibular gland. There is also some inflammatory thickening of the right mylohyoid muscle. In **B**, a more caudal scan, the lower portion of the calcification is seen in a somewhat diffusely fatty, atrophic gland. This patient had chronic submandibular sialolithiasis, sialadenitis, and early glandular atrophy.

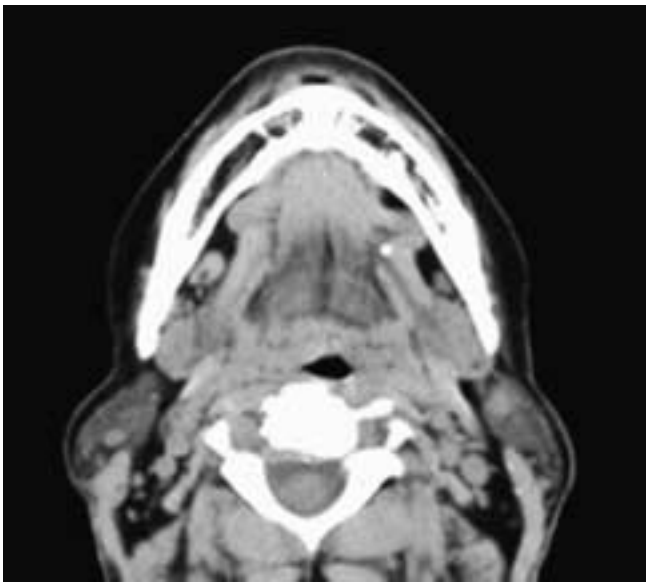
VIEW IMAGE

FIGURE 39-38 Axial contrast-enhanced CT scans (**A**, **B**) show two calculi in the left submandibular gland system (*arrows*). The stone at the hilum of the gland has caused an acute sialadenitis with a cellulitis. In **B**, an abscess is also seen around the gland. The formation of an abscess in acute submandibular sialadenitis is uncommon, and testing found this male to be HIV positive. This patient had submandibular sialolithiasis, sialadenitis, cellulitis, and an abscess.

subsequent study failed to confirm this. During the 1990s, it was demonstrated that *Rochalimaea henselae*, later reclassified as *Bartonella henselae*, was a causative agent. Multiple studies have subsequently shown that three *Bartonella* species may produce either CSD in humans, usually *B. henselae* or *B. clarridgeiae*, or bacteremia in healthy cats. Also, these two bacteria and *B. quintana* cause bacillary angiomatosis, bacillary peliosis, and relapsing bacteremia in humans.

Histologically, early cat-scratch lymphadenitis may reveal only nonspecific reactive changes and sinus histiocytosis. Epithelioid granulomas coalesce to form necrotizing microabscesses with polymorphonuclear cells and fibrin. Palisading epithelioid histiocytes rim ''stellate'' zones of necrosis. Bacilli are rarely present within the granulomas but have been noted within capillaries and macrophages.

CSD follows a self-limiting course of 2 to 4 months. Rarely, patients with CSD may progress to severe systemic infections such as encephalitis, osteomyeitis, hepatitis, or pleuritis. In complicated CSD, treatment with trimethoprim-sulfamethoxazole, ciprofloxacin, azithromycin, or gentamicin may be necessary.[123–125]



VIEW IMAGE

FIGURE 39-39 Axial CT scan shows a small calculus in the midportion of the left Wharton's duct. The duct is obstructed and dilated proximal to this stone. This patient had submandibular sialolithiasis and early sialadenitis.

Toxoplasmosis

Toxoplasmosis is a protozoan infection caused by *Toxoplasma gondii* transmitted by (1) inhalation of oocysts passed through cat feces, (2) ingestion of oocysts from poorly cooked or raw meats, (3) transplacental infection, or, rarely, (4) blood transfusions or organ transplantation. It is one of the most common infections affecting humans, infecting 5% to 95% of the population, depending on the geographic location. Normal hosts commonly have an asymptomatic infection. Cervical lymphadenopathy as well as fever, myalgias, anorexia, headache, sore throat, and rash are uncommon symptoms. In the parotid region, the disease may be clinically and radiographically indistinguishable from CSD, sarcoidosis, and TB.

Necrotizing systemic infections (retinitis, encephalitis, myocarditis, hepatitis, pneumonitis) rarely develop in the immune competent. But patients with AIDS or those who are immunosuppressed for other reasons are much more likely to develop severe and fatal infections. Toxoplasma encephalitis is the most frequent cause of intracerebral mass lesions in AIDS, and chronic or recurrent infection is the result of persistence of tissue cysts.

The histology of acute toxoplasmosis is characteristic. One sees epithelial granulomas with central ''stellate necrosis'' and an influx of monocytoid lymphocytes. Tachyzoites, especially in an extracellular location, may be observed with a tissue Giemsa stain. They are banana-

Copyright © 2003, Mosby, Inc. All rights reserved.

shaped or crescent-shaped, with a nucleus. The encysted forms of *T. gondii* are more easily visualized; they can be seen with hematoxylin and eosin stain, but are rarely present in lymph nodes.

Severe infection may be treated with pyrimethamine and sulfadiazine. Immune-competent patients require no specific therapy, as the lesion is self-limited due to the onset of cell-mediated immunity in the host.

Actinomycosis

Actinomycosis is caused by an anaerobic commensal gram-positive, filamentous, branching bacterium, *Actinomyces israelli*, and may result in oropharyngeal and locoregional draining infections. *Actinomyces israelii* is normally present in tonsillar crypts and around teeth, especially those with caries. Antecedent trauma or other precursors are necessary predisposing factors for invasive infection. The three common sites of *Actinomyces* infections are cervicofacial, thoracic, and abdominal. The most common form is cervicofacial infection. Soft-tissue abscesses and draining cervical fistulas develop as a result of secondary actinomyces infection of periapical abscesses. Actinomycosis can also present as a neck mass without the characteristic sinuses. Sinus tracts may occasionally become very extensive, creeping into the soft tissues of the back and chest. Parotid and submandibular lymph nodes may become secondarily infected via sinus tract extension of chronic mandibular infection.[60] The surrounding soft tissues have an inflammatory infiltrate; thus, a parotid infection may extend into the masticator space. Rarely, the disease can spread to the parotid in a retrograde manner from the oral cavity. Parotid disease can be acute, presenting with pain, swelling, abscess, and fistula formation. The presentation of chronic parotid infection is similar to that of TB, manifesting as a painless parotid mass.

The pale yellow ‘‘sulfur granules’’ or grains observed clinically represent microcolonies of bacilli. On hematoxylin and eosin stain, one sees only blue amorphous masses;

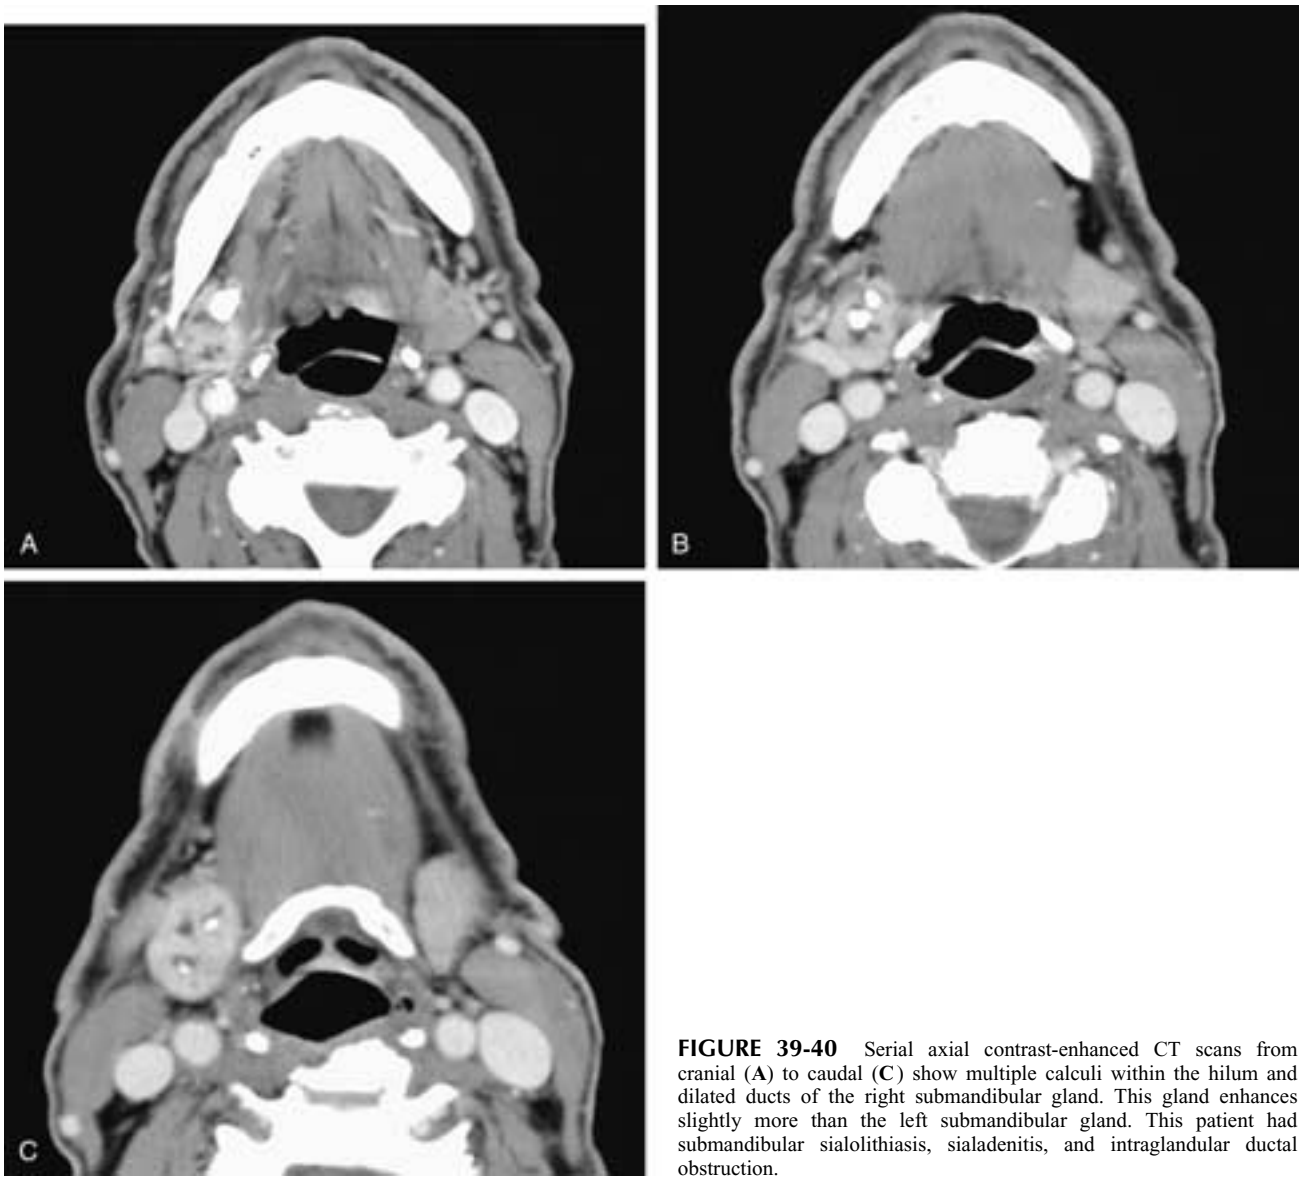


FIGURE 39-40 Serial axial contrast-enhanced CT scans from cranial (**A**) to caudal (**C**) show multiple calculi within the hilum and dilated ducts of the right submandibular gland. This gland enhances slightly more than the left submandibular gland. This patient had submandibular sialolithiasis, sialadenitis, and intraglandular ductal obstruction.

the slender, filamentous nature of these bacilli is apparent on Brown and Brenn stain or Gomori methenamine silver stain. The filaments have a club-shaped or ''beaded'' end. The diagnosis of actinomycosis is confirmed by anaerobic culture.

Sarcoidosis

Sarcoidosis is a systemic disease of presumed infectious etiology characterized by noncaseating granulomas involving multiple organ systems. The exact agent of sarcoid is unknown, but existing data implicate an L-form of mycobacteria. The parotid glands are affected in 10% to 30% of patients, and in some cases the parotid disease may be the initial and only manifestation of the disease. Usually in such patients, a careful medical history will indicate that there was prior pulmonary disease, albeit presently quiescent. In 83% of these patients bilateral parotid gland enlargement is present, and there is decreased salivary flow. In some patients, involvement of the minor salivary glands can cause xerostomia.[60, 126] In most patients, a nontender, nonpainful, chronic enlargement of the gland occurs. The gland is often multinodular and clinically may mimic a malignancy.

The parotid glands can also be involved in patients with sarcoidosis who have uveitis and facial nerve paralysis. This triad of findings is called *Heerfordt's syndrome*.

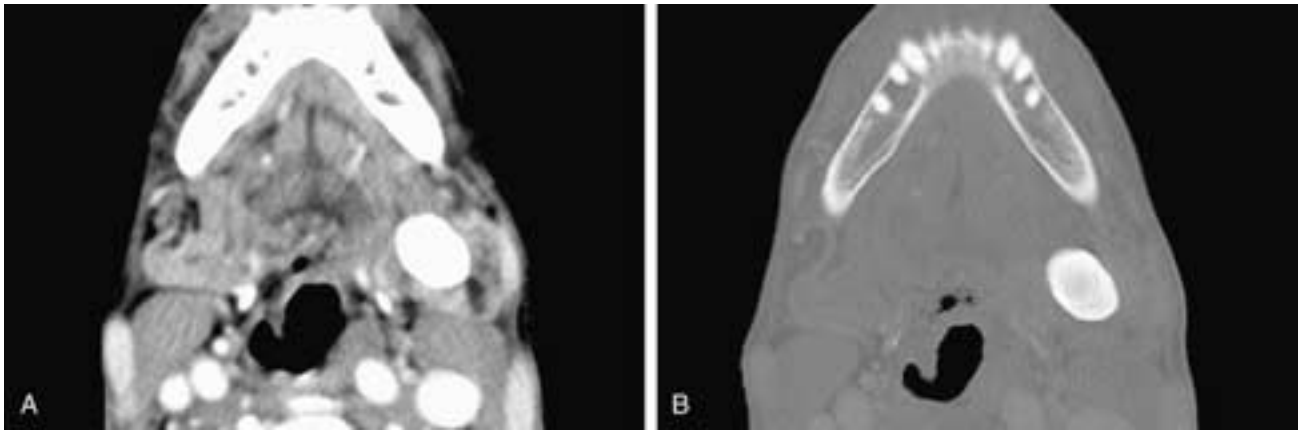

FIGURE 39-42 Axial CT scans viewed at narrow (**A**) and wide (**B**) windows show a large laminated calculus in the hilum of the left submandibular gland. There is some intraglandular ductal dilatation. This patient had submandibular sialolithiasis and early sialadenitis.

Importantly, one should not confuse parotid fullness or a mass and an ipsilateral facial nerve paralysis with a parotid gland malignancy. Most cases of such salivary gland sarcoidosis usually resolve as the underlying disease is treated.

On CT or MR imaging the parotid granulomas are usually multiple, benign-appearing, noncavitating masses. In fact, these nodes are frequently described radiographically as being ''foamy'' in appearance. This appearance most often is associated with adjacent cervical adenopathy (Figs. 39-43 and 39-44). In this circumstance, the diagnosis can be suggested on the basis of the radiologic findings. The main differential diagnosis is lymphoma. However, if the sarcoid granuloma is a solitary parotid mass, it cannot be differentiated from the other benign-appearing parotid lesions. Occasionally, small interstitial sarcoid granulomas may occur within the parotid gland. These are usually subclinical and are discovered incidentally if surgery is performed for other reasons. At present, they cannot be diagnosed reliably on either CT or MR imaging.

Other Causes: "Iodine Mumps"

A case of iodine mumps after a CT examination with 100 ml iopamidol was reported in a 70-year-old woman with a history of right nephrectomy due to right renal cancer. Three hours after the CT study, she complained of nausea, vomiting, facial flushing, bilateral jaw pain, and fever. The laboratory findings 12 hours after CT showed an increased white blood cell count and elevated serum amylase enzymes, 86% of which originated from the salivary glands. Her symptoms continued for 4 days, with decreasing severity.[127]

Sialolithiasis

Between 80% and 90% of salivary gland stones occur in the submandibular gland, 10% to 20% occur in the parotid glands, and only 1% to 7% occur in the sublingual glands.[8, 60] Minor salivary gland calculi are rare, occurring most often in the upper lip and buccal mucosa.[21] About 75% of stones are solitary; however, about 25% of patients with one stone have multiple stones, with 32% of parotid calculi and 22% of submandibular stones being multiple. Bilateral salivary stones are rare (2.2%).[60, 62] In patients with chronic sialoadenitis, at least one calculus is present in two thirds of the cases, and 80% of submandibular stones and 60% of parotid stones are radiopaque on plain films.[12]

Some of the reasons given for the increased incidence of sialolithiasis in the submandibular gland compared to the parotid gland include the thicker, more mucous nature of submandibular gland secretions; their more alkaline pH, which helps precipitate salts; the higher concentration of hydroxyapatite and phosphatase; the narrower orifice of Wharton's duct compared to the caliber of the duct itself; and the uphill grade in the erect position of Wharton's duct.[8, 12, 60, 112]

About 85% of submandibular gland stones occur within Wharton's duct: 30% near the duct's ostium, 20% in the middle portion of the duct, 35% at the bend in the duct as it goes around the back of the mylohyoid muscle, and only 15% in the hilum and gland proper (see Figs. 39-11, 39-37 to 39-42).[60, 128] Symptomatic parotid gland stones occur primarily in Stensen's duct; however, incidental asymptomatic, small intraparotid ductal calculi are not uncommonly seen on CT scans (Figs. 39-31 to 39-36).

Sialoliths in Wharton's duct are diagnosed after longer symptomatic periods than those stones in Stensen's duct (up to 1 year versus up to 2 months, respectively). This is

Copyright © 2003, Mosby, Inc. All rights reserved.

because Wharton's duct can accommodate to the obstruction, and saliva will still flow due to the wide duct width and the presence of ductal pseudodiverticula. If the stone causes a ball-valve effect, the patient has intermittent obstruction and glandular swelling, usually at times of increased salivation. Larger stones may cause complete obstruction with an initial prolonged glandular swelling that, if left untreated, may eventually result in glandular atrophy. Stasis may result in a secondary bacterial infection. Rarely, a giant intraparotid calculus has been reported in a patient with recurrent parotitis.[129]

Gout is the only systemic disease known to cause salivary calculi, which are composed of uric acid. The majority of routine salivary calculi are composed primarily of calcium phosphate, with small amounts of magnesium, ammonium, and carbonate in a carbohydrate and amino acid organic matrix.

The initial radiographic investigation of sialolithiasis is the plain film examination. Larger, well-calcified stones are clearly seen with this technique (Figs. 39-10 and 39-11); however, small or partially calcified stones may elude detection. It is estimated that about 20% of submandibular gland stones and 40% of parotid gland stones are unseen on routine plain films.[112] Because CT has a 10-fold increased sensitivity compared to plain films in detecting focal calcium deposits, noncontrast CT scans can identify most of the stones that are unobserved on the plain film examination. Such small, faintly calcified stones may also be obscured on a sialogram and may be undiagnosed unless a plain scout film or a CT scan was obtained prior to the introduction of sialographic contrast medium. Noncalcified stones are best seen on a sialogram; however, some of the larger ones can also be identified on postcontrast CT scans (see Fig. 39-36A).

A stricture of a major salivary gland duct can occur secondary to a calculus, with or without associated recurrent infection. Less often, trauma or ill-fitting dentures can cause a stricture near the duct orifice or along the course of the duct. Whatever the cause, if there is significant obstruction to salivary flow, recurrent or chronic bacterial infection results. Treatment is either by periodic dilatation, surgical repair if the stricture is near the oral cavity, or a partial parotidectomy or submandibular gland resection if the stricture is closer to the hilum of the gland.[112] If salivary flow is completely obstructed, glandular atrophy eventually occurs. If incomplete obstruction occurs, the gland usually continues to produce saliva and a glandular mucocele may develop.

A Küttner tumor is a palpably enlarged, firm mass of the submandibular gland that results from chronic inflammation. One third of these cases are due to sialolithiasis; other cases may be autoimmune or idiopathic in origin.

A cavernous hemangioma in the submandibular gland was reported that clinically and radiologically (both on plain radiographs and on CT) resembled salivary calculous disease. Numerous phleboliths were present in the hemangioma.[130] In most cases, phleboliths are circular, laminated, and multiple.[21]

In general, stones within the distal parotid and submandibular salivary ducts are easily removed by transoral ductotomy, while more proximal stones are usually treated by excision of the salivary gland and its duct. Since the 1980s, extracorporeal shock wave lithotripsy has been used for the treatment of renal and gallbladder stones. In the early 1990s, this technique was used to treat sialolithiasis.[131] After this treatment, clinical symptoms such as pain and swelling disappeared, and gland excision was unnecessary. However, stones larger than 10 mm have a tendency to respond incompletely. Although CT findings correlated with success in breaking up gallstones, they did not predict success in destroying salivary stones. It was concluded that sialolithiasis can be treated successfully by extracorporeal shock wave lithotripsy without adverse effects in selected patients.[132] In the opinion of some investigators, the results of this procedure are uncertain, and it has not become a modality of choice in the treatment of salivary stones.

Chronic Recurrent Sialoadenitis

Chronic recurrent sialoadenitis is characterized by recurrent diffuse or localized, painful swelling of the salivary gland. It usually is associated with an incomplete obstruction of the ductal system; however, on occasion, a nonobstructive variant is present.[112, 116] A sialogram performed during a clinically quiescent period in a patient with the obstructive form of this disease usually shows a focal narrowing (stricture) of the main duct and central ductal dilatation (sialectasia); these dilated ducts often taper rather dramatically to normal peripheral ducts (and acini). In these patients, if the obstruction in the main salivary duct can be relieved, the gland may function normally and may not require resection (Figs. 39-45 and 39-46). This is because the

FIGURE 39-45 Lateral view of a parotid sialogram shows dilatation of Stensen's duct and the central parotid ducts behind a noncalcified stone (*arrow*). Most of the peripheral ducts are not visualized, and the patient eventually required a parotidectomy because of recurrent infections after initial surgery for removal of the stone. This patient had sialadenitis, sialolithiasis, and ductal stricture.

FIGURE 39-46 Frontal view of a parotid sialogram shows a stricture (*arrow*) in the anterior portion of Stensen's duct. There is marked dilatation of Stensen's duct and the central parotid ducts behind the stricture. The peripheral ducts are almost normal. The patient did well after dilatation of the stricture site. This patient had sialodochitis, sialadenitis, and a ductal stricture.

salivary acini were not entirely destroyed despite the often considerable dilatation of the main ductal system. Alternatively, the peripheral ducts and acini may not be visualized on a technically good sialogram. In these cases, the acini are not visualized because they are compressed and destroyed by the cellular infiltrate (Figs. 39-47 to 39-50). As a result, saliva production decreases, causing further sialoadenitis. Thus, if the peripheral ducts and acini are not visualized on a technically adequate sialogram, it is unlikely that this gland will function normally, and eventually a partial gland resection will probably have to be performed.

Areas of ductal branch point narrowing may in part represent focal inflammatory changes. In addition, scattered localized globular collections of contrast material may be encountered. These represent focal abscesses. When multiple, they usually are nonuniform in size and distribution throughout the gland, a factor that distinguishes most cases from the autoimmune diseases (Figs. 39-24, 39-25, 39-49, and 39-50).

On CT, the involved gland is usually enlarged, diffusely dense, and enhancing, and there may be a few scattered areas of calcification. Surrounding fasciitis and reactive adenopathy are usually not present. On MR imaging, the gland is usually enlarged, and there is a nonhomogeneously low T1-weighted and an intermediate to high T2-weighted signal intensity. The signal intensity apparently reflects the degree of a chronic inflammatory cellular infiltrate versus the presence of associated edema fluid.

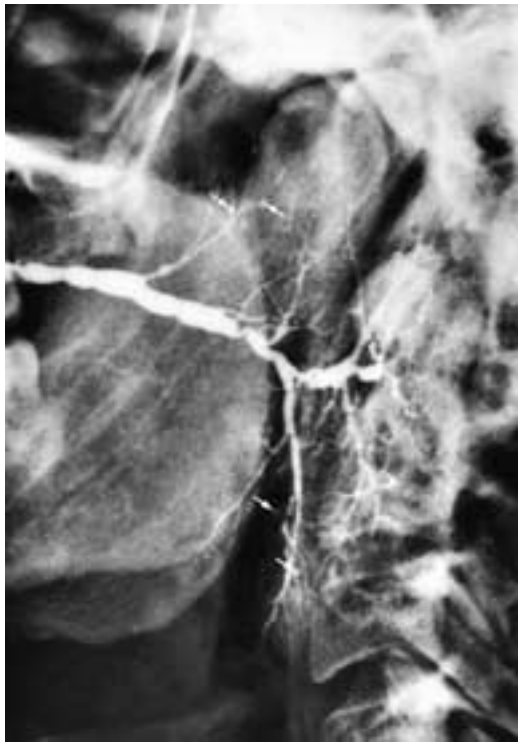

FIGURE 39-47 Lateral view of a parotid sialogram shows dilatation of Stensen's duct and the central intraparotid ducts. The peripheral ducts are not dilated. There are scattered small collections of contrast material (*arrows*), which represent small abscesses. Areas of stricture and functional spasm are also seen in the central ducts. This patient had sialadenitis.

FIGURE 39-48 Lateral view of a parotid sialogram shows mild dilatation of Stensen's duct and some of the central parotid ducts. There are areas of branch point narrowing and small abscesses (*arrows*). The majority of the peripheral ducts are visualized. This patient had chronic sialadenitis.

Sialodochitis Fibrinosa (Kussmaul's Disease)

Sialodochitis fibrinosa is an unusual disease characterized by recurrent, acute, painless or painful attacks of parotid or submandibular gland swelling secondary to a mucous or fibrinous ductal plug. The clinical appearance of this plug in either Stensen's or Wharton's duct orifice is diagnostic. This disease occurs primarily in dehydrated and debilitated patients. The treatment is glandular massage, the use of secretogogues to release the plug, ductal orifice dilatation to help prevent a recurrence, and, when clinically possible, rehydration.[112, 133]

Ductal Foreign Bodies

Ductal foreign bodies have been reported approximately 50 times in the literature. The cause in unknown, and spontaneous resolution has been reported in some cases. Most of the foreign bodies have been vegetable products such as grass seeds. The foreign body may cause chronic recurrent sialoadenitis, calculus formation about the foreign body, abscess formation, and sinus tract formation.[121]

Trauma

Blunt trauma injuries occur mainly in the parotid gland and result in edema, contusions, hemorrhage, and/or hematoma. Such injury is uncommon to the submandibular glands and sublingual glands, presumably due to the protection of the mandible.[21] Penetrating injuries may result

Copyright © 2003, Mosby, Inc. All rights reserved.

in laceration of Stensen's duct, the parotid parenchyma, and/or the facial nerve.

Stenosis of Stensen's duct orifice can occur as a result of repeated cheek biting or ill-fitting dentures, or secondary to epithelial injury from either stones or surgical manipulation. Injury to the gland parenchyma can also result in either a parenchymal laceration or an intracapsular hematoma. Calcification of such intraparenchymal hemorrhage can occur.[60]

Autoimmune Diseases (Including Benign Lymphoepithelial Lesion)

Sjogren's syndrome (SS) is a systemic autoimmune disorder of the exocrine glands that occurs either alone (referred to as *primary Sjogren's syndrome*) or with any of several connective tissue diseases (referred to as *secondary Sjogren's syndrome*). Traditionally, the diagnosis is established when two or more of the following clinical hallmarks are present: keratoconjunctivitis sicca, xerostomia, and/or a connective tissue disease, usually rheumatoid arthritis.[133] Patients complain of oral dryness, difficulty in swallowing food, oral soreness and intraoral ulcers, decreased ability to taste foods, severe dental problems, ''grittiness'' in the eyes, and inability to cry. The autoimmune diseases represent a diffuse exocrinopathy that primarily affects the lacrimal and salivary glands. However, other exocrine glands can also be involved. Thus, clinically, the exocrine involvement may cause not only dryness of the eyes and mouth, but also bronchial dryness (tracheobronchitis with a nonproductive cough), dry skin (itching), esophageal dryness (dysphagia), and genital dryness (atrophic vaginitis with burning and/or dyspareunia). Involvement of the glands of the gastrointestinal tract also occurs but is less frequent.[134, 135] Often the involvement of these other exocrine gland systems is histologically present but not clinically apparent.[128]

In the late nineteenth century, Mikulicz described the clinical findings in a Prussian farmer who presented with symmetric enlargement of all of his major salivary glands and his lacrimal glands, which was most likely of autoimmune etiology. Soon afterward, a similar clinical entity was observed in children and became known as recurrent parotitis in children. In the late 1930s, the term *Mikulicz's syndrome* was introduced to describe patients who presented with what clinically appeared to be Mikulicz's disease but who actually had another disease such as lymphoma, TB, or sarcoidosis. Unfortunately because of the overlapping terminology, confusion ensued between what comprised Mikulicz's disease and Mikulicz's syndrome, and this eventually lead to the complete elimination of the name Mikulicz. The term *sicca syndrome* temporarily replaced *Mikulicz's disease*. Currently, the term that refers to autoimmune disease limited to the salivary and/or lacrimal glands is primary Sjogren's syndrome.[134–136]

SS is the result of a lymphocyte-mediated destruction of exocrine glands that causes decreased secretions and dryness. SS is often associated with extrasalivary manifestations. In a study of 114 patients with SS, 42% had articular manifestations, 35% had neurologic manifestations, 21% had pulmonary involvement, and 13% had hepatic manifestations.[137] The pulmonary invasion leads to an intense lymphocytic infiltration, diffuse interstitial pneumonitis, fibrosis, or restrictive lung disease.[138] Eleven of these patients (9%) also developed vasculitis associated with hepatitis C infection, and three (2%) developed lymphoproliferative disorder. Involvement of the central nervous system is typified by polyneuropathy and/or mononeuritis multiplex.

Histologically, SS is characterized by periductal lymphocytic aggregates that extend into and destroy the salivary acinar parenchyma. The lymphocytes are mainly (CD45RO+) CD4-positive T lymphocytes. As the inflammation progresses, ectopic germinal centers are seen. When SS involves the major salivary glands, most often the parotid gland, the lymphoid infiltrate produces a localized parenchymal mass referred to as a benign lymphoepithelial lesion (BLEL) or Godwin's tumor[135] (Fig. 39-51). The BLEL is seen as a localized lymphoid infiltrate within the major salivary glands, usually the parotid. It is composed of small lymphocytes, germinal centers, and a periductal lymphoid infiltrate. Proliferation of ductal epithelium results in the obliteration of ductal lumina and the production of epithelial (epimyoepithelial) islands, which may undergo squamous metaplasia and hyalinization. Although these islands may be few in number, their identification is necessary for a pathologic diagnosis of BLEL to be made.[134, 135] BLEL is usually solid but occasionally may have a pronounced cystic component. BLEL may present clinically in the setting of a known autoimmune disease or independently of autoimmune symptomatology.

The mechanism of SS involves altered ductal cell antigenic statement. The ductal epithelial cells are activated in SS, expressing elevated levels of human leukocyte antigen-DR (HLA-DR) and secreting high levels of proinflammatory cytokines. This results in inappropriate activation and retention of B cells within the major and minor salivary glands. Once recruited, these lymphocytes survive due to their low rate of apoptosis, which is facilitated in part by alterations in cytokine production (interleukin-2, interleukin-10, tumor necrosis factor alpha).[139]

Although no specific virus has been identified as the cause of SS, retroviruses are now believed to be involved in the induction of autoimmunity. There have been eight case reports of the combination of human T-cell lymphocytic virus type 1 (HTLV-1)–associated myelopathy, SS, and lymphocytic pneumonitis, all occurring in areas endemic for HTLV-1.[140]

The actual incidence of SS is difficult to establish because the symptoms can be nonspecific and the specific autoimmune antibodies (SS-A and SS-B) may be elevated only during active disease or not elevated at all, as in the case of antibody-negative men with SS. An autopsy study in 1957 estimated the incidence to be 1 case per 225 people. Thus, of the autoimmune diseases, SS was considered second in frequency only to rheumatoid arthritis.[134] There is a marked female predominance for SS, and the mean age of diagnosis is within the sixth decade of life.[137] However, there is a subgroup of patients diagnosed within the first two decades of life (see below).[141]

A slight male predominance has been described in some series of juvenile SS but not in other series.[141, 142] The

FIGURE 39-51 Benign lymphoepithelial lesion. **A**, Lymphoid infiltrate with a germinal center (*G*) adjacent to the parotid ducts (*D*). **B**, High-power view of one of these epithelial islands (*E*), which represent transformed ducts.

clinical picture of juvenile SS is similar to that of adults, but oral involvement is generally milder and there is an extremely high prevalence of recurrent parotitis. Most juvenile cases resolve spontaneously at puberty. Thus it is important to establish the diagnosis as early in the course of the disease as possible so that unnecessary surgery prior to puberty can be avoided. There are only a few cases of recurrent parotitis in children that have progressed to the adult form of the disease.[143]

The adult form of SS is most commonly diagnosed between the ages of 40 and 60 years. As mentioned, there is a striking female predominance (90% to 95%) and the parotid disease tends to be progressive, occasionally requiring a parotidectomy to relieve symptoms of recurrent infection.[60, 134]

Parotid gland enlargement is slightly more common in the primary form of SS than in the secondary form of the disease. The incidence of parotid enlargement has varied from 25% to 55% of cases, and either parotid or submandibular gland enlargement occurs in 80% of all patients with SS.[128]

Secondary SS occurs in 50% to 67% of all patients with SS. Most patients with the secondary form of the disease have rheumatoid arthritis. Conversely, the incidence of the sicca complex (dry eyes and mouth) in patients with rheumatoid arthritis is estimated to be 15% to 25%.[134] Other connective tissue diseases associated with secondary SS are systemic lupus erythematosus (SLE), progressive systemic sclerosis, polymyositis, polyarteritis nodosa, and mixed connective tissue disease.

Establishing the diagnosis of SS requires (1) clinical symptoms of dry eyes and dry mouth, (2) clinical confirmation of xerostomia and xerophthalmia, (3) serologic evidence of autoantibodies, and (4) histologic evidence of a minor salivary lymphocytic infiltrate. Confirmation of decreased saliva production can be assessed by unstimulated and stimulated whole saliva collection, salivary gland scintigraphy, and parotid sialography. Decreased lacrimation can be confirmed by the Schirmer's test, tear fluid lactoferrin level, and Rose Bengal score.[144] Serologic elevation of antinuclear antibodies can be seen in 50% to 70% of the patients—specifically, SS-A and SS-B antibodies in patients with either active SS or SLE. Up to 70% to 80% of SS patients have high titers of serum antibodies against the RO (60 kd and 52 kd) and LA (48 kd) ribonucleoproteins. Thus the absence of both of these antinuclear antibodies excludes the diagnosis of SS. A notable exception occurs in men with primary SS; they have a strong tendency to be seronegative for rheumatoid factor, SS-A, and SS-B (78%, 91%, and 94%, respectively).[145] Furthermore, patients who are SS-A positive are more likely to have parotid gland enlargement, vasculitis, and a serologic profile that suggests an exaggerated immune response. Patients with primary SS tend to have the haptotypes HLA-B8 and HLA-DRW3, while patients with secondary SS do not have an association with these antigens but are associated with HLA-DRW4, an antigen found in patients with rheumatoid disease.[128] Phenotypic characterization of the glandular infiltrative lymphocytes in SS shows a predominance of CD4-positive T cells. Biopsy of the labial minor salivary glands is also considered a useful diagnostic test of SS (positive in about 60% of cases), and this procedure is usually performed in consort with the antinuclear antibody studies. However, some reports suggest that incisional biopsies of the superficial lobe of the parotid gland are more diagnostic and have less morbidity than incisional labial biopsy.[126, 134–136, 142, 143, 145, 146]

The clinical presentations of patients with SS and parotid gland involvement vary from recurrent acute episodes of tender glandular swelling, to chronic glandular enlargement with superimposed acute attacks, to nontender, nonpainful glandular enlargement.[128] Although the gland is usually diffusely affected, in some patients a localized area may be more involved, clinically simulating a solitary mass. If accessory parotid glands are present, they can also be affected by SS, and they present as a mass in the cheek. If surgery is performed for the BLEL tumor, the surgeon should be aware of the possibility of a recurrent mass involving the ipsilateral, contralateral, or accessory glands. Submandibular gland enlargement is less common than parotid gland enlargement, with a clinical incidence

Copyright © 2003, Mosby, Inc. All rights reserved.

varying between 2.5% and 16% of cases with parotid gland disease.

The risk of developing non-Hodgkin's lymphoma in the setting of SS is estimated to be about 44 times greater in patients with SS than in control subjects. The tendency is to develop lymphoma in extraparotid as well as intraparotid sites.[128, 135, 143] Clinical findings associated with the development of lymphoma include parotid gland enlargement, lymphadenopathy, and splenomegaly. Local irradiation or immunosuppression (either secondary to therapy or a primary disease) further increases the risk of developing lymphoma. Lymphoma development is related to a malignant transformation in the autoreactive B-cell clonal expansion.[60, 128, 143] Loss of immunoregulation and prolonged B-cell clonal expansion promote this transformation. Gene rearrangement studies reveal that clonal rearrangements are common to the precursor benign lymphoepithelial lesions, indicating a prelymphomatous state.[60, 134, 147]

Lymphomas developing in SS are classified as MALT (mucosa-associated lymphoid tissue) lymphomas, which can be further subclassified as either low- or high-grade. The majority of these lymphomas are extranodal (78.8%), most often involving the salivary glands (54.6%). Associated lymphadenopathy (65.6%), skin vasculitis (33.3%), peripheral nerve involvement (24.2%), low-grade fever (25.0%), anemia (48.1%), and lymphopenia (78.6%) are more common in these patients than in the general SS patient population.[148–150]

Because SS initially involves the most peripheral intraglandular ducts and acini, in the initial stages of the disease the sialogram shows a normal central ductal system and numerous peripheral punctate (1 mm or less in diameter) collections of contrast material scattered uniformly throughout the gland. These punctate changes are the earliest sialographic findings that are diagnostic of SS (Figs. 39-52 to 39-55). On a sialogram, larger or globular collections of contrast material may also be seen scattered uniformly throughout the gland. This may represent a progression from the punctate appearance of the disease (Figs. 39-52 and 39-54). These sialographic appearances have been referred to as looking like a ''leafless fruit-laden tree'' or a ''mulberry tree.'' Once the disease has progressed to the point where there is sufficient acinar destruction, salivary production decreases and ascending infection develops. Sialographically, this is seen as dilatation of the central ducts, with the other associated changes of sialoadenitis superimposed on the punctate or globular findings of SS (Figs. 39-56 and 39-57). Thus the so-called cavitary and destructive forms of SS represent progressive inflammatory changes in the gland that eventually result in large peripheral collections of contrast material combined with the central changes of sialodochitis and sialoadenitis. This process finally leads to abscess formation that usually involves the entire gland (Fig. 39-58).[52]

If a secretogogue is given at the end of the sialogram, the contrast material drains from the main ducts but remains within the punctate and globular collections (Fig. 39-53B). The sialographic changes of SS described above are sufficiently specific that they allow the sialographer to differentiate cases of SS from those of sialosis and from most cases of chronic sialoadenitis. Occasionally, patients with a chronic bacterial or granulomatous infection can develop multiple abscesses within the parotid gland (Figs. 39-25, 39-49 and 39-50). These collections tend to vary in size and are not usually distributed uniformly throughout the gland. By comparison, the collections associated with SS tend to be uniform in size and uniformly distributed throughout the gland.[52, 151, 152]

On both CT and MR in the earliest stages of SS, the involved glands appear normal. This is a limitation of sectional imaging in these patients. As the disease progresses, glandular enlargement occurs, and on CT the gland is denser than normal. The appearance is similar to that seen in patients with either chronic sialoadenitis or sialosis (Fig. 39-59). If a prior sialogram was performed with fat-soluble contrast material, the retained droplets of contrast in the punctate and globular glandular collections will be seen on CT for many years after the initial sialogram was done (Fig. 39-60). As the parotid disease continues to progress, on CT a honeycomb glandular appearance develops. This CT appearance was once thought to be diagnostic of SS; however, other granulomatous diseases and even chronic sialoadenitis can also produce similar CT findings. On MR imaging, once globular changes are present within the parotid glands, these collections can be seen on T1-weighted scans as discrete collections of low signal intensity, reflecting the watery saliva contained within them (Fig. 39-61). This MR

appearance is diagnostic of SS. However, the development of lymphoma in BLEL has no characteristic imaging appearance.

A study analyzed the fat deposition in the parotid and submandibular glands of 33 patients with SS by using short inversion time inversion recovery (STIR) and fat-saturation MR sequences and CT. All three in vivo techniques substantially confirmed premature deposition of fat in the major salivary glands in association with SS. Furthermore, this change was characteristic of SS, and the severity of fat deposition correlated well with the impaired rates of salivary flow in these patients. It was concluded that monitoring of fat deposition might be useful in diagnosing SS and

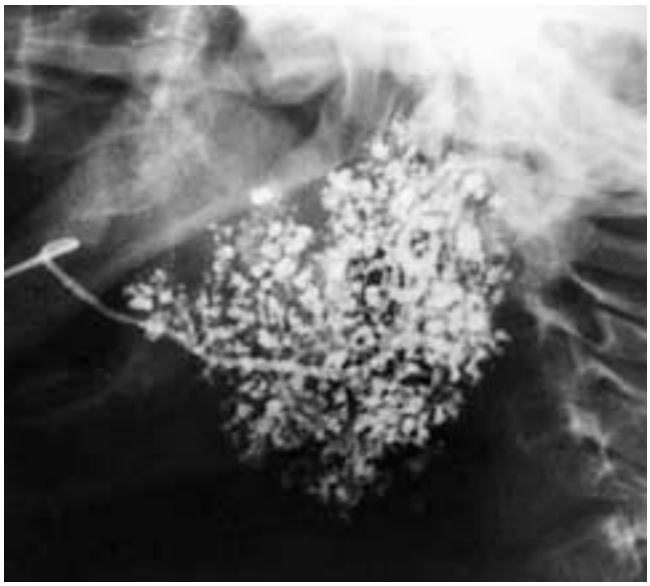

FIGURE 39-54 Lateral oblique view of a parotid sialogram shows larger globular collections of contrast material that are fairly uniform in size and distribution throughout the gland. The central ductal system is normal. This patient had autoimmune disease.

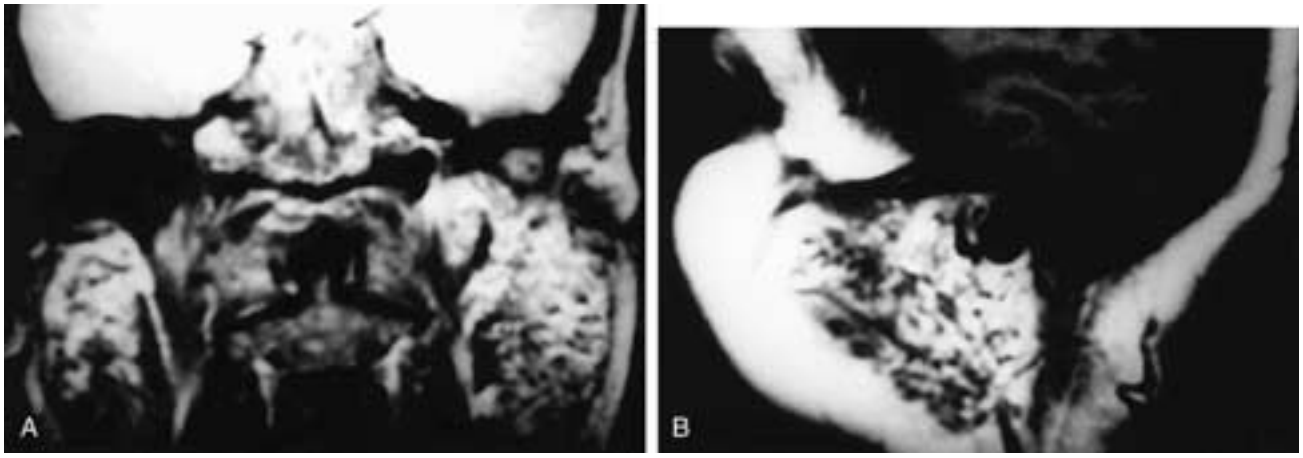
assessing its progress in patients whose clinical and serologic findings are suggestive of the disease.[153]

MR sialography was discussed earlier. This technique has specifically been applied to SS (Fig. 39-62). Gradient and spin-echo MR sialography was performed with a 1.5-T system, and the MR sialographic findings were compared with conventional sialographic findings. In 89% of the patients, the stage of salivary gland disease determined with MR sialography accurately correlated with that determined with conventional sialography. Both the sensitivity and the specificity of MR sialography in the diagnosis of SS were 100%.[154] In another study, MR sialography was performed on a 1.5-T unit with a neck phased-array coil. MR sialographic source images were obtained using a heavily T2-weighted, fast spin-echo sequence with spectral fat suppression. All images were analyzed on the basis of maximum intensity projection reconstruction. In patients with SS, a punctate, globular, cavitary, or destructive appearance was well seen within the parotid glands. Findings obtained at MR sialography correlated well with the results of labial gland biopsy.[155]



VIEW IMAGE

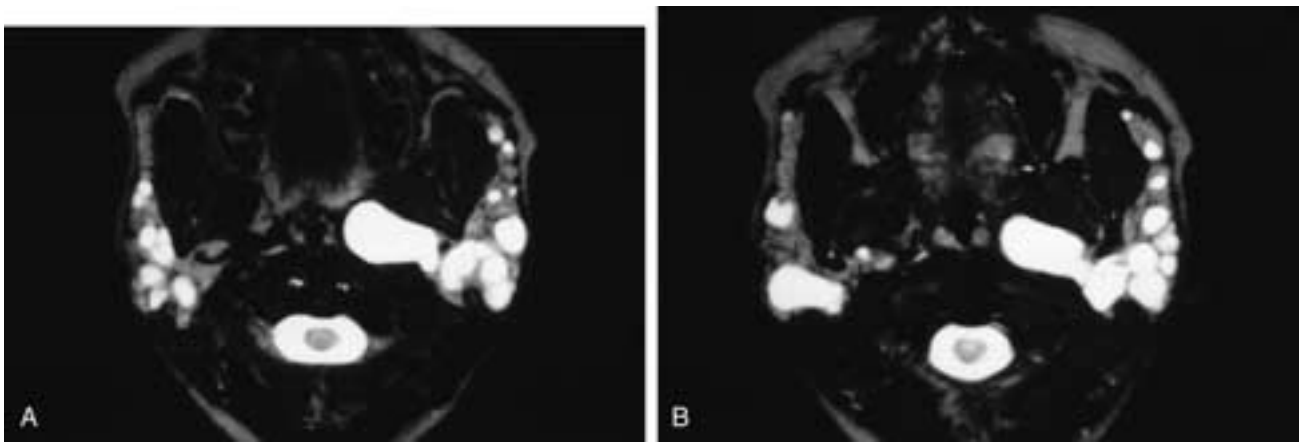
VIEW IMAGE

FIGURE 39-63 Axial contrast-enhanced CT scans (**A**, **B**) show multiple bilateral parotid cysts of varying size. The parotid parenchyma is denser than normal, and the parotid glands are slightly enlarged. This patient had end-stage cystic changes of autoimmune disease (SS).

Rarely, diffuse, bilateral macroscopic cystic change within the BLEL can develop. The cysts can vary from a few millimeters to several centimeters in diameter. When this occurs, the CT and MR appearances in the parotid gland are similar to that of the lymphoepithelial cysts associated with HIV infection (Figs. 39-63 and 39-64). The distinguishing feature is that in the autoimmune disease there is no diffuse cervical adenopathy, while such lymph node enlargement is part of the HIV disease process (especially in patients who have not yet received treatment).

Sicca syndrome can also occur in other conditions not necessarily associated with other clinical and serologic manifestations of SS. Symptomatic xerostomia and xerophthalmia can occur with viral infections [HIV and hepatitis C virus (HCV)], sialosis, sarcoidosis, amyloidosis, primary biliary cirrhosis, and graft-versus-host disease.[134, 156, 157] A recent report on 35 patients with chronic HCV infection and documented SS (SS-HCV) revealed some distinctions when compared with 60 patients with primary SS and negative HCV serology. Parotidomegaly was less common in the SS-HCV group; elevated anti-parietal cell gastric antibodies, antimitochondrial antibodies, and cryoglobulins, plus hypocomplementemia and a lower prevalence of anti-Ro/SS-A, were more common to the SS-HCV group.[158]

Diffuse infiltrative lymphocytosis syndrome (DILS) occurs in patients who are HIV positive. The patients have parotid gland enlargement, and only a few have xerostomia and keratoconjunctivitis sicca. As discussed, lymphoepithelial parotid cysts may be present. Minor salivary gland labial biopsies may show at least 50 lymphocytes per 4 mm^2 of tissue, a grade 4 positive biopsy for SS according to the Mason and Chisholm criteria.[143] Phenotypic characterization of the glandular infiltrative lymphocytes shows a predominance of CD8-positive T cells. Extraglandular manifestations of DILS include generalized lymphadenopathy, lymphocytic interstitial pneumonitis, and, less often, lymphocytic hepatitis, gastritis, nephritis, and neurologic involvement. HIV infection also produces a sicca syndrome and has a CD8 phenotype in the lymphocytic infiltration.



VIEW IMAGE

Chronic graft-versus-host disease can produce a sicca syndrome and has associated extraglandular manifestations that are primarily cutaneous, gastrointestinal, and pulmonary. The phenotype of the infiltrative lymphocyte is CD8; however, there are no related autoantibodies or HLA associations.[159] These instances indicate that in atypical cases of apparent SS, further immune testing may lead to the proper diagnosis and thus to appropriate treatment.

SLE is a disease that may affect a number of organ systems, particularly the joints, skin, kidneys, heart, lungs, and immune system. Salivary gland involvement is usually associated with SS, in which lymphocytic acinar infiltrates predominate histologically. A case was presented of a 29-year-old woman with SLE who developed bilateral parotid gland enlargement with a unilateral focus of parotid necrosis that was consistent with a cystic mass on CT. A biopsy specimen from this lesion was histologically similar to a cervical lymph node biopsy specimen from the same patient, with both specimens showing loss of architecture and foci of necrosis consisting of nuclear dust, histiocytes, and scattered plasma cells without formation of granulomas or the presence of multinucleated giant cells; these findings are classic for SLE lymphadenopathy. This was believed to be the first reported case of focal necrosis in the parotid gland directly associated with SLE.[160]

Hyperlipidemia

Hyperlipidemia is characterized by elevated levels of plasma triglycerides and/or total cholesterol, especially low density lipoprotein cholesterol. Such elevations are considered risk factors for cardiovascular disease. Although some patients with hyperlipidemia can have symptoms of a sicca syndrome that clinically may mimic SS, these two diseases can be easily distinguished by other criteria. A few patients with hyperlipidemia have been reported to have parotid gland enlargement. In these patients, there is extensive uniform lipid infiltration of the parotid glands that can be well seen on MR imaging. Elevated plasma triglyceride levels correlate with parotid swelling, and elevated cholesterol levels adversely affect salivary flow. The submandibular glands may also be affected, albeit to a lesser degree.[161]

Sialosis

Sialosis is a nonneoplastic, noninflammatory, nontender, chronic or recurrent enlargement of the parotid glands.[143, 146] Far less commonly, the submandibular, sublingual, and minor salivary glands can be affected.[7]

The parotid disease is usually bilateral and symmetric but can be unilateral and/or asymmetric. The onset is usually insidious, with no symptoms of inflammation. The disease may worsen or improve, depending on whether the underlying condition is treated, and resolution of the sialosis can occur in only a few days if fatty replacement of the gland has not taken place. Decreased salivary flow and/or xerostomia may or may not occur; however, these findings usually reflect the underlying disease and are not specific findings of sialosis.[126]

Sialosis is associated with a variety of endocrine diseases, nutritional states, and certain medications. Sialosis is found especially in patients with diabetes, and the parotid gland enlargement may be the first clinical evidence of the underlying disease. Sialosis has also been reported with abnormalities of the ovaries, thyroid glands, and pancreas, and it has been associated with acromegaly.[126, 128] Sialosis is found in 26% to 86% of patients with chronic alcoholism and alcoholic cirrhosis, as well as with other states of malnutrition or abnormal nutrition such as prolonged starch ingestion (Argo laundry starch), causing zymogen depletion and compensatory acinar hypertrophy, pellagra, kwashiorkor, anorexia nervosa, and bulimia.[159, 162] The term *nutritional mumps* has been coined for these conditions. Other conditions associated with sialosis include hypertension, hyperlipidemia, obesity, pregnancy, brucellosis, bacillary dysentery, Chagas' disease, esophageal carcinoma, ankylostomiasis, and celiac disease.[21]

Sialosis has also been associated with a variety of medications, including phenylbutazone, oxyphenbutazone, sulfisoxazole, iodide, isoproterenol, atropine, imipramine, chloramphenicol, oxytetracycline, phenothiazides, benzodiazepines, monoamine oxidase (MAO) inhibitors, reserpine, guanethidine, heavy metals (lead, copper, mercury), methimazole, thiocyanates, and thiourea drugs such as thiouracil and propylthiouracil. With these pharmacologic sialoses both the submandibular and parotid glands may be involved, and the glandular swelling may be painful.[126, 134, 146] Sialosis may also lead to xerostomia.[163]

Pathologically, enlargement and degranulation of the parenchymal cells and/or fatty replacement of the parenchyma can occur. Usually acinar hypertrophy with increased zymogen granulation is the predominant early finding, while fibrosis and fatty atrophy dominate the later stages of the process. The fibrosis is confined to the interlobular septa, and there is no pathologic evidence of inflammatory changes. Experimental destruction of the sympathetic nervous system has resulted in tissue changes similar to those of sialosis, and it has been suggested that degeneration of the autonomic nervous system may be the common pathologic principle in all types of sialosis.[164]

In the end stages of sialosis, lipomatosis of the parotid gland can occur. Such deposition of lipid is distinguished from a lipoma of the parotid gland by the lack of a fibrous capsule in the former condition.[15]

On sialography, the parotid gland is enlarged, and the ducts are usually normal in appearance but splayed by the increased gland volume. There may be some compression of the smaller peripheral ductal branches by the increased interstitial fibrosis and/or fat. Because these sialographic changes are sufficiently different from those of chronic sialoadenitis or SS, sialosis can be distinguished sialographically from these entities (Fig. 39-65).

On both CT and MR imaging, the parotid glands are enlarged but may appear either dense or fatty, depending on the dominant pathologic change. As such, the CT and MR imaging appearances may be similar to those seen in SS and chronic sialoadenitis (Fig. 39-66).[165]

Postirradiation Sialoadenitis

Postirradiation sialoadenitis can occur in an acute or a chronic form. The acute type is rare today and is characterized by a tender, painful swelling of the gland within 24 hours after it has been irradiated, usually by a single dose of 1000 cGy or more. These manifestations usually subside within 3 to 4 days, and there may be an associated transient xerostomia. The chronic form occurs in glands irradiated as part of a curative treatment plan, usually for oral cavity or pharyngeal tumors. Animal studies and investigations of patients receiving radiotherapy reveal that the initial response to irradiation is a reduction in salivary flow rate. The observed increase in salivary viscosity is then a result of this reduced flow rate rather than of salivary compositional alterations.[166, 167] The parotid gland is more sensitive to the effects of irradiation than is the submandibular gland. Experimentally, parotid saliva reveals a decrease in total protein concentration and amylase activity, the severity of which increases with time in a radiation dose-dependent manner. Less effect is observed for the submandibular saliva. Saliva electrolyte concentrations are flow-rate dependent, decreasing with decreasing salivary flow rate.

If a portion of the gland is spared the full tumoricidal dose, there may be some hyperplasia of the residual acini. This corresponds to the clinical observation of decreasing xerostomia, usually after 6 to 12 months.[121] After a full dose of irradiation, the gland atrophies and xerostomia occurs because of direct effects on both the major and minor salivary glands. A sialogram shows patchy areas of lack of acinar filling and focal areas of ductal pruning. Sectional imaging shows a usually smaller than normal cellular and fibrotic gland that is dense on CT and that can enhance after contrast administration. On MR imaging, the glands usually have low to intermediate signal intensity on all imaging sequences. External irradiation is a tumor promoter, with an increased incidence of benign and malignant salivary tumors as a late sequela (10 to 25 years) in children who were irradiated for nonmalignant conditions.[134, 168]

It has been suggested that partial parotid gland sparing is feasible by using three-dimensional planning in patients undergoing bilateral head and neck irradiation. Approximately 50% of the saliva flow from the spared glands may be retained, and most of these patients have no or mild xerostomia in the early period after the completion of radiation treatment. Whether tumor control and late complications are comparable to those of standard irradiation will be assessed as more experience is gained.[169]

Necrotizing Sialometaplasia

Necrotizing sialometaplasia is a benign, self-limiting disorder that can be mistaken for a malignancy. This entity is found three times more commonly in males than in females, and most patients are over the age of 40 years. It usually involves the mucoserous glands of the hard palate, although it can arise in any salivary gland tissue including the major salivary glands. Most often there is a painless, round, deep ulcer in the palate. Less commonly, the ulcers can be linear and multiple. The process probably is reparative secondary to ischemic necrosis of the minor salivary gland tissue.[7] In the major salivary glands, the lesion appears as a consequence of focal lobular sialoadenitis. The lesion(s) heals slowly but spontaneously over a 6- to 10-week period. It can occur in two forms: (1) as a spontaneous mucosal ulcer, usually of the palate, or (2) as a reaction to injury to the minor salivary gland tissue of the oral cavity, nasal fossae, or larynx, or to a major salivary gland.[21] Necrotizing sialometaplasia is associated with squamous metaplasia as part of the regenerative process. Because it is an unfamiliar lesion to the general surgical pathologist, it may be misdiagnosed as either squamous cell carcinoma or mucoepidermoid carcinoma. On imaging, a nonspecific soft-tissue mass may be seen in the palate, without any associated bone erosion.

Adenomatoid Hyperplasia of Mucous Salivary Glands

Adenomatoid hyperplasia of mucous salivary glands is a rare entity that arises as a nonulcerated, asymptomatic, tumor-like sessile mass or swelling. The majority of cases occur on the palate, but other intraoral sites (e.g., the retromolar trigone) are occasionally affected. The condition is usually mistaken for a salivary gland neoplasm or fibroma. The overlying mucosa may appear normal or slightly blue. The etiology of this lesion has remained idiopathic, although it has been suggested that chronic local trauma may be an important factor in its development. Microscopically, adenomatoid hyperplasia appears as a predominance of lobules of normal mucinous acini coalescing with the lamina propia and submucosa. These lesions are well circumscibed but unencapsulated. Treatment is simple excision; recurrence has not been reported.[7, 170] Such masses are usually biopsied and excised without any imaging procedures.

Cystic Processes

Salivary gland cysts can be classified according to their site (major salivary versus minor salivary). Major salivary cysts can be subclassified as developmental (branchial cleft, lymphoepithelial, or dermoid) versus ductal (sialocyst, ranula). Minor salivary cysts are mucoceles. Additionally, various tumor-like entities, such as AIDS-related parotid cysts (benign lymphoepithelial cysts), can have a major cystic component and are discussed with acquired cysts. The clinical differential diagnosis of salivary cysts will be influenced by the patient's age. In children, an intraparotid cystic lesion may be a dermoid, an epidermoid, an inclusion cyst, a cystic hygroma (or another lymphangioma), an inflammatory cyst, a branchial cyst, or polycystic disease. In adults, most cystic masses are Warthin's tumors or AIDS-related parotid cysts (ARPC). Branchial cleft cysts, mucoceles, retention cysts, lymphangiomas, and some of the lesions of childhood may also occur in adults. Some salivary malignancies may also present as cysts. Low-grade mucoepidermoid carcinoma, the papillo-cystic variant of acinic cell carcinoma, and mucus-producing papillary adenocarcinoma are the three low-grade lesions that may also present as parotid cystic tumors.

Congenital Cysts

Developmental cysts may be present at birth but often do not become clinically evident until adulthood. They present as painless unilateral parotid swellings. Pain may be present if the cyst becomes infected; sinus tracts and fistulas to the skin and external auditory canal may coexist (Figs. 39-67 to 39-72).[7]

Lymphoepithelial Cyst

Lymphoepithelial cysts are rare lesions that historically have been erroneously termed *branchial* cysts. This terminology is misleading, since the probable origin of these lesions is from intra–lymph nodal salivary gland inclusions. This reasoning is based on the observation that the branchial apparatus normally disappears by the 45th day of intrauterine (iu) life, while the lymphatic system does not start to develop until the second month (iu), and lymph nodes cannot be recognized until after the third month (iu). According to the proponents of this theory, the presence of lymphoid tissue makes it unlikely, on a temporal basis, that the inclusions are of branchial origin. In addition, the branchial cleft theory fails to explain (1) the rare occurrence of these cysts within the parotid gland, which is not at all of branchial origin; (2) the fact that these cysts are seldom present at birth, as are branchial cysts; and (3) the observation that these cysts are rarely connected to either the external auditory canal, the pharynx, or the skin. Therefore, the term *lymphoepithelial cyst* rather than *branchial cleft cyst* was proposed.

These lesions arise in adults, presenting as painless masses. They have a predilection for men (1.6 to 2.9∶1 ratio); however, they may also have a 5∶1 female-to-male ratio for intraparotid cysts and an equal sex incidence for periparotid cysts. The average age at presentation is in the mid-forties to early fifties, with a range in several series of 13 to 81 years. Rare cases have been associated with facial paralysis. The vast majority of lymphoepithelial cysts are unilateral; however, rare patients present with bilateral involvement. The cysts can measure up to 6 cm in diameter (average, 2.5 cm) and generally occur within and around the parotid gland.

Grossly, the cysts are well circumscribed and predominantly unilocular; a multilocular presentation is unusual. The cyst content is variable, ranging from fluid to mucoid to yellow-white and caseous in appearance. The luminal surface is frequently granular. Microscopically, the typical lesion is an encapsulated, smooth-walled cyst, free of internal papillae, lined by stratified squamous epithelium, although cuboidal, columnar, mucous, and sebaceous cells may be present. The cyst wall exhibits dense lymphoid tissue composed of small lymphocytes, plasma cells,

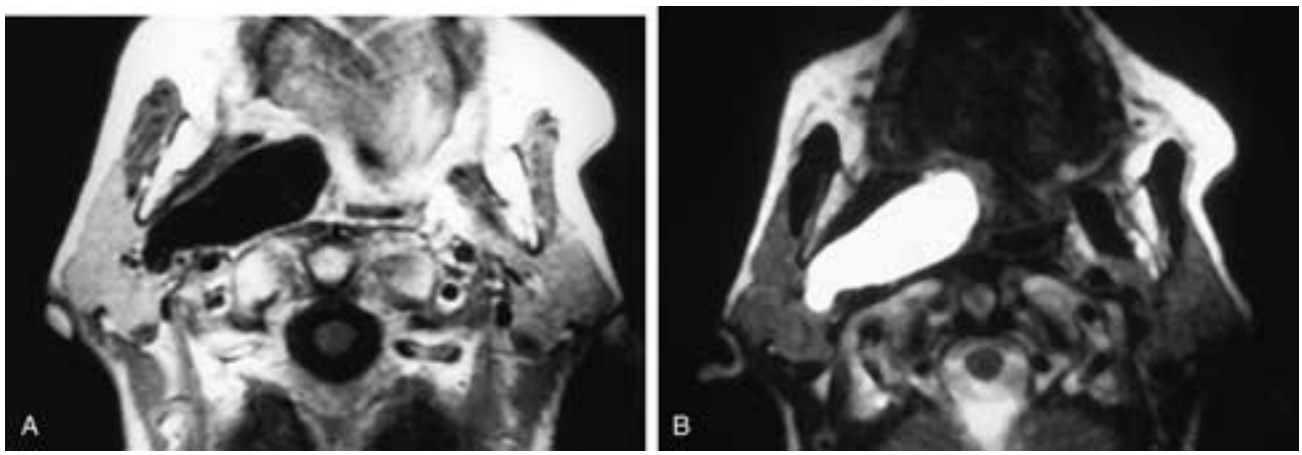
germinal centers, and a surrounding thick band of collagen. The nodal origin of the lesion can frequently be demonstrated by the persistence of subcapsular and/or medullary sinusoids (Figs. 39-73 to 39-77).

True Branchial Cleft Cyst

True branchial cleft cysts within the major glands are rare. Remnants of the first branchial groove, and presenting within and adjacent to the parotid gland, they comprise less than 5% of all branchial anomalies (see Chapter 35). Clinical correlation is necessary to make this diagnosis. When such a cyst has a fistulous connection in or around the external auditory canal, its origin from the first branchial cleft is clear. First branchial cleft cysts are classified as either type I or type II. Type I cysts are related only to the membranous external auditory canal, while type II cysts occur primarily near the angle of the mandible, and any tract extends through the parotid gland toward the membranous and cartilaginous external auditory canals. These cysts usually occur in the preauricular region of the parotid gland and can vary from 1 to 7 cm in diameter. Histologically, they are lined by squamous epithelium, ciliated columnar epithelium, or a mixture of both. Most of these cysts contain both skin appendages and cartilage, a feature not seen in lymphoepithelial cysts (Figs. 39-67 to 39-71).[7, 52]

Second branchial cleft anomalies usually occur along the anterior border of the sternocleidomastoid muscle, and any tract courses between the internal and external carotid



VIEW IMAGE

arteries heading toward the palatine tonsil. Occasionally, cysts occurring in the lower pole of the parotid gland are classified as being of second branchial origin, although without a demonstrable tract, this origin is of questionable validity.

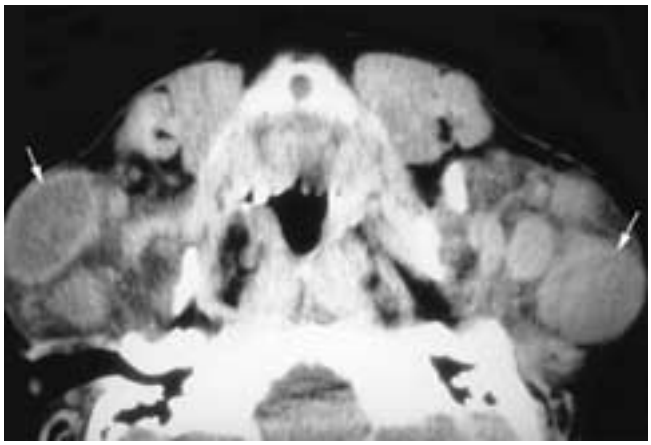

FIGURE 39-72 Axial CT scan shows multiple bilateral parotid masses and cervical lymphadenopathy in a patient with sarcoidosis. On either side, there is a solitary cyst (*arrows*) that developed several years after the appearance of the multiple sarcoid granulomas. At biopsy these were found to be lymphoepithelial cysts in a patient with long-standing sarcoidosis.

VIEW IMAGE

Epidermoid Inclusion Cyst

Rarely, epidermoid or dermoid cysts also occur within or adjacent to the major salivary glands. In the head and neck, dermoid cysts generally occur in the midline nose, the orbit, or the midline floor of the mouth. Distinction from an epidermoid cyst is based on the presence of skin adnexa in a dermoid cyst. The midline location and the lack of a lymphoid infiltrate, moreover, aid in distinguishing dermoid cysts from branchial cleft remnants.

Polycystic (Dysgenetic) Disease

Polycystic (dysgenetic) disease is a developmental abnormality of the salivary gland duct system that has histologic similarity to polycystic disease of the kidney. Extraordinarily rare, its incidence is 0.02% to 0.06% of large salivary series. Seventeen cases have been reported to date, 16 in the parotid gland and 1 in the submandibular gland. There is a pronounced female predominance, with an age range from 6 to 65 years. Most patients have bilateral involvement; however, occasionally a single gland is involved. Patients typically present with recurrent, painless swelling of the affected gland, with no abnormality of salivary flow. Sialography exhibits multicystic ductal changes.

Microscopically, the parotid parenchyma is replaced by varying degrees of honeycombed cystic change. The cysts are of variable size, but are usually no more than several

millimeters in diameter, and are lined with a flat, cuboidal, and/or columnar epithelium. The cysts may be filled by inspissated proteinaceous secretions and eosinophilic bodies with concentric radial patterns similar to those of spheroliths and microliths. This cystic process may affect ectopic salivary gland tissue in cervical lymph nodes; therefore, involvement of cervical nodes should not be construed as evidence of a malignancy. Polycystic disease is a completely benign process. It may be necessary to remove the involved glands surgically for cosmetic reasons or to establish the diagnosis.[171, 172]

Congenital Sialectasis and Merkel's Cyst

Congenital sialectasis is a rare unilateral or bilateral cystic condition arising in children and adults. It accounts for 1.4% of nonneoplastic salivary gland cysts. Histologically, the salivary ducts are dilated with inspissated secretions. If there is no secondary sialadenitis, then the histology will support a congenital process. However, patients with congenital sialectasis eventually develop recurrent sialadenitis; thus, the histology will appear identical to that of acquired duct ectasia. Merkel's cysts are developmental simple cysts of the submandibular gland.

In **D** note that the cysts are not uniformly distributed throughout the gland, as they are in SS (Fig. 39-61). This patient was HIV positive and had lymphoepithelial cysts.

Acquired Cysts

Ductal Cysts/Sialocysts

Many acquired cysts of the major salivary glands develop as a result of ductal obstruction that may be caused by a postinflammatory stricture, a calculus, trauma, a postsurgical complication (from stenosis or ligature of a duct), or a mass. Almost always the causative obstruction is incomplete or intermittent, since an initial complete obstruction of the glandular ducts results in acinar and glandular atrophy rather than cyst formation (Figs. 39-78 to 39-83).[7, 143] The resultant thin-walled cyst has been called a ductal cyst, sialocyst, retention cyst, major salivary gland mucocele, or extravasation cyst. It is believed that all of these cysts are different stages of the same pathogenetic process. Salivary duct cysts, or sialocysts, usually arise in the parotid gland and represent true cysts with epithelial linings. When seen in the sublingual gland, the cyst is called a ranula (see below).

Patients most commonly present in the fifth decade of life with a slowly enlarging, painless, mass-like lesion. The most common site for a sialocyst is the submandibular gland. Histologically, sialocysts may be multicystic or show ectasia of the adjacent ducts. The epithelial lining may be cuboidal/columnar, squamous, or mucous (goblet), and/or clear cells may be seen. These cysts are treated by complete but conservative surgical excision. They should not recur if completely excised.

A sialocele arises when saliva accumulates within a cystic area that develops secondary to a complete or incomplete traumatic interruption of the excretory ducts draining the region. If some communication with the main

VIEW IMAGE

FIGURE 39-78 Axial contrast-enhanced CT scan shows several small cysts in the anterior superficial portion of the right parotid gland (*arrow*). The right parotid gland is denser than normal. These were posttraumatic acquired cysts.

ductal system persists, a sialogram will reveal a communicating cyst within the gland (Figs. 39-84 to 39-86). If no such communication exists, the sialogram will appear as a benign mass that displaces the adjacent ducts. These sialoceles develop rapidly after trauma, and needle aspiration of saliva from the cyst confirms the diagnosis.[152]

Pneumoceles

A pneumocele is a rare cause of a sialocyst. It is caused by the retention of air in a major salivary gland duct that may extend into the parenchyma. This occurs after an increase in intrabuccal pressure. Although it is associated with adult occupations such as glass blowing and trumpet playing, it commonly occurs in children who cause retrograde insufflation of air into the gland via Stensen's duct or, less commonly, Wharton's duct (Figs. 39-87 and 39-88). It has been suggested that in children, Stensen's duct has a more perpendicular insertion into the buccal mucosa than in adults, in whom the angle of insertion is more acute posteriorly. This allows a buccal mucosal fold to provide better protection in adults against the retrograde air traveling into Stensen's duct when intraoral pressure is increased. The clinical presentation of a recurrent painless soft-tissue glandular fullness usually establishes the diagnosis.[152]

AIDS-Related Parotid Cysts

HIV infection may manifest itself in the head and neck under myriad guises. Kaposi's sarcoma (KS), candidial or herpetic oropharyngitis, and cervical lymphadenopathy are the three most common presenting head and neck complaints for HIV infection. Less commonly, patients with AIDS develop cystic and solid intraparotid tumors that have been referred to as either cystic benign lymphoepithelial lesions, or BLEL in AIDS, or AIDS-related parotid cysts (ARPC). The last term is recommended, as the other terms may cloud the distinctions between BLEL and AIDS, two clinically and prognostically different entities. Patients typically present with unilateral or bilateral painless, enlarging masses; imaging studies reveal that bilaterality is the rule rather than the exception, even when the involvement clinically appears unilateral (Figs. 39-73 to 39-77). Cervical lymphadenopathy and nasopharyngeal lymphoid enlargement commonly accompany the parotid findings. In recent years, as better medical control of HIV-infected patients has developed, multiple ARPCs have been seen without associated cervical lymphadenopathy and/or adenoidal hypertrophy. In such cases, history as to medical therapy becomes important.

Histologically, ARPC appears as cystic spaces lined by squamous epithelium, accompanied by abundant reactive lymphoid stroma. Florid follicular hyperplasia, loss of mantle zone lymphocytes, and follicle lysis can be seen. The lesions may have an encapsulated, segmented appearance, or the inflammatory infiltrate can extend into the parotid parenchyma without encapsulation. Epimyoepithelial islands, identical to those seen in BLEL, can often be observed. Warthin-Finkeldey-type multinucleated giant cells may also be seen within involved lymph nodes.

What is the relationship between ARPC, BLEL, and SS?

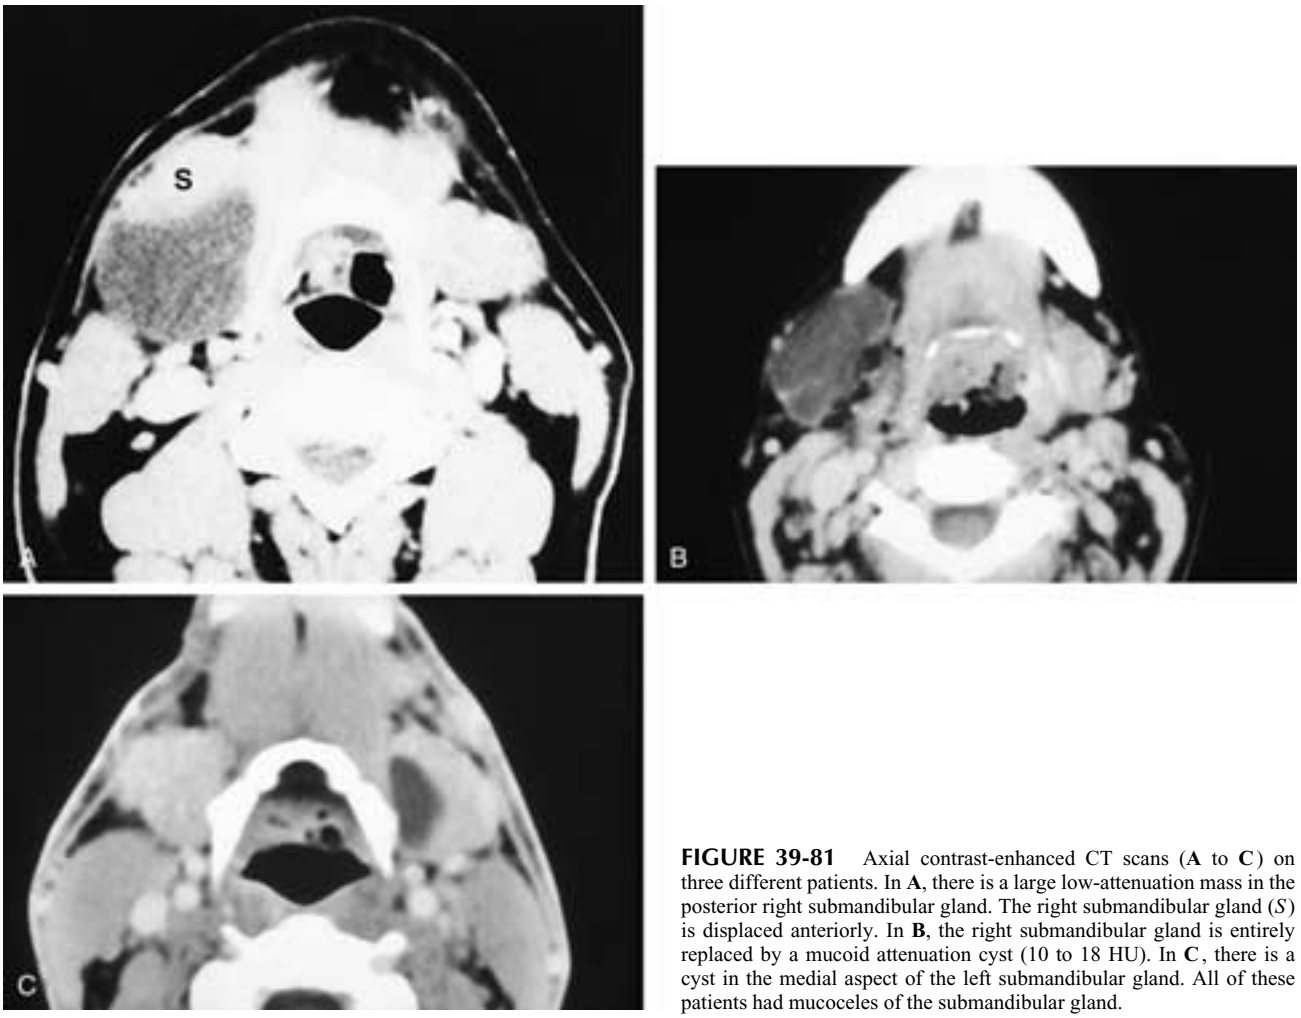

FIGURE 39-81 Axial contrast-enhanced CT scans (**A** to **C**) on three different patients. In **A**, there is a large low-attenuation mass in the posterior right submandibular gland. The right submandibular gland (*S*) is displaced anteriorly. In **B**, the right submandibular gland is entirely replaced by a mucoid attenuation cyst (10 to 18 HU). In **C**, there is a cyst in the medial aspect of the left submandibular gland. All of these patients had mucoceles of the submandibular gland.

VIEW IMAGE

The majority of patients with ARPC have no autoimmune symptomatology and lack serum autoimmune antibodies. The prevailing theory is that ARPC is the result of AIDS-related hyperplastic adenopathy [persistent generalized lymphadenopathy (PGL)] of periparotid/intraparotid lymph nodes causing obstruction, squamous metaplasia, and cystification of intranodal ducts. However, a recent study by Ihrler and colleagues did not support this theory. They found a continuous spectrum of lymphoepithelial salivary parenchymal lesions, developing initially from lymphoid infiltra-

tion of salivary lobules to lymphoepithelial duct lesions with cystic dilatation, up to large ductal cysts (up to 3.5 cm in diameter) with parenchymal atrophy. The ductal and cystic lesions demonstrate an intense basal cell hyperplasia without participation of myoepithelial cells. The MR imaging findings indicated involvement of the entire tissue of both parotid glands. The authors concluded that the enormous cystic dilatation of the duct lesions presumably is a consequence of ductal obstruction due to basal cell hyperplasia of striated ducts and intense intraglandular

VIEW IMAGE

lymphofollicular hyperplasia. At present, it is believed that both pathophysiologies may coexist. Thus, cystification of lymph nodes and periductal obstruction may both be causes of the observed ARPC.

A small, distinct subgroup of AIDS patients also have Sjogren's-type symptoms of xerostomia, xerophthalmia, and arthritic pain; however, autoantibodies (antinuclear antibodies) have been identified in only one of all the reported patients.[173–175] Labial biopsies of minor salivary glands have revealed, for some patients, severe sialadenitis on a par with that seen in SS. Nonetheless, although ARPC and the BLEL of SS share similar histologic features, their

underlying pathophysiology is different, and therefore they warrant separate clinical and pathologic designations. There can be significant morphologic overlap between the individual features of ARPC and BLEL; obviously, this differential diagnosis has an enormous clinical impact, as ARPC may herald the diagnosis of HIV infection. Epimyoepithelial islands, a prominent feature of BLEL, may also be observed in ARPC. Warthin-Finkeldey-type multinucleated giant cells are more often seen in ARPC but are occasionally seen in BLEL. BLEL also tends to be less cystic and generally more solid, although cystic change has been observed in 3% of patients with BLEL.

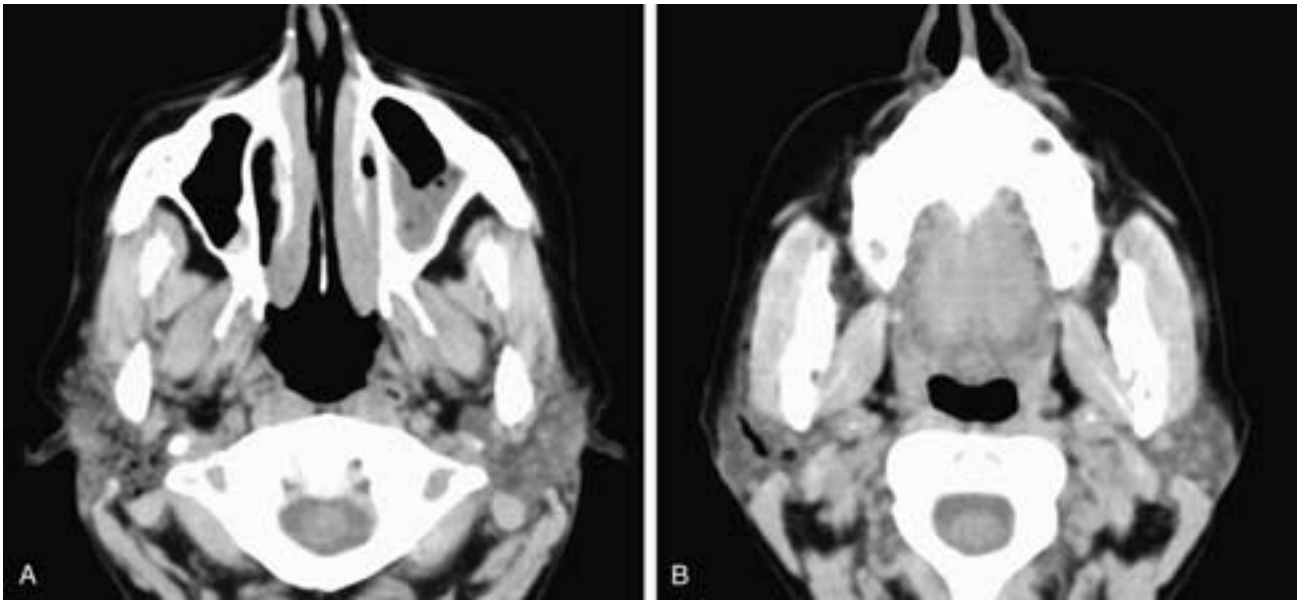
An established radiologic/cytologic diagnosis of ARPC obviates the need for surgical excision. Patients treated by fine needle aspiration may develop repeated collections of cyst fluid and may require periodic fine needle aspiration.[174, 176–181]

Ranula

The term *ranula* refers to a mucous retention cyst that occurs primarily in the sublingual gland. Rarely, this term is also applied when a minor salivary gland in the oral cavity is involved. A ranula occurs in two forms. A simple ranula, which is the most common form, is a retention cyst (almost always of the sublingual gland) that remains in the floor of the mouth above the level of the mylohyoid muscle. The simple ranula is a true cyst because it has an epithelial lining. This lining is either the capsule of the sublingual gland or the epithelial wall or capsule of a minor salivary gland (Figs. 39-89 to 39-93). The second type of ranula is the deep or plunging ranula, which is a mucocele that develops from the rupture of the wall of a simple ranula. The irritating saliva is rapidly contained by an inflammatory response. Thus, the wall of the ranula is composed of both epithelium and inflammatory elements and, in reality, is a pseudocyst. It may or may not extend below the mylohyoid muscle; however, usually it does extends below this level (Figs. 39-91 and 39-93). Although a plunging ranula is also said to be present whenever the lesion simply extends below the mylohyoid muscle, this is not always true, and the pathologic definition remain the final means of establishing this diagnosis.

Plunging ranulas appear to occur more frequently in the Maori and Pacific Island Polynesian populations. The precise etiology of their predisposition is unknown, although local trauma or inherent mylohyoid dehiscences may play an important role. Removal of the sublingual gland via either a cervical or an intraoral approach is the treatment of choice.[182]

The simple ranula occurs as a mass in the floor of the mouth, off the midline in the area of the sublingual gland.



VIEW IMAGE

The left submandibular gland (*S*) is displaced backward by the cyst. This patient had a ranula. By comparison, axial contrast-enhanced CT scans through the floor of the mouth (**C**) and the submandibular glands (**D**) on another patient show a massively dilated right Wharton's duct and dilatation of the intraglandular ducts. The gland also enhances. This patient had a stricture of the opening of Wharton's duct, with dilatation of the ducts and sialadenitis.

This ranula remained above the mylohyoid muscle. This long-standing ranula has slightly remodeled the lingual cortex of the mandibular symphysis.

VIEW IMAGE

The elevated mucosa of the floor of the mouth often has a characteristic bluish color, and the appearance of this mucosa is reminiscent of the appearance of the gullet pouch of a frog (dim. French *rana*). Because of the simple ranula's location, the differential diagnosis includes lateral dermoid or epidermoid cyst, lipoma, and salivary gland tumor. The plunging ranula appears clinically as a painless mass in the submandibular or submental triangles of the neck, with or without evidence of a mass in the floor of the mouth. The differential diagnosis includes dermoid and epidermoid cysts, thyroglossal duct cysts, cystic hygroma, and lymphadenopathy.[151]

Although there is a diversity of proposed etiologies, ranulas most commonly result from trauma (including surgery) or obstruction to the sublingual salivary gland or its ductal elements. Ranulas are reported in approximately 5% to 12% of patients undergoing submandibular duct relocation for management of uncontrolled sialorrhea, presumably because, during this procedure, there is invariably surgical trauma to the sublingual gland components.[166, 168] Treatment of ranulas is directed primarily to transoral drainage of the cyst and excision of the ipsilateral sublingual gland.[169, 170] The more surgically difficult complete dissection of the ranula's lining or the exteriorization of the cyst have been shown to be unnecessary.[166, 167, 171, 172]

A sialogram performed on a patient with a cyst reveals smooth displacement of the glandular ducts around the mass. In general, no direct communication with the ductal system is demonstrated; however, the best method of demonstrating a communicating cyst is by sialography (Figs. 39-84 and 39-85). In patients with main ductal stenosis, the site and degree of this stenosis can be assessed accurately by a sialogram, provided that the stenosis is not at the main ductal orifice. Similarly, lacerations of the ducts can be identified by sialography, and in some cases any fistulas or sinus tracts can be visualized. In cases of parenchymal laceration or intracapsular hematoma, the sialogram reveals an area(s) of absent parenchymal filling, with splaying of the ducts around the region(s).

On CT, a cyst is identified as a smooth, well-delineated ovoid mass that usually has a homogeneous, low central attenuation of 10 to 20 HU. The cyst wall in these cases is easily identified, and is usually thin and uniform in

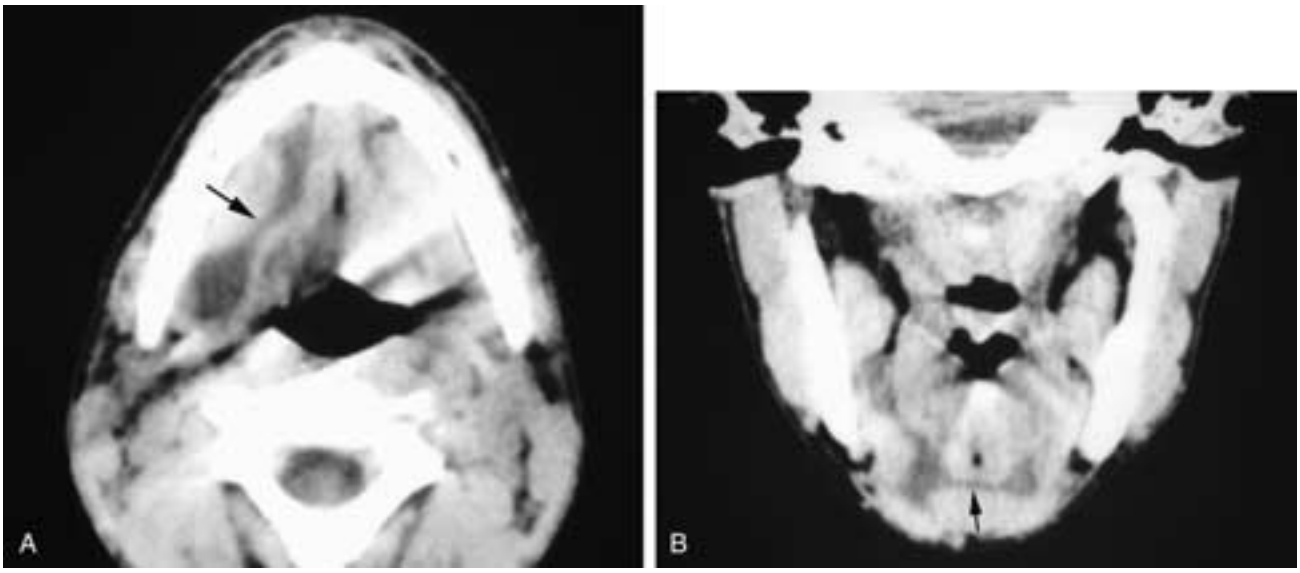

FIGURE 39-93 Axial (**A**) and coronal (**B**) CT scans show a low-attenuation (mucoid) collection (*arrows*) in the right floor of the mouth that has tracked down and across the midline floor of the mouth to the left side. This patient had a plunging ranula.

appearance. If the cyst contents are very proteinaceous (usually after repeated episodes of infection and/or hemorrhage), the attenuation of the cyst contents increases, approaching that of the cyst wall. In these uncommon cases, the cyst can appear on CT as a homogeneous, benign-appearing solid mass. If the cyst has become infected, the cyst wall enhances and becomes thicker and less well differentiated from the adjacent glandular parenchyma; the central portion of the cyst remains of lower attenuation. This CT appearance is indistinguishable from that of an abscess. The adjacent parenchyma in such cases usually has increased attenuation (compared to that of the normal gland), reflecting the cellular infiltration associated with the inflammation. In some cases, fistulas or sinus tracts can be demonstrated on CT scans; however, these are usually better identified by sialography. If contrast has been injected into a sialocele, the lesion will be well seen on CT (Fig. 39-86).

On CT, the simple ranula is usually a roughly ovoid-shaped cyst with a homogeneous central attenuation region of 10 to 20 HU. The cyst wall is either very thin or not seen, and the lesion is positioned lateral to the genioglossal muscles and above the mylohyoid muscle (Fig. 39-89). Uncommonly, the cyst can extend anteriorly, behind the symphysis of the mandible, above the genial muscles (Fig. 39-92). The plunging ranula often infiltrates the adjacent tissue planes, extending inferiorly and dorsally to the submandibular gland region, while ventrally it may cross the midline to the contralateral floor of the mouth (Fig. 39-93). The CT differential diagnosis includes dermoid, epidermoid, cystic lymphangioma, lipoma, lateral thyroglossal duct cyst, and cystic/necrotic lymph node.[152] A Wharton's duct that is obstructed anteriorly near the papilla may dilate and simulate a ranula in the lateral floor of the mouth on imaging. However, the changes in the obstructed duct extend back into the submandibular gland, and the gland has dilated ducts and usually enhances more than the contralateral normal submandibular gland. Although a plunging ranula may extend into the submandibular triangle and displace the submandibular gland, it does not intrinsically affect this gland.

On MR imaging, the ranula's characteristic appearance is usually dominated by its high water content. Thus, it has a low T1-weighted, an intermediate proton density, and a high T2-weighted signal intensity (Figs. 39-90 and 39-91). This appearance, especially in a plunging ranula, may be similar to that of a lymphangioma, a lateral thyroglossal duct cyst, and possibly an inflamed lymph node. However, if the protein concentration of the ranula's contents is high, the signal intensities can vary, often being high on all imaging sequences. In such cases, the MR differential diagnosis includes entities such as dermoids, epidermoids, and lipomas.

On MR imaging, the cyst wall's thickness, smoothness, or uniformity may occasionally be defined on T1-weighted images, but this is usually better accomplished on postcontrast fat-suppressed studies. One of the potential difficulties with noncontrast-enhanced MR images is that cysts and solid lesions that have a high water content can appear identical. The cyst wall may not be adequately visualized on any MR imaging sequence. This problem rarely exists with CT or ultrasound. The treatment of choice for ranulas and cysts is surgery.[165, 183–190]

TUMORS AND TUMOR-LIKE CONDITIONS

In the general population, salivary gland neoplasms represent less than 3% of all tumors.[191] It has been estimated that about 1% of all head and neck malignant tumors arise in the salivary glands, and these tumors result in about 750 deaths annually. However, a higher incidence of such salivary neoplasms has been reported in selected populations such as Eskimos, survivors of atomic bomb blasts, and persons exposed to previous radiation.[192, 193] From 70% to 80% of parotid gland tumors, 40% to 58% of submandibular gland tumors, 15% to 30% of sublingual gland tumors, and 20% to 51% of minor salivary gland tumors are benign. Generally, these figures indicate that the smaller the salivary gland involved, the greater the likelihood that a tumor is malignant.[192–194]

The TNM staging of salivary gland tumors according to the American Joint Committee on Cancer is weighted heavily on the size of the primary lesion and is presented in Table 39-1. Generally, tumor stage correlates inversely with overall survival for salivary malignancies. However, tumor grade is also an important prognosticator. In most circumstances, tumor stage and grade are more significant predictors than actual histologic subclassification. One exception to this rule concerns salivary duct carcinoma (see below). This high-grade neoplasm has a dismal prognosis despite its presentation as a T1 neoplasm.

Although overall cure rates traditionally are calculated on the basis of no evidence of disease (NED) for 5 years, several of the major salivary gland tumors (notably adenoid cystic carcinoma) may have late recurrences, some appearing 10 to 25 years after the initial treatment. For this reason, statistics citing 5 years of curability must be viewed with some circumspection.[192, 195]

Although salivary gland tumors are uncommon in children, there is a higher frequency of malignancies in children compared to adults. Thirty-five percent of all epithelial and nonepithelial salivary gland tumors in children are malignant.[196] The most common tumors in the pediatric age group are hemangiomas, followed in descending frequency by pleomorphic adenomas, mucoepidermoid carcinomas, lymphangiomatous tumors, acinic cell carcinomas, and undifferentiated carcinomas.[197]

For all parotid malignancies, the presence of metastatic regional lymph node disease indicates a poor prognosis. The frequencies of clinically palpable lymph node metastases per specific histologic diagnosis are: high-grade mucoepidermoid carcinoma, 44%; squamous cell carcinoma, 37%; adenocarcinoma, 25%; undifferentiated carcinoma, 23%; carcinoma ex pleomorphic adenoma, 21%; acinic cell carcinoma, 13%; and adenoid cystic carcinoma, 5%. The rates of occult nodal metastasis per diagnosis are: salivary duct carcinoma, 60%; squamous cell carcinoma, 40%; high-grade mucoepidermoid carcinoma, 16%; adenocarcinoma, 9%; and acinic cell carcinoma, 6%.[196] For malignancies of the submandibular, sublingual, and minor salivary glands, the rates of occult nodal metastasis per diagnosis are: carcinoma ex pleomorphic adenoma, 42%; mucoepidermoid carcinoma (all grades), 33%; squamous cell carcinoma, 33%; and adenoid cystic carcinoma, 13%. The difference between these two sets of data reflects the parotid predilection for salivary duct carcinoma and

acinic cell carcinoma. Salivary malignancy that can be classified only as undifferentiated has a high rate of cervical metastasis.[198]

Facial nerve tumor invasion correlates directly with an increased rate of nodal metastasis (66% to 77%). Facial nerve paralysis is most commonly associated with parotid undifferentiated carcinoma (24%), squamous cell carcinoma (19%), adenoid cystic carcinoma (17%), adenocarcinoma (11%), mucoepidermoid carcinoma (9%), carcinoma ex pleomorphic adenoma (7%), and acinic cell carcinoma (1%). Overall, if the facial nerve is paralyzed at clinical presentation, the 5-year survival rate is only between 9% and 14%.[196]

The presence of pain is not necessarily a criterion of malignancy, since 5.1% of benign tumors and 6.5% of malignant tumors present with parotid pain. However, pain in a patient with a known malignancy is a very poor sign, as it is principally secondary to neural invasion.[196] Overall, the 5-year survival rate in patients with salivary malignancy and pain is 35% compared to 68% for those with no pain.

Distant metastasis also indicates a poor prognosis. Overall, about 20% of all parotid malignancies have distant metastases: salivary duct carcinoma, 57%; adenoid cystic carcinoma, 42%; undifferentiated carcinoma, 36%; adenocarcinoma, 27%; carcinoma ex pleomorphic adenoma, 21%; squamous cell carcinoma, 15%; acinic cell carcinoma, 14%; and mucoepidermoid carcinoma, 8%.[196]

In the past decade, the treatment philosophy for parotid gland malignancies has changed as the limitations of surgery for the more aggressive neoplasms have become known. Postoperative irradiation is now used frequently to improve local control, and chemotherapy is being utilized more often to control distant metastasis. Although specific chemotherapy regimens are constantly changing, the adenocarcinomas, adenoid cystic carcinomas, acinic cell carcinomas, and carcinoma ex pleomorphic adenomas seem to respond to a combination of adriamycin, cisplatinum, and 5-fluorouracil. The squamous cell carcinomas and the mucoepidermoid carcinomas have exhibited some response to a combination of methotrexate and cisplatinum.[196]

Many classifications of salivary gland tumors have been proposed.[8, 26, 199] Table 39-2 presents the most recent World Health Organization Classification of salivary tumors. Table 39-3 presents a refinement of that classification proposed in 1996.

Epithelial Tumors

Pleomorphic Adenoma (Benign Mixed Tumor) and Carcinoma ex Pleomorphic Adenoma (Malignant Mixed Tumor)

Pleomorphic adenoma, also referred to as *benign mixed tumor*, is the most common salivary gland tumor and represents 70% to 80% of all benign tumors of the major salivary glands. Table 39-4 shows the distribution of almost 700 pleomorphic adenomas seen at the Armed Forces Institute of Pathology.

Of all pleomorphic adenomas, 84% occur in the parotid gland, 8% in the submandibular gland, 6.5% in the minor salivary glands, and 0.5% in the sublingual glands. Of the parotid tumors, 90% arise lateral to the plane of the facial nerve.[7, 192] Although about 50% of all minor salivary gland tumors are malignant, pleomorphic adenoma is still the single most common tumor of these glands. Most of the minor salivary gland tumors occur in the palate and upper lip region; however, these tumors have also been reported in the lower lip, nasal septum, paranasal sinuses, base of the tongue, and larynx.[7]

Typically, these tumors occur as a slow-growing, painless mass that has an average interval between the onset of signs and symptoms and initial workup of 1 to 6 years. The tumors vary greatly in size from a few millimeters to

Copyright © 2003, Mosby, Inc. All rights reserved.

several centimeters. There is a female predominance, and most cases occur over the age of 40 years. The lesions are usually solitary, ovoid, well-demarcated masses despite having a capsule of variable thickness and completeness. The larger tumors may have pedunculated outgrowths from the main lesion that grossly simulate multiple masses.

The term *pleomorphic adenoma* summarizes the multifaceted (hence ''pleomorphic'') appearance of these tumors. They contain epithelial elements, which may be either glandular, ductal, or solid. The intercalated duct–myoepithelial cell unit is the proported origin of these tumors; certainly pleomorphic adenomas recapitulate these structures.[7] They also contain mesenchyma-like tissue, derived from the myoepithelial cells, which may contain chondroid and fibromyoid tissue (Fig. 39-94). Sites of necrosis, hemorrhage, hyalinization, calcification, and, rarely, ossification may be present.[7]

The recurrence rate varies between 1% and 50% and is directly related to the initial surgical procedure. The higher reported recurrence rates are in studies that included patients who were treated by enucleation rather than parotidectomy, as well as patients who had capsular rupture at surgery. For this reason, tumor enucleation is no longer considered an acceptable surgical technique. Conversely, some studies have very low reported recurrence rates because their follow-up period was of insufficient duration, since some recurrences take many years to develop. When recurrences occur, they are often multiple and clustered about the region

of the original tumor (cluster of grapes appearance). Recurrences result from transection of the finger or pod-like tumor projections, which characteristically cause a multinodular recurrence pattern. It has been noted that pleomorphic adenomas with a high stromal chondroid/myoid content have a greater recurrence rate than predominant cellular epithelial tumors.[200, 201] Myxoid-predominant pleomorphic adenomas have more numerous, obvious pseudopods and thinner capsules. Recurrences may be single but are more characteristically multiple. Myssiorrek et al. noted that the interval to recurrence was somewhat predictive. Patients with more than one recurrence tended to have their first recurrence earlier (mean, 47 months) than patients who were cured after reexcision of their only recurrence (mean, 105 months).[200] In a similar vein, MacGregor et al. noted that pleomorphic adenomas that ultimately recurred were more likely to have their initial onset prior to the age of 30 years.[201] Other series have indicated that younger patients tend to develop recurrences more often than older ones. Most investigators report a 10% to 18% incidence of further recurrence after surgery for the first recurrence (range, 5% to 60%).[202] Radiation has been used to treat recurrences; however, its utility is still uncertain.

True multiple pleomorphic adenomas are rare, with only isolated reports in the literature, and a primary multicentric origin is estimated to occur in 0.5% of parotid mixed tumors. The less common Warthin's tumors and oncocytomas are far more often multicentric than are pleomorphic adenomas.[7, 44, 98]

Three types of malignancies are associated with pleomor-

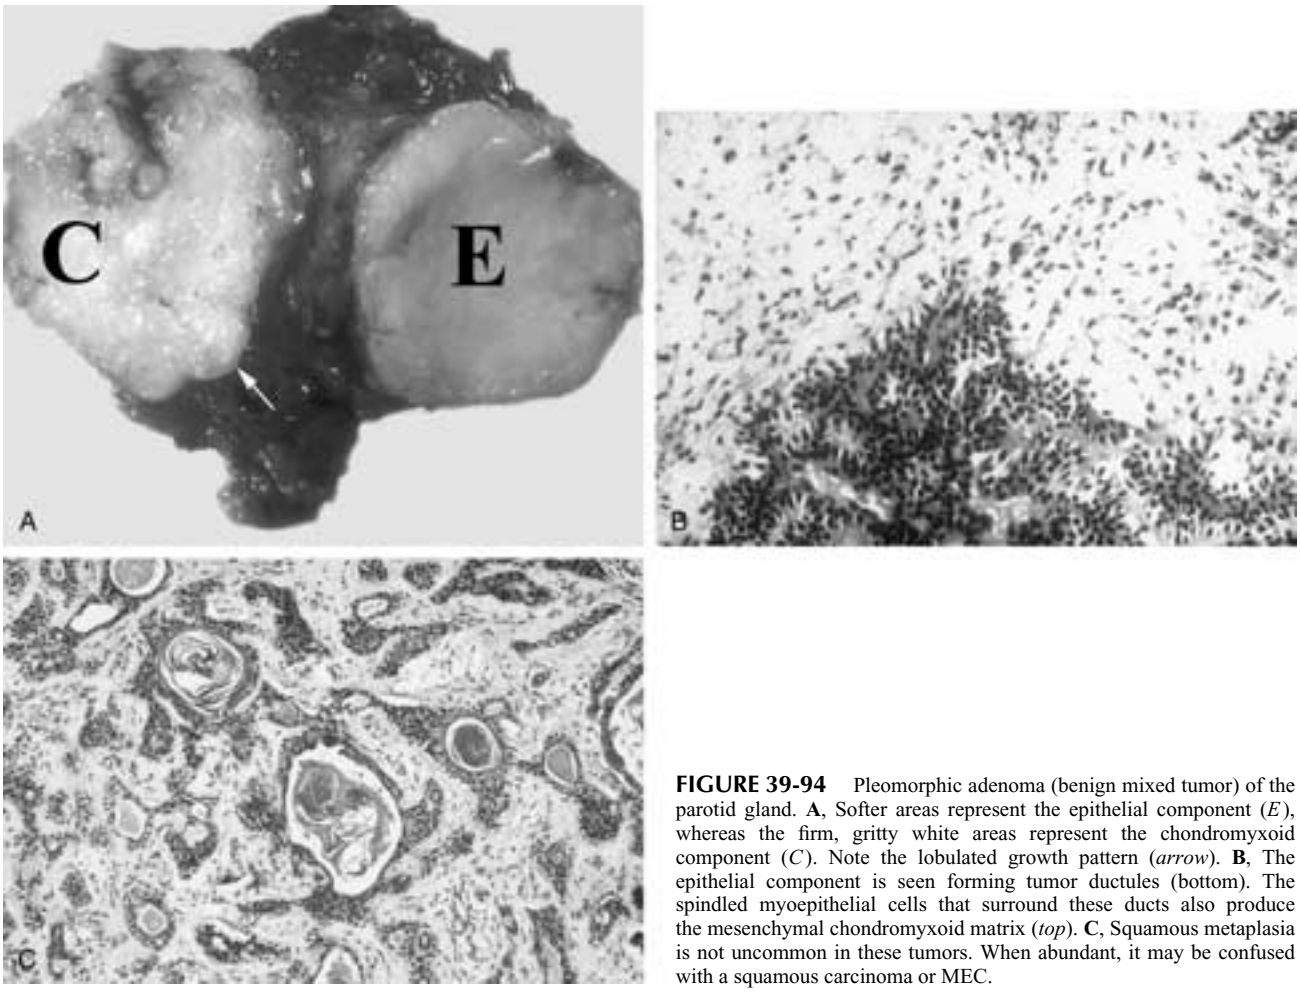

FIGURE 39-94 Pleomorphic adenoma (benign mixed tumor) of the parotid gland. **A**, Softer areas represent the epithelial component (*E*), whereas the firm, gritty white areas represent the chondromyxoid component (*C*). Note the lobulated growth pattern (*arrow*). **B**, The epithelial component is seen forming tumor ductules (bottom). The spindled myoepithelial cells that surround these ducts also produce the mesenchymal chondromyxoid matrix (*top*). **C**, Squamous metaplasia is not uncommon in these tumors. When abundant, it may be confused with a squamous carcinoma or MEC.

phic adenomas: carcinoma ex pleomorphic adenoma (also referred to as malignant mixed tumor) and rarer variants such as true malignant mixed tumor (also referred to as carcinosarcoma) and metastasizing benign mixed tumor.[203, 204] The carcinoma ex pleomorphic adenoma is either a malignant change in a benign mixed tumor in which elements of the benign lesion can still be identified or the development of a malignant tumor in a patient known to have a previously resected pleomorphic adenoma. Usually the malignancy is an adenocarcinoma, but any epithelial subtype can and does occur in approximately 2% to 5% of all mixed tumors.[7, 44, 203] The usual clinical presentation is in a patient with a long history (average, 10 to 15 years) of a benign mixed tumor that suddenly demonstrates a period of rapid growth (average, 3 to 6 months). Pain and facial nerve paralysis are often present; these patients most commonly are about 60 years of age. However, malignancies may be seen, usually a carcinoma ex pleomorphic adenoma, developing rapidly in a young person.[205, 206]

The malignant degeneration within a pleomorphic adenoma may be a function of time, and it has been estimated that, left untreated, nearly 25% of all pleomorphic adenomas may undergo malignant change.[7, 44] For this reason, surgeons no longer widely hold the concept of not operating readily on a benign mixed tumor because it is a ''benign'' lesion. In essence, the longer this tumor remains in the patient, the greater the chances that it will undergo malignant transformation. Carcinoma ex pleomorphic adenomas also have an accelerated recurrence rate and a high metastatic rate, which varies from 25% to 75%. Overall, the 5-year survival rate is approximately 50%; however, death usually occurs within 1 year of the discovery of metastases. The main sites of metastases are the regional lymph nodes, lungs, bones, and brain.[193] The degree of invasion of these tumors into the surrounding parotid parenchyma is an important prognosticator of survival.[207] A subgroup of noninvasive or minimally invasive malignant mixed tumor has recently been reported. This tumor has a better prognosis than the classic malignant mixed tumor.[205] No locoregional metastases or disease-related deaths have been reported in these minimally invasive (low-grade) malignant mixed tumors (Fig. 39-95).

The true malignant mixed tumor (*true* referring to truly mixed) is rare and contains both epithelial and stromal malignant elements. It is thus a true carcinosarcoma and usually has a grave prognosis. The metastasizing ''benign'' mixed tumor is the rarest form of malignancy associated with pleomorphic adenomas. Curiously, there are no tumor features (histology, flow cytology) that predict a malignant course. It has been postulated that multiple recurrences and surgical procedures allow some tumors to gain venous access and ''benignly'' metastasize. Karyotypic chromosomal analysis in one such tumor has revealed numerous translocations, including unbalanced rearrangements of chromosomes 1–13, 9–12, and monosomy 22, which differ from the typical balanced 8Q or 12Q translocations seen in pleomorphic adenomas. This suggests that more than happenstance allows a mixed tumor to gain venous access.[208–211]

Metastases may be multiple; involve lungs, bones, and soft tissues; and occur over many decades. Despite their indolent course, the pulmonary metastases may be massive, resulting in patient death. Therefore, it was recommended

that the adjective *benign* be deleted from the name of this tumor.[7, 44, 212]

The treatment of choice is surgical excision, with aggressive treatment of distant metastases. Half of the tumors metastasize to bone, 30% to the lung, and 30% to the lymph nodes; rarely, tumors metastasize to other body sites. Forty percent of patients died with disease, usually from distant metastases, 47% were alive and well, and 13% were alive with disease.

Carcinosarcoma (true malignant mixed tumor) is composed of a mixture of carcinomatous and sarcomatous elements. Unlike carcinoma ex pleomorphic adenoma, in which only the carcinomatous elements may metastasize, both the carcinomatous and sarcomatous elements of carcinosarcoma may metastasize. Carcinosarcoma is extremely rare, slightly over 40 cases having been reported to date.[213, 214] Two thirds of these tumors have arisen in the parotid glands, approximately 19% in the submandibular glands, and 14% in the palate; one case has been reported in the tongue. The mean age at presentation was 58 years, with a range of 14 to 87 years. A number of patients had a history of recurrent pleomorphic adenoma. Elements of chondrosarcoma and osteosarcoma are the most common sarcomatous elements, and moderate to poorly differentiated ductal carcinoma or undifferentiated carcinoma is the most common carcinomatous component. Local tissue infiltration and destruction are characteristic of this neoplasm.

Treatment is wide surgical excision combined with radiotherapy. Almost 60% of patients die of local recurrence and/or metastatic disease (lungs, bones, central nervous system), usually within 30 months.

The imaging of a pleomorphic adenoma shows the typical picture of a benign-appearing mass. On sialography, pleomorphic adenoma displaces the parotid ducts smoothly around the tumor mass (Fig. 39-96). On CT, most small benign mixed tumors are smoothly marginated, spherical tumors that have a higher attenuation than the surrounding parotid parenchyma. On occasion, these tumors can have a lower attenuation than the surrounding parotid parenchyma and mimic the appearance of a cyst. A good correlation between CT attenuation and tumor histology has not yet been established. All of these tumors enhance variably on contrast-enhanced studies (Figs. 39-97 to 39-102). The smaller lesions are usually fairly homogeneous in appearance. If delayed contrast-enhanced CT scanning is not performed in these cases, the mass may be overlooked. The larger masses most often have a nonhomogeneous appearance, with sites of lower attenuation representing areas of necrosis, old hemorrhage, and cystic change (Fig. 39-101). Localized areas of increased attenuation most often represent sites of recent hemorrhage and are associated clinically with a sudden increase in tumor size and localized pain. The larger tumors tend to develop a lobulated contour that, when present, is highly suggestive of the diagnosis (Figs. 39-99 and 39-100). Such a lobulated mass on CT may appear as multiple adjacent masses rather than a solitary lesion; however, on MR imaging they are clearly seen as a solitary mass (Fig. 39-99). On MR imaging, these tumors typically have a low T1-weighted and a high T2-weighted signal intensity (Fig. 39-102). A low signal intensity ''capsule'' is often seen on T2-weighted scans and on fat-suppressed, contrast-enhanced, T1-weighted images (Fig. 39-103). Dystrophic calcifications or ossifications can occasionally be seen scattered throughout the tumor, and such densities are highly suggestive of this diagnosis (Fig. 39-104) (also see the section on Clinical and Imaging Assessment of the Parapharyngeal Space in Chapter 38).

FIGURE 39-96 Lateral view of a parotid sialogram shows a mass (*arrows*) that smoothly displaces the adjacent parotid ducts around it. This patient had a pleomorphic adenoma (benign mixed tumor).

VIEW IMAGE

On CT, occasionally the outer contour of a pleomorphic adenoma may appear to be slightly indistinct. This is usually secondary to surrounding inflammation and/or hemorrhage. In these cases, the CT appearance can simulate that of a more aggressive tumor. However, on MR imaging, the lesion's contour is sharp and benign-appearing (Fig. 39-100).

Overall on MR imaging, these tumors, when small, have a fairly homogeneous low T1-weighted and a high T2-weighted signal intensity. However, when large, these tumors usually have a nonhomogeneous, low to intermediate T1-weighted and an intermediate to high T2-weighted signal intensity. Areas of hemorrhage appear as regions of high signal intensity on both T1-weighted and T2-weighted images. Regions of necrosis usually have low T1-weighted and high T2-weighted signal intensity. The nonhomogeneous MR appearance is not unique to this tumor and can be seen in other lesions, including malignancies. On MR imaging, the dystrophic calcifications seen on CT usually cannot be visualized or distinguished from focal areas of fibrosis.[45, 68, 69]

A carcinoma ex pleomorphic adenoma may have one of several CT appearances: (1) It may look like a large pleomorphic adenoma, with no CT evidence of malignancy. (2) It may look like a benign mixed tumor with a focally aggressive appearance. This aggressive area has a necrotic center, thick, irregular walls, and infiltrating margins. (3) Last, the tumor may be entirely aggressive in its CT

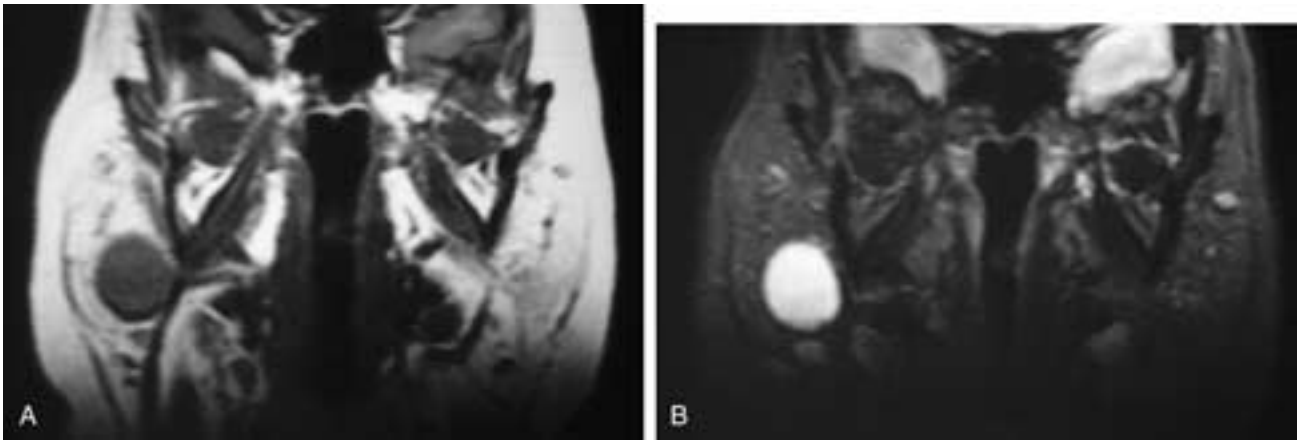
appearance, with no remaining evidence of a benign pleomorphic adenoma. On MR imaging a similar variation can be encountered, with such a tumor having either a smooth margin or a focally or totally invasive margin (Fig. 39-105). Occasionally, like problems encountered with cervical lymph node metastasis, obviously necrotic, thick-walled areas of tumor seen on CT may be poorly identified on MR imaging. In such cases, contrast-enhanced, fat-suppressed, T1-weighted images usually show the necrotic region (Fig. 39-106).



VIEW IMAGE

VIEW IMAGE

FIGURE 39-103 Axial T2-weighted MR image shows a nonhomogeneous but primarily high signal intensity, well-delineated mass in the left parotid gland. Although this is a nonspecific appearance, it is suggestive of a pleomorphic adenoma. The patient had a pleomorphic adenoma.

Most of the carcinomas that occur in pleomorphic adenomas are high-grade cellular masses, and they tend to have fairly low signal intensities on both T1-weighted and T2-weighted sequences. Thus, when a benign-appearing parotid mass is seen that has a low T2-weighted signal intensity, the diagnosis of a benign mixed tumor should be questioned and an explanation for the low signal intensity must be sought. Most often it is the result of a high-grade tumor; however, other lesions can cause similar signal intensities, including fibrosis, granulation tissue, and occasionally some benign or low-grade neoplasms. As previously mentioned, the presence of a low T2-weighted signal intensity only serves to alert the radiologist that a carcinoma ex pleomorphic adenoma may be present.

These imaging appearances hold true whether the pleomorphic adenoma is in the parotid gland proper, the deep portion of the parotid gland extending into the parapharyngeal space (Fig. 39-107), an accessory parotid gland (Fig. 39-108), or the submandibular gland (Figs. 39-109 and 39-110). There may be a tendency for the tumors within the submandibular gland to have a greater cystic component.

When postoperative recurrences occur, invariably there was violation of the original tumor capsule at surgery. This results in seeding of the operative bed, and tumor regrowth can occur anywhere from a few years to decades after sur-

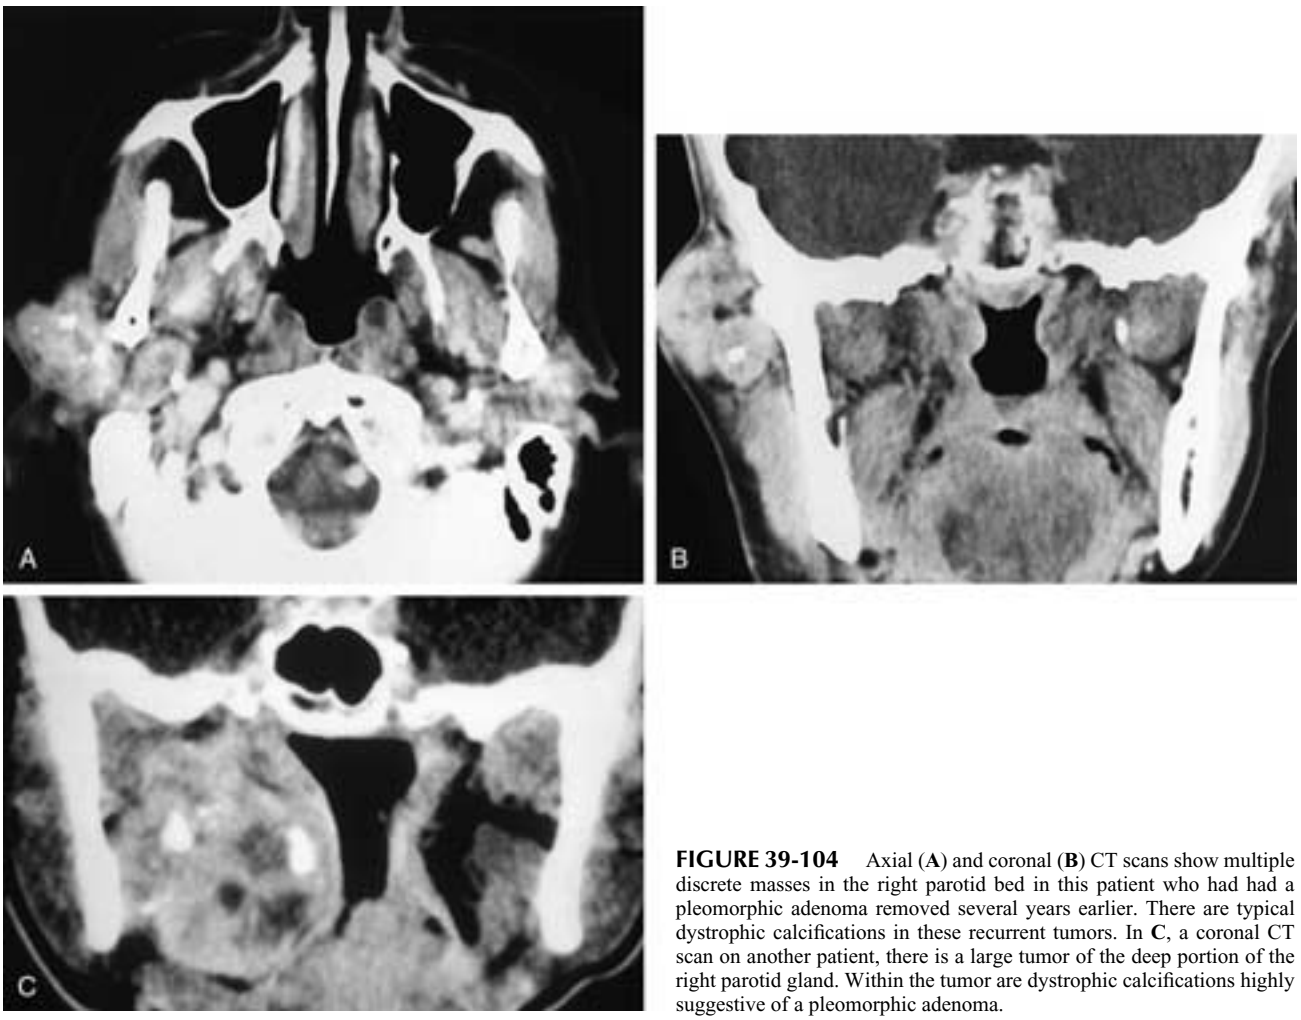

FIGURE 39-104 Axial (**A**) and coronal (**B**) CT scans show multiple discrete masses in the right parotid bed in this patient who had had a pleomorphic adenoma removed several years earlier. There are typical dystrophic calcifications in these recurrent tumors. In **C**, a coronal CT scan on another patient, there is a large tumor of the deep portion of the right parotid gland. Within the tumor are dystrophic calcifications highly suggestive of a pleomorphic adenoma.

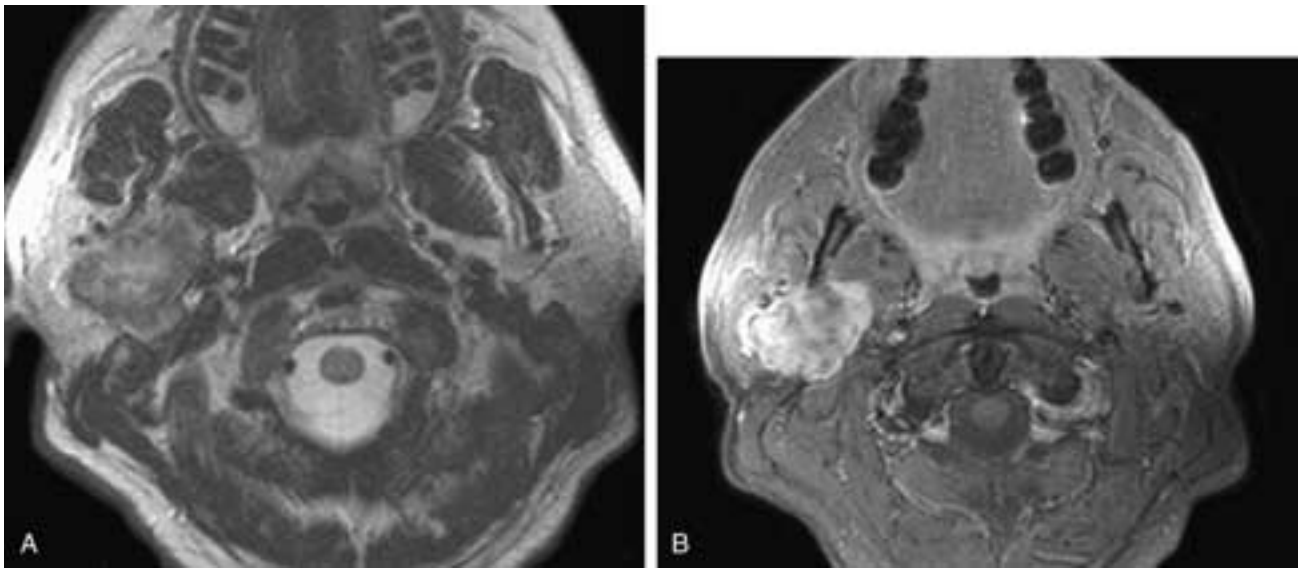
gery. MR imaging is the best way to identify these recurrent tumors, as they have high T2-weighted signal intensity and are grouped like a cluster of grapes (Fig. 39-111).

Warthin's Tumor

Warthin's tumor, also referred to as papillary cystadenoma lymphomatosum, is the second most frequent benign tumor arising in the parotid gland after benign mixed tumor. Previously, it was referred to in the literature as adenolymphoma; this is a misnomer, as it may give the mistaken impression that one is dealing with a lymphoma. Warthin's tumor comprises 4% to 15% of all salivary gland epithelial tumors and 4% to 10% of all parotid tumors, with occasional series showing relative frequencies as high as 30%. It is a slow-growing, commonly cystic neoplasm that arises almost exclusively in the parotid gland, frequently in its lower portion over the angle of the mandible. Occasional tumors (2.7% to 12%) may arise in extraparotid locations, most frequently in periparotid lymph nodes in the area of the parotid tail or in the upper neck, where they can mimic a



VIEW IMAGE

lymph node metastasis. Rare Warthin's-like tumors have also been reported in the oral cavity, larynx, lacrimal gland, and nasopharynx, although these tumors may actually be oncocytomas.

Patients typically present with swelling, and only an occasional patient complains of pain. Warthin's tumor has a peak incidence in the fifth to seventh decades of life, with the youngest and oldest patients in one review being 2.5 and 92 years, respectively. It is considered to be more common in males than in females, with earlier studies demonstrating male:female ratios of up to 10:1; however, more recent reports have demonstrated a more equal incidence between the sexes. There appears to be a definite positive association between Warthin's tumor and cigarette smoking, and there is an increasing incidence of this tumor associated with increasing radiation exposure. It is the most common salivary gland tumor to present with multifocal or bilateral involvement, with 5% to 14% of patients presenting with bilateral masses, 25% of which present simultaneously and 75% metachronously.

Warthin's tumors present grossly as round to oval, well-circumscribed masses that are typically encapsulated. Their cut surfaces range from a brown to a tan-white color, depending on the relative percentage of oncocytic epithelium to lymphoid stroma, and contain a variable number of cysts that exude yellowish, mucoid, brown to clear fluid and, rarely, semisolid caseous material. Most tumors measure 2 to 4 cm in diameter; however, occasional tumors may be over 12 cm in their greatest dimension. Histologically, the appearance of Warthin's tumor is distinctive and pathognomonic, composed of varying proportions of lymphoid stroma and epithelium. The epithelial component is characterized by epithelium-lined cystic spaces, often with numerous papillary projections and containing homogeneous eosinophilic, granular material. This lining and the papillae are composed of two layers of oncocytic cells, an inner row of tall columnar cells with central or luminally located nuclei and an outer layer of cuboidal and polygonal cells. The cytoplasm in both cells is usually granular and intensely eosinophilic due to abundant mitochondria, which is one of the classic characteristics of this neoplasm. Frequently, scattered mucin-secreting cells and foci with squamous metaplasia are seen. The lymphoid stroma is always benign and reactive, with germinal centers (Fig. 39-112).

Malignancy developing in Warthin's tumor is an extremely rare event, representing less than 1% of Warthin's tumors in several large series. Carcinomas and lymphomas occur with approximately equal frequency, with squamous cell carcinoma, mucoepidermoid carcinoma, undifferentiated carcinoma, adenocarcinoma (oncocytic and other types), and other carcinomas having been reported.

Several theories concerning the pathogenesis of Warthin's tumor have been advocated. The most popular of these contends that the tumor develops from heterotopic salivary gland epithelium present in preexisting intra- or periparotid lymph nodes. However, other authors have suggested that these tumors result from an adenomatous or metaplastic epithelial proliferation with secondary lymphocytic infiltration. Epstein-Barr virus (EBV) appears to have some role in the pathogenesis of Warthin's tumor. The virus has been found in tumor epithelium, especially in patients with multifocal and/or bilateral lesions, and there appears to be a higher frequency of autoimmune disorders in patients with

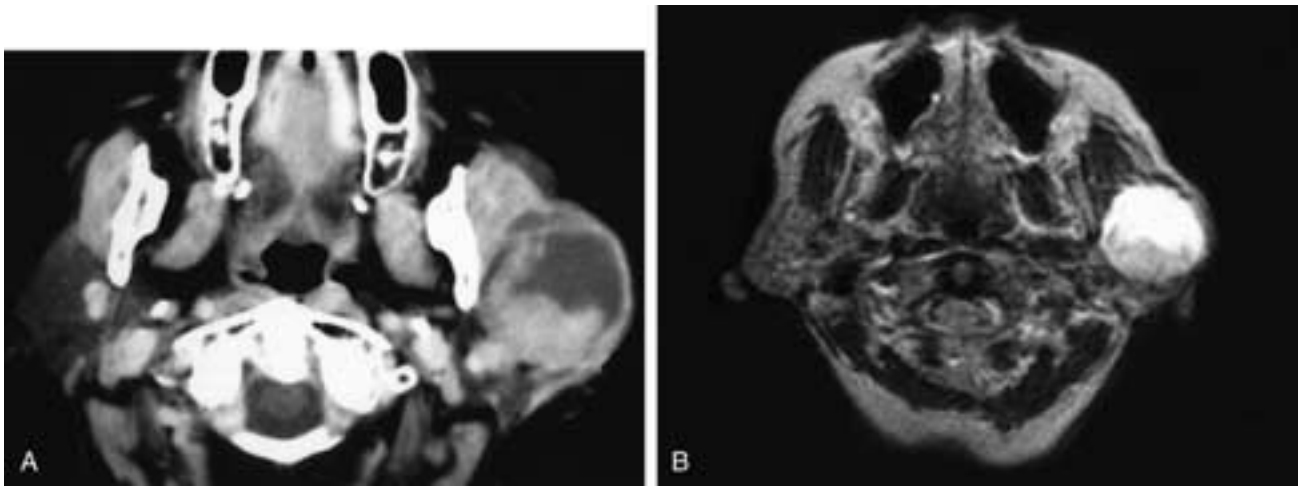
Warthin's tumor than in patients with mixed tumors or in healthy subjects.[215–221]

The recommended treatment is superficial parotidectomy, with preservation of the facial nerve plus good operative exposure to exclude multifocal disease, especially in periparotid lymph nodes. To reduce the risk of facial nerve damage, some observers recommend enucleation whenever feasible. Earlier studies demonstrated recurrence rates as high as 25%, most likely due to multifocal disease, but the majority of recent studies document rates of 2% or less. Similar results are achieved by investigators using enucleation.

VIEW IMAGE

FIGURE 39-113 Oblique frontal technetium sialograms show multiple masses with intense uptake in both parotid glands. This patient had bilateral Warthin's tumors.

The mitochondrium-rich oncocytes of Warthin's tumors are the cells that accumulate ^{99m}Tc pertechnetate on salivary radionuclide scans (Fig. 39-113). The only other tumor to accumulate ^{99m}Tc pertechnetate is an oncocytoma.[222] On CT, most Warthin's tumors appear as small, ovoid, smoothly marginated masses in the posterior aspect of the superficial lobe (tail) of the parotid gland. They are homogeneous soft-tissue density lesions with no dystrophic calcifications. However, cyst formation is common, and on CT the cyst contents usually consist of a homogeneous (10 to 20 HU) material. The cyst wall is usually thin and fairly smooth, but at some point there is a focal tumor nodule, which indicates that this lesion is a cystic tumor rather than a branchial cleft or lymphoepithelial cyst (Figs. 39-114 to 39-117). When a Warthin's tumor is large and arises either from the periphery of the parotid gland or from a juxtaparotid lymph node, most



VIEW IMAGE

FIGURE 39-117 Axial contrast-enhanced CT scan (**A**) shows multiple bilateral parotid masses. The largest lesion on the left side is partially cystic. This patient had Warthin's tumors. In **B**, an axial contrast-enhanced CT scan shows multiple thinned-walled cysts in both parotid glands. No tumor nodules were seen in the cyst walls. This patient also had cervical adenopathy. These were lymphoepithelial cysts in an HIV-positive patient.

or all of the tumor is outside the normal gland contour. In such cases, imaging confusion with a second branchial cleft cyst or a necrotic node may occur.

When multiple lesions are seen either in one parotid gland or bilaterally, the most likely diagnosis is Warthin's tumor. If the neoplasms are cystic or partially cystic, the differential diagnosis includes lymphoepithelial cysts of HIV-positive patients, end-stage parotid Sjögren's syndrome, and possibly multiple cavitated metastatic nodes. If the multiple Warthin's tumors are not cavitated, the radiologic differential diagnosis includes lymphoma, granulomatous disease (primarily sarcoidosis), and benign adenopathy.

On MR imaging, when solid, these tumors appear similar to pleomorphic adenomas in that they have low T1-weighted, intermediate proton density, and high T2-weighted signal intensities. However, if the Warthin's tumor is cystic, the cyst fluid usually has a sufficiently different signal intensity from the solid tumor component that the cyst can be identified on some or all of the imaging sequences (Fig. 39-114). For this reason, when small or moderate in size, Warthin's tumors may be more nonhomogeneous than pleomorphic adenomas. When large, both of these tumors tend to be nonhomogeneous. Occasionally, the cystic nature of some of these tumors is not as apparent on MR imaging as it is on CT.

Benign and Malignant Oncocytic Tumors

Major Salivary Gland Oncocytic Tumors

Oncocytes derive their name from the Greek word *onkos*, meaning ''swelling.'' These cells are swollen with abundant pink granular cytoplasm as a result of a mitochondrial ''defect'' or proliferation. The mitochondria have abnormal rounded shapes or are stacked like erythrocytes in a rouleaux formation. Oncocytes are normally found within endocrine organs (thyroid, parathyroid, pituitary, etc.) And oncocytic metaplasia of minor salivary glands is especially common in older individuals.[7, 8]

Oncocytic tumors are relatively rare, representing 1.6% of 13,749 primary epithelial salivary gland tumors and 1.9% of over 8000 parotid gland tumors at the Armed Forces Institute of Pathology. The major salivary glands were the dominant site, comprising 86% of 226 cases (200 benign and 26 malignant). In general practice, oncocytomas represent 1% or less of all parotid tumors. In a series of 68 patients with oncocytic salivary tumors, 84% occurred in the parotid gland and 11% in the submandibular gland, and 5% were incidental findings within cervical lymph nodes. There is no gender predilection for these tumors, and most patients present with unilateral painless masses. A history of previous radiation exposure has been documented in 20% of patients with oncocytic tumors; these patients tend to present with oncocytomas two decades earlier than the mean. Oncocytomas may be multifocal or bilateral, and in up to 7% of cases they may consist of diffuse oncocytosis rather than single tumor nodules.

Most oncocytic carcinomas, also referred to as malignant oncocytomas, arise in the parotid gland; about 10% arise in the submandibular gland. To date, slightly over 50 cases have been reported. The average age of patients is about 60 years (range, 29 to 91 years), and there is a 2:1 male:female predominance.[2, 12] The most common clinical presentation is that of a slow-growing mass often associated with pain or facial paralysis.

On gross examination, parotid or submandibular oncocytomas appear as single, small, well-circumscribed brown tumors, which may have central star-like fibrosis and occasional cyst formation. Oncocytomas may also occur as part of a generalized process, oncocytosis, in which the entire gland undergoes multifocal oncocytic metaplasia and hyperplasia. In this case, the glandular architecture is entirely replaced by multiple brown or tan nodules, some of which may have central scarring, with one or more dominant tumor nodules that overgrow and distort the normal architecture (Fig. 39-118). Oncocytic carcinomas range from well circumscribed to widely invasive.

On imaging, solitary or multiple solid masses with sharp, well-delineated margins are seen. These lesions also accumulate ^{99m}Tc pertechnetate on salivary radionuclide scans (Fig. 39-119).

Oncocytic Tumors of Minor Salivary or Seromucinous Gland Sites

Larynx The clinicopathologic features of minor salivary or seromucinous gland oncocytic tumors are sufficiently distinctive from those of major salivary tumors to warrant separate discussion. Laryngeal oncocytic lesions produce polypoid masses, most often involving the supraglottis. Rather than being true neoplastic processes, laryngeal oncocytic lesions, referred to as papillary oncocytic cystadenomas, are the result of oncocytic metaplasia and hyperplasia of minor salivary glands, with prominent cyst formation. They have been appropriately likened to extraparotid Warthin's tumors.

Oral Cavity A small fraction (5%) of all oncocytic lesions arise in the oral cavity; the palate and cheek are the most common sites. These lesions may span the spectrum from oncocytic papillary cystic tumors (oncocytic papillary cystadenomas) with a variable degree of lymphocytic infiltration to more solid oncocytomas. An association of parotid Warthin's tumors and oral oncocytic papillary cystadenomas has been reported. These lesions may occur on the lips, buccal mucosa, tonsillar fossa, or palate. They form submucosal circumscribed swellings; only one case has been documented as locally invasive.

Sinonasal Cavity Oncocytic processes at this anatomic site are classified as variations of oncocytic Schneiderian (cylindrical cell) papilloma (OSP), as discussed in Chapter 6, or as seromucinous gland neoplasia. Unlike major salivary gland oncocytomas, which are usually benign, sinonasal oncocytic tumors have a greater tendency toward local aggression. These tumors have a predilection for the lower septum or vestibule. Oncocytic tumors of the superior nasal cavity may also originate from the lacrimal apparatus.

A number of sinonasal oncocytic tumors have shown histologic evidence of local invasion from the onset. These tumors have a male preponderance (male:female ratio of 5:3), and most are diagnosed after the fifth decade of life. They are generally larger than benign tumors and more clinically aggressive, with a propensity to affect the maxillae or nasal cavity.

Histologically, oncocytic tumors of the salivary gland are classified as oncocytosis (nodular or diffuse) or oncocytoma (benign or malignant), as well as tumors with oncocytic metaplasia (oncocytic mixed tumor, oncocytic mucoepidermoid carcinoma, etc.). Oncocytosis is the replacement of normal portions of the salivary gland with oncocytes. These may diffusely replace normal parenchyma (diffuse oncocytosis) or, more typically, produce multiple nodules (oncocytic hyperplasia or nodular oncocytosis). The distinction between a large, hyperplastic nodule and oncocytoma is sometime difficult and often arbitrary. Usually an oncocytoma presents as a mass lesion, is larger than other adjacent hyperplastic nodules, and is well circumscribed, with at least a partially formed capsule. Most benign oncocytic tumors are solid, with a variable cystic component. The oncocytes form organoid nests and trabeculae with very occasional ducts. Cytologically, oncocytes are cuboidal or columnar, with abundant bright pink granular cytoplasm, and have decreased nuclear/cytoplasmic ratios compared to normal parotid ductal cells. Oncocytic nuclei are typically very round and centrally placed; the nucleoli may be single and prominent.

Patients with oncocytic carcinoma typically present with a single or multinodular unencapsulated gray-brown mass. The tumor cells are usually more pleomorphic than their benign counterparts. Their nuclei are often centrally located and contain large, irregular nucleoli, although occasional cases may lack significant atypia. Invasive growth into adjacent tissues is characteristic; scattered mitotic figures and perineural invasion are frequent, and foci of necrosis may be found.

The majority of parotid and submandibular oncocytomas behave in a benign fashion after complete surgical resection, even if rare aggressive features such as perineural invasion have been identified. Local recurrence of an oncocytoma is unusual and is often the result of persistent multifocal oncocytosis in the remaining deep parotid lobe. Most malignant parotid or submandibular oncocytomas are high-grade neoplasms with frequent recurrences and metastatic spread. They should be treated by wide local excision. Adjuvant radiation therapy should be strongly considered, and the appropriate neck should be treated either surgically or with radiation. These tumors are often locally aggressive and infiltrative and can metastasize, either to cervical lymph nodes or in a widespread fashion to the central nervous system, bone, liver, and lung. Although many of these reports have short follow-up periods, some of them have documented a protracted course with single or multiple local recurrences and distant metastases. In a recent review of 37 cases with follow-up, almost 85% of malignant oncocytomas developed regional or distant metastases and 32% developed local recurrences. Half of the patients died of disease with the average survival for patients with metastasizing tumors being 3.8 years. Distant metastasis is a poor prognostic sign, with all patients dying of disease. Tumor-related mortality may occur up to a decade after the original diagnosis. Malignant parotid and submandibular oncocytomas usually appear aggressive from the onset; rarely is there evidence of a preexisting benign oncocytoma or oncocytosis.

Locally invasive sinonasal oncocytic tumors appear to follow a low-grade malignant course with multiple recurrences. Three of eight patients developed recurrent disease 3 to 7 years after the initial diagnosis. Two of these patients had multiple recurrences—one at 3 and 10 years, the other at 5 and 7 years. Both of these patients were disease free 1 year after treatment of the second recurrence. It appears that recurrent tumors remain localized, with no attributable deaths due to disease.[98, 223–225]

Oncocytic Papillary Cystadenoma

Oncocytic papillary cystadenoma is a rare lesion that can occur in the parotid gland, although it most often occurs in the larynx. It may represent oncocytic metaplasia and hyperplasia of preexisting salivary gland ductal epithelial rather than a true neoplasm. This lesion is usually a benign rounded cyst. In the parotid gland, it is somewhat of a hybrid between an oncocytoma and a Warthin's tumor.[7]

Basal Cell Adenoma and Basal Cell Adenocarcinoma

Basal cell adenoma (BCA), as defined by the World Health Organization, is a distinctive benign neoplasm composed of basaloid cells organized with a prominent basal cell layer and distinct basement membrane–like material. It

Copyright © 2003, Mosby, Inc. All rights reserved.

lacks the myxochondroid stromal component of pleomorphic adenoma. Although it was first established as a specific entity in the late 1960s, there has been disagreement about the spectrum of tumors belonging to this group and about their proper designation. Many series in the 1970s and 1980s classified these tumors with other nonmixed tumors, including canalicular adenomas, into the category of monomorphic adenomas. In 1991 the World Health Organization separately classified BCA and its malignant counterpart, basal cell adenocarcinoma, as well as canalicular adenoma. BCA accounts for 1% to 2% of all salivary gland epithelial tumors, and over 80% of them arise in the major salivary glands, mostly the parotid gland. Less frequently, these tumors may be found in minor glands, with the upper lip being the most common site, followed by the buccal mucosa. BCAs arise almost exclusively in adults, with the average patient age being 57.7 years, more than a decade older than the average age of patients with pleomorphic adenoma. There is a 2:1 female predominance for most BCAs; however, the membranous variant has an equal male:female distribution. Clinically indistinguishable from pleomorphic adenoma, the typical BCA presents as a mobile superficial parotid tumor.

BCAs present as round to oval, well-encapsulated, soft to firm neoplasms; most measure 3 cm or less in diameter. On cut section, they are typically uniform and solid, without necrosis; however, they can occasionally be cystic. Membranous-type BCAs are noteworthy in that they can be multifocal, with a multinodular growth pattern.

Microscopically, BCAs are benign tumors composed of relatively basaloid cells, a conspicuous basal cell layer, and distinctive basement membrane–like material. Most tumors are well circumscribed and encapsulated, although any of the subtypes may have a multinodular microscopic pattern (Fig. 39-120). BSAs lack the characteristic myxochondroid matrix of pleomorphic adenoma. Based on their architecture, BSAs may be divided into four subtypes: solid, trabecular, tubular, and membranous. The solid variant is most common, and individual tumors commonly display several architectural growth patterns. BCAs are composed of two cell types. The first type, the basaloid cells, are found peripherally, frequently in a palisading arrangement within the cell nests and cords. They are cuboidal or columnar small cells with round, deeply staining nuclei and little discernible cytoplasm. The second cell type, the epithelioid cells, are larger, with modest cytoplasm, indistinct cell borders, and a pale-staining oval nucleus; the nuclei may exhibit small, eosinophilic nucleoli. Larger cells predominate centrally within the epithelial nests, sheets, and trabeculae. The membranous BCA, also known as the dermal anlage tumor, deserves special mention. A small percentage of patients with membranous BCAs may develop multiple dermal cylindromas (turban tumors), trichoepitheliomas, eccrine spiradenomas, trichilemmomas, and basal cell epitheliomas. In contrast to the other subtypes, membranous BCA tends to be multilobulated or multinodular and is often not encapsulated. This explains the high recurrence rate of 25% to 37%, similar to that of dermal cylindroma. Despite its multinodularity, no BCA should demonstrate soft-tissue invasion or perineural invasion. If these features are seen, diagnoses such as basal cell adenocarcinoma (see below) or adenoid cystic carcinoma should be considered.

BCAs are amenable to conservative resection (i.e., superficial parotidectomy). However, recurrence may develop in a significant percentage of patients (25%) with the membranous variant of BCA. Although exceedingly rare, malignant transformation of BCA has been reported.[226, 227]

Basal cell adenocarcinoma (BCAC) is a distinct type of low-grade carcinoma that is the malignant counterpart of BCA. BCAC may arise either de novo or from a preexisting BCA. These tumors account for 1.6% of all salivary gland tumors and 2.9% of malignant salivary gland neoplasms. Almost 90% of cases arise in the parotid gland, where they account for 0.6% of parotid tumors and up to 5% of primary parotid carcinomas. Less commonly, they occur within the submandibular gland, minor salivary glands, or sinonasal tract and, rarely, in the sublingual gland. No gender predominance has been noted. BCAC occurs over a wide age range (third to tenth decades), with a mean age at diagnosis of 60 years. The majority of BCACs arise de novo; however, slightly less than one quarter of cases have been

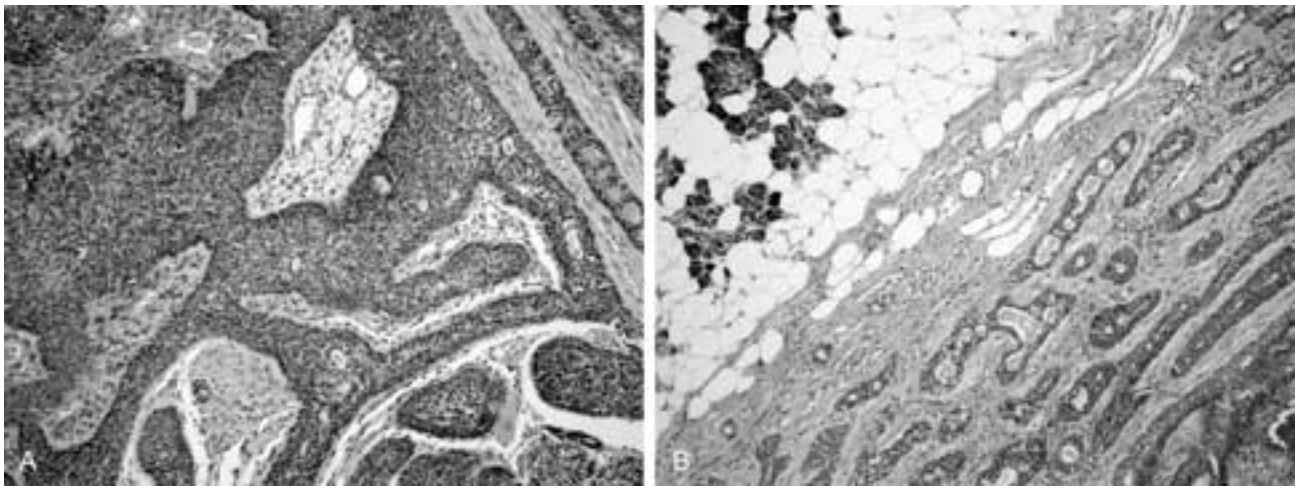

FIGURE 39-120 **A**, Low power reveals an encapsulated parotid mass. **B**, Interconnecting trabeculae of benign basaloid cells with oval nuclei and scanty cytoplasm, with characteristic pallisading. Basal cell adenoma (BCA).

documented to arise within their benign counterpart, the BCA. The presenting symptoms are nonspecific, including a parotid or submandibular mass and occasionally pain. Facial nerve involvement is uncommon. Association with concurrent skin adnexal tumors (especially eccrine cylindromas and trichoepitheliomas) has been noted in 14% of patients with BCAC, which is less frequent than the association of concurrent BCA and adnexal tumors (25% to 35%).

BCAC ranges in size from 0.7 to 7.0 cm. Histologically, BCAC mimics the architectural patterns of BCA: solid, membranous, trabecular, or tubular. The solid pattern, most commonly encountered, has predominantly confluent tumor islands with areas of palisading basaloid cells. Low-power scanning of BCAC reveals the standard features of aggressive neoplasia: infiltration into or destructive overgrowth of surrounding tissue, possible necrosis, and perineural or vascular invasion. Multicentricity is rarely seen in major salivary gland BCAC. Basement membrane hyaline can be quite prominent in the trabecular, membranous, and tubular patterns, with hyaline material deposition dissecting between tumor cells, resulting in a pseudocribriform pattern. Nuclear palisading is frequent at the periphery of the infiltrating nests and islands. Squamous differentiation with keratin pearls can be seen toward the center of islands. Cytologically, BCAC is composed of basaloid cells with oval to round nuclei and usually a high nuclear/cytoplasmic ratio. Mitotic figures and cellular pleomorphism may be marked, although tumors frequently have minimal atypia, with the diagnosis of carcinoma being based on invasive growth and/or perineural or vascular invasion. Perineural and/or intravascular invasion are common, and when they are present in an otherwise typical BCA, the diagnosis of BCAC should be given serious consideration.

BCAC is optimally treated by wide surgical resection with negative margins. With adequate resection, additional therapy is not warranted; however, adjuvant radiotherapy may be used for cases with close or positive resection margins. Elective neck dissection is not warranted. Reported cases of major salivary BCAC with clinical follow-up reveal a low-grade malignant biology. The general impression is that major salivary gland BCAC is less aggressive than adenoid cystic carcinoma. Muller and Barnes culled 45 cases of BCAC with clinical follow-up from the literature that demonstrated a local recurrence rate of 37%, a local metastatic rate of 8%, and a distant metastatic rate of 4%; disease-related mortality occurred in 2% of patients. In addition, Nagao et al. recently reported 11 cases, 10 with follow-up: 50% recurred, none metastasized, and there were no deaths from disease. Minor salivary or seromucinous gland BCACs have a more aggressive course due to the advanced tumor stage at presentation and the inherently poorer resectability of minor salivary gland tumors. Four of 12 patients reported by Fonseca and Soares with intraoral or sinonasal BCAC died of disease within 4 to 7 years.[228–233]

Canalicular Adenoma

Until the World Health Organization's classification in 1991, canalicular adenoma was classified as a variant of BCA or monomorphic adenoma. There are, however, sufficient clinicopathologic and histologic differences between BCA and canalicular adenoma to warrant separate classification.

Canalicular adenoma is a benign neoplasm that arises almost exclusively from the minor salivary glands of the oral cavity, where it accounts for 4% to 6% of minor salivary gland tumors. These tumors commonly affect older patients, with a peak incidence in the seventh decade. Females are more commonly affected than males; the female : male ratio ranges from 1.2 to 1.8 : 1. Clinically, canalicular adenoma presents as a slow-growing, asymptomatic, mobile nodule, most commonly arising in the upper lip (73% to 100% of cases in reported series). It is the second most common upper lip salivary gland tumor after benign mixed tumor. In decreasing frequency of occurrence, these tumors may occasionally arise in the buccal mucosa, lower lip, palate, and major salivary glands. Rarely, canalicular adenoma may present with multiple clinically palpable nodules; metachronous tumors may also be seen. The tumor is usually small at the time of diagnosis, with a mean diameter of 1.7 cm. The overlying mucosa is usually intact and normal; occasionally, it is slightly bluish, mimicking a mucocele.

Microscopically, canalicular adenoma is characterized by a circumscribed or encapsulated tumor composed of interconnecting strands or cords of uniform, single, cuboidal to columnar cells, usually with scanty eosinophilic cytoplasm, oval nuclei with diffuse granular nuclear chromatin, and indistinct borders. The tumor cells form characteristic parallel columns, producing long canaliculi with scattered duct-like or gland-like structures. Because of the absence of myoepithelial cells, the epithelial cells are sharply demarcated from the surrounding stroma. Cellular pleomorphism is minimal, and mitoses, if present, are rare. In addition, occasional tumors have papillary projections into the cystic spaces. The stroma separating parallel rows of cells is delicate, well vascularized, commonly mucoid, and sparsely cellular. Multifocal microscopic foci of canalicular adenoma are common (22% in one series of 49 patients); in these cases, the main tumor frequently is encapsulated, while the smaller foci often are not.

Treatment is complete surgical excision. Recurrence after surgical removal is rare and most likely is due to multifocality rather than true recurrence.[234–236]

Myoepithelioma and Myoepithelial Carcinoma

Myoepithelial cells are integral to the normal functioning of the salivary glands and are common components of benign and malignant salivary neoplasia. The contractions of normal myoepithelial intracytoplasmic myofibrils help express secretions from the salivary glands.[7] Myoepithelial cells are ectodermally derived but can function as mesodermal cells, producing mesenchyme-type products.

Myoepithelioma (benign myoepithelioma) is a rare salivary tumor composed entirely or predominantly of myoepithelial cells; it represents one extreme in the histologic spectrum of pleomorphic adenoma. Generally, if a tumor's composition contains more than 95% of myoepithelial elements, it is classified as a myoepithelioma, whereas if more than 5% of the tumor is composed of epithelial, ductal, or mesenchymal components, it is classified as a myoepithelium-rich pleomorphic adenoma. Myoepitheliomas are rare, accounting for less than 2% of salivary tumors, 2.2% of all major benign salivary tumors, and 5.7% of all benign minor salivary tumors. Approximately half of all cases arise in the parotid gland, 10% in the submandibular gland,

Copyright © 2003, Mosby, Inc. All rights reserved.

and 42% in minor salivary gland sites, most commonly the palate. There is no significant sex predilection. The reported age range is wide: from 6 to 85 years. The most common presentation is that of a slow-growing, asymptomatic mass.

Myoepithelioma is a well-circumscribed or encapsulated tumor. However, those arising on the palate or in other minor salivary gland sites are circumscribed but not usually encapsulated.

Histologically, the tumor is composed of various proportions of spindle-shaped, plasmacytoid, polygonal epithelioid, and, rarely, clear myoepithelial or modified myoepithelial cells commonly arranged in sheets, irregular collections, nests, interconnecting trabeculae, or ribbons. Nuclear pleomorphism is usually minimal; however, similar to mixed tumors, a mild to moderate degree of nuclear pleomorphism and/or atypia may be noted in occasional tumors. Stroma may be minimal or abundant and is usually acellular and mucoid, myxoid, or hyalinized.

Since benign myoepitheliomas are considered to represent one extreme of the histologic spectrum of mixed tumors, the treatment and prognosis are essentially the same as for benign mixed tumors. Patients with these tumors should be treated by complete excision that ensures a tumor-free margin; in minor gland sites this usually involves surgical excision with a rim of normal surrounding tissue.

Occasional myoepithelial tumors can behave in a locally aggressive or malignant fashion. These malignant myoepitheliomas are also referred to as *myoepithelial carcinomas.* Histologically, they appear cytologically and architecturally similar to benign myoepitheliomas. Additionally, however, they are characterized by cellular atypia and/or an infiltrative growth pattern, often with prominent necrosis and mitotic activity, and are capable of metastasis. Seventy cases of myoepithelial carcinoma culled from three series reveal that 64% (45 cases) arose in the parotid gland, 23% (16 cases) in the minor salivary glands sites, most frequently the palate, and 11% (8 cases) in the submandibular gland. Patients' age ranged from 14 to 86 years, with a mean in the sixth decade. A 4:1 male:female ratio was seen in one series, but others revealed a similar sex distribution. The tumors ranged in dimension from 2 to 20 cm and were usually unencapsulated.

These tumors should be considered intermediate to high-grade neoplasms. Treatment consists of wide surgical excision combined with radiation therapy. Tumor recurrence developed in 63% of 46 patients with follow-up, and multiple recurrences were frequent. The mortality rate was 28% (13 patients); 20% (9 patients) were alive with persistent disease, and 37% (17 patients) developed distant metastases, most frequently to the lung. Thirty-three percent (15 patients) were free of disease.[237, 238]

The CT findings show a fairly well defined heterogeneous lesion with smooth margins and slight enhancement. MR images show a mass with intermediate T1-weighted and relatively high T2-weighted signal intensities. The CT and MR studies are nonspecific.[239]

Epithelial-Myoepithelial Carcinoma

As experience with rare salivary tumors accrues, it is becoming increasingly evident that *primary clear cell tumors* (not variants of other known salivary tumors) represent a heterogeneous group of neoplasms. Historically, the entire group of primary salivary clear cell tumors had been referred to as clear cell carcinoma, clear cell adenoma, glycogen-rich adenoma, glycogen-rich adenocarcinoma, and so on. In 1979, Donath et al. described eight cases of a previously unrecognized clear cell tumor of salivary gland origin, which they termed *epithelial myoepithelial carcinoma* (EMEC).[7] However, it was not until 1982 that Corio and colleagues introduced this neoplasm into the English language literature and expounded upon it in their report on 16 cases from the Armed Forces Institute of Pathology series.[240] Prior to that publication, many cases of EMEC referred to in the literature as clear cell carcinoma, glycogen-rich adenoma, and so on. Thus EMEC became recognized as a distinct biphasic tumor forming ductules and glands surrounded by a variable clear cell component of myoepithelial origin and a variable hyaline background.

A literature meta-analysis of 96 patients with EMEC reveals a median age of 67 years and a female:male ratio of 2.4:1. Eighty-three percent of cases occurred in the parotid gland, 6% were intraoral, and 9% arose in the submandibular gland. Patients typically present with slowly enlarging masses, occasionally associated with facial nerve pain or weakness. Grossly, EMECs are well-delineated, firm, bulky tumors that may infiltrate adjacent soft tissue.

Histologically, they are often well circumscribed and may have a single or multinodular growth pattern; they are usually surrounded, at least partially, by a thick, fibrous capsule. They are biphasic tumors with islands, large nests, or sheets of tumor cells composed of scattered small ducts lined by cuboidal epithelium similar to normal intercalated ducts. The ducts are immediately surrounded by varying numbers of clear cells that often, in turn, are surrounded by dense hyalinized basement membrane material. Occasionally, columnar cells and small foci of early squamous metaplasia may be seen proliferating within ductal structures. The clear cell component may also be arranged in solid nests or sheets. The proportion and arrangement of nodular aggregates of the biphasic component and the sheets of clear cells are quite variable from tumor to tumor. In occasional tumors, the clear cell component may predominate and the more typical biphasic portions of the neoplasm may not be readily apparent. Mitotic figures, necrosis, perineural invasion, and, less frequently, intravascular growth may be found. Wide surgical excision is the treatment of choice for this neoplasm.

There is a significant likelihood (60%) of recurrence, which may be multiple and may happen up to two decades after the initial presentation (median 3 years). The rates of metastatic disease and tumor-related mortality are 9% and 9%, respectively, which may also happen after two decades. Metastases have involved regional lymph nodes, as well as hematogenous spread to the lung and kidney.[237, 240–242]

The imaging appearance is nonspecific, but in general these tumors are low-grade, benign-appearing masses, which may be cystic. As such, their imaging findings may be similar to those of a Warthin's tumor (Fig. 39-121).

Clear Cell Carcinoma

Milchgrub and colleagues first distinguished clear cell carcinoma [hyalinizing clear cell carcinoma (HCC)] as

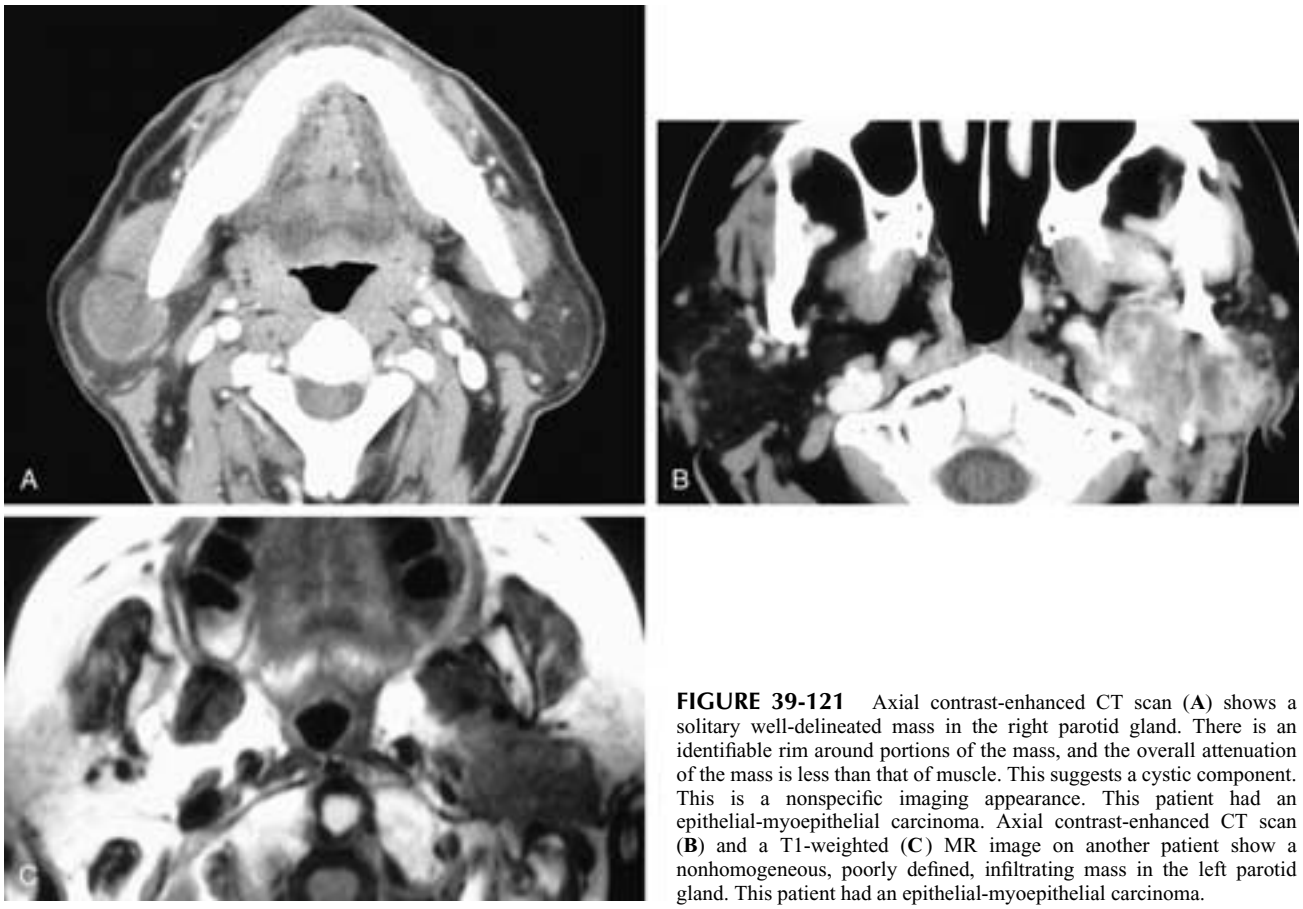

FIGURE 39-121 Axial contrast-enhanced CT scan (**A**) shows a solitary well-delineated mass in the right parotid gland. There is an identifiable rim around portions of the mass, and the overall attenuation of the mass is less than that of muscle. This suggests a cystic component. This is a nonspecific imaging appearance. This patient had an epithelial-myoepithelial carcinoma. Axial contrast-enhanced CT scan (**B**) and a T1-weighted (**C**) MR image on another patient show a nonhomogeneous, poorly defined, infiltrating mass in the left parotid gland. This patient had an epithelial-myoepithelial carcinoma.

VIEW IMAGE

an entity distinct from EMEC.[243] A literature meta-analysis of 103 cases reveals a wide age range (1 to 86 years; median, 52.5 years) and a slight female predominance (female:male ratio of 1.6:1). The majority of cases occur within the oral cavity (65%), usually on the palate, followed by the tongue; 21% of cases occur in the parotid gland. Patients typically present with a painless mass that had been present for months to several years.

Grossly, this tumor has been described as infiltrating and scar-like. Microscopically, clear cell carcinoma is a low-grade carcinoma characterized by nests of clear cells in a densely amyloid-like, fibrous, hyalinizing stroma surrounding cords, nests, sheets, and trabeculae of tumor cells. This hyalinization is not a constant feature, and some tumors may be relatively solid. The tumor cells are characterized as round to polygonal in shape, with clear, periodic acid-Schiff–positive cytoplasm and a high nuclear/cytoplasmic ratio. The nuclei are relatively peripheral, with mild pleomorphism, condensed chromatin, and inconspicuous nucleoli. Ductule formation is not seen.

Surgical resection with negative margins is the recommended treatment. The recurrence rate is 17%, and recurrence can occur up to two decades after initial therapy (median, 84 months). Multiple recurrences are possible. The metastatic rate is 21%, involving cervical lymph nodes, lungs, and soft tissue. Nevertheless, clear cell carcinoma is an indolent tumor, and no direct tumor-related deaths have been described, even after pulmonary metastases.[243–245]

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma (MEC) comprises 2.8% to 15.5% of all salivary gland tumors, 12% to 29% of malignant salivary gland tumors, and 6.5% to 41% of minor salivary gland tumors, representing the most common type of malignant minor salivary gland tumor in most series. About half of the cases occur in the major salivary glands; over 80% of these occur in the parotid gland, 8% to13% in the submandibular gland, and 2% to 4% involve the sublingual gland. In the minor salivary glands, MEC most commonly arises on the palate, but a significant number may also be found in the retromolar area, floor of the mouth, buccal mucosa, lip, and tongue. Rarely, MEC can arise as primary jaw or heterotopic intranodal tumors or as laryngeal, lacrimal, nasal, paranasal sinus, tracheal, or pulmonary tumors. MEC is most frequently seen in the 35- to 65-year age group but may be found at any age. It is the most common malignant salivary gland tumor to arise in children and adolescents under 20 years of age. MEC has a slight predilection for women. The most commonly implicated etiologic factor is radiation; as many as 44% of patients with a history of a radiation-associated salivary tumor developed MEC. Latency periods in this group ranged from 7 to 32 years.

On gross examination, MEC may appear circumscribed but it is seldom encapsulated. High-grade tumors have poorly defined margins and may grossly infiltrate adjacent skin and soft tissues. The cut surface ranges from gray to tan-yellow to pink, and cystic features are common and may

Copyright © 2003, Mosby, Inc. All rights reserved.

be prominent. The tumors usually range in size from 1 to 4 cm in their greatest dimension; however, occasional patients may present with larger tumors (over 12 cm).

Microscopically, MEC is composed of varying proportions of epidermoid cells, mucus-secreting cells, and cells intermediate between the other two cell types. Intermediate cells include the smaller basal cells, as well as larger cells that are differentiating toward squamous and mucin-secreting cells. Clear cells, many of which contain glycogen and/or mucin, are present in most MECs and often are a prominent feature. Tumors, especially low-grade neoplasms, frequently have distinct columnar cells containing intracellular mucin (goblet-like cells). Epidermoid cells have abundant eosinophilic cytoplasm and are occasionally associated with keratin production, including pearl formation. A given tumor may have a large variety of cell types. Cellular pleomorphism and atypia may be found and range from minimal to severe (Fig. 39-122).

Traditionally, MECs were classified histologically as low, intermediate, and high-grade based on the relative proportions of cell types. Other suggested grading criteria have included the degree of tumor invasiveness, anaplasia, the pattern of invasion, the degree of maturation of the various cellular components, mitotic rates, the presence or absence of necrosis, neural or vascular invasion, and the proportion of tumor composed of cystic spaces relative to solid growth. Grading of MEC is subjective, with different criteria used in various series. Auclair et al. established a set of more uniform histologic criteria that correlated with the clinical outcome.[246] Brandwein and colleagues have recently shown that this grading system, while enhancing reproducibility, tends to ''downgrade MEC,'' and they have proposed further refinements to this weighted grading criteria[247] (Table 39-5).

Treatment planning for MEC starts with a preoperative biopsy and diagnosis. However the issue of preoperative grading is often raised with respect to treatment planning. The major decision point here would be grade I MEC versus grade II/III MEC, as a grade I tumor would have no (or minimal) likelihood of requiring addition lymph node dissection. Lymph node dissections are included as standard therapy for grade III tumors, and grade II tumors are left to the surgeon's discretion. However, it is difficult to establish the tumor grade on a preoperative biopsy specimen due to the possibility of sampling error. Thus these biopsy specimens are often graded as MEC ''at least grade I'' or ''at least grade II,'' allowing for final grading after excision.

Prognosis is a function of the histologic grade, adequacy of excision, and clinical staging. Complete surgical excision is the treatment of choice for MEC. Adequate excision is important for all grades of tumor, with much higher recurrence rates reported for tumors with positive surgical margins (on the order of 50% for low- and intermediate-grade tumors and slightly over 80% for high-grade tumors). Adjuvant radiation therapy should be added for high-grade tumors and for patients with residual microscopic disease at the surgical margins.

Patients with low-grade tumors have a 5-year survival rate of 90% to 100%; with the exception of submandibular gland tumors, these tumors have been reported to recur or metastasize, albeit rarely. Metastatic, recurrence, and death rates from low-grade submandibular gland tumors have been reported as 13%, 9%, and 13%, respectively. Spiro et al. also found more frequent metastases from submandibular gland MEC than from other major gland sites; however, other series have not confirmed this association.[7] This may be a technical issue: when resecting the submandibular gland, surgeons may be more inclined to hug the capsule for

Table 39-5
GRADING OF MUCOEPIDERMOID CARCINOMA

	Characteristic Features	Defining Features
Grade I	Prominent goblet cell component Cyst formation Intermediate cells may be prominent Circumscribed growth pattern	Lack of grade III defining features Lack of aggressive invasion pattern

FIGURE 39-123 Axial CT scan shows a nodular mass in the right parotid gland. The mass has cystic areas within it, and the medial wall of the lesion is nodular and slightly unsharp as it merges with the adjacent parotid gland. This patient had a low-grade MEC.

fear of damaging the marginal mandibular nerve. Thus there is usually less of a cuff of surrounding normal tissue compared to the parotid gland. Therefore any tumor of the submandibular gland, irrespective of grade, should be treated aggressively.

Intermediate- and high-grade tumors have a greater tendency to infiltrate, recur, and metastasize. For intermediate-grade tumors, Healy reported a recurrence rate of 20%. Brandwein et al.[247] reported a recurrence rate of 30%, a rate of metastasis to cervical lymph nodes of 18%, and a disease-related mortality rate of 5%. For high-grade tumors, Brandwein et al.[247] reported a recurrence rate of 70%, a rate of metastasis to cervical lymph nodes of 63% and to distant sites of 6%, and a disease-related mortality rate of 63%. Survival is improved for tumors arising in younger patients and among females but is poorer in patients over 60 years of age. In a recent study, Plambeck et al. reported 5- and 10-year survival rates of 91.9% and 89.5%, respectively, regardless of tumor grade.[253] Stage appeared to be a better prognosticator: all patients who died had stage 3 or 4 disease with 5- and 10-year survivals for this group of 63.5% and 52%, respectively.[246–253]

The CT findings of mucoepidermoid lesions vary with the grade of the tumor (Figs. 39-123 to 39-129). Low-grade lesions are benign in appearance, with apparently well-delineated, smooth margins. Cystic areas may be present, with a low attenuation of 10 to 18 HU (Figs. 39-123, 39-124 and 39-126). Rarely, focal calcification may be seen. The appearance is similar to that of a benign mixed tumor. On MR imaging, these low-grade tumors also have signal intensities that are indistinguishable from those of pleomorphic adenomas. By comparison, the high-grade lesions have indistinct infiltrating margins and may destroy salivary ducts (Fig. 39-128). On CT they usually have few cystic areas, and they tend to be more homogeneous in appearance than the low-grade tumors. On MR imaging, these cellular tumors tend to have low to intermediate signal intensities on both T1-weighted and T2-weighted images (Fig. 39-129).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (AdCC) accounts for 2% to 6% of parotid gland tumors, 12% of submandibular gland tumors, 15% of sublingual gland tumors, 30% of minor salivary gland tumors, and 50% of lacrimal gland tumors.[7, 194, 254–256] Overall, 4% to 8% of all salivary gland tumors are adenoid cystic carcinomas, and they occur most commonly in the parotid gland, the submandibular gland, and the palate. AdCC occurs over a very wide age range, from the first to the ninth decades of life, but with a preponderance in the fourth to seventh decades. The female:male ratio is approximately 3:2.

Typically, AdCC is a slow-growing, widely infiltrative tumor with a tendency toward perineural spread. Patients present with symptoms of pain and a mass that may have evolved over several years. Mucosal ulceration, especially of the palate, is common. Occasional tumors present with intracranial involvement, closely mimicking a meningioma clinically and radiographically; rarely, a tumor may have an occult presentation. Table 39-6 presents a compilation of tumor sites for AdCC derived from over 1600 cases. The parotid gland, palate, submandibular gland, and sinonasal tract are the most commonly affected upper aerodigestive tract sites; minor salivary sites are more frequently involved than all the major salivary glands combined. AdCC is the second most frequent malignant tumor of the trachea after squamous carcinoma; 45.5% of patients have tumors in the upper trachea. At this site, the male:female ratio is almost 1:1, and the average age at presentation is between 45 and 60 years (range, 15 to 80 years).

Grossly, these tumors are firm and gray-white, and can appear as subtle scar-like lesions. Smaller tumors may be circumscribed or, rarely, encapsulated. They have a tendency to extend along nerves, and ''skip lesions'' may be seen considerable distances away from the main tumor mass.

The World Health Organization's classification divides AdCC into the following microscopic patterns: tubular, cribriform (glandular), and solid. The cribriform type is the

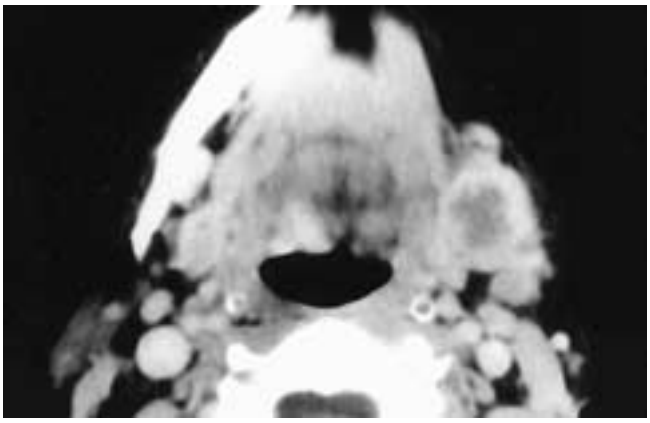

FIGURE 39-124 Axial CT scan shows a necrotic mass in the left submandibular gland. The tumor has a thick, irregular rim and an infiltrative outer contour. This patient had a high-grade MEC.

VIEW IMAGE

most frequent pattern observed; the solid pattern is least common. Adenoid cystic carcinomas are composed of two types of cells: ductal and abluminal myoepithelial. Cytologically, they are composed of a somewhat uniform, bland population of cells with oval basophilic nuclei with a homogeneous chromatin distribution, and usually with little cytoplasm, reminiscent of basal cell carcinoma of the skin. The nuclei are frequently angulated and rarely have coarse chromatin and prominent nucleoli (Fig. 39-130). While these latter two features are more likely to occur in the solid high-grade tumors, high-grade cytology may occasionally be seen with intermediate-grade tumors. A mixture of architechtural patterns is common, and grading depends on the predominant pattern. If a tumor has more than 30% of the solid pattern, it is classified as the solid variant. The tubular pattern (well differentiated or grade I) is characterized by slender tubules, solid cords, and glandular structures infiltrating a well-hyalinized background. These tumors are composed of myoepithelial cells often surrounding central lumina forming epithelial structures. The cribriform pattern (moderately differentiated or grade II) is characterized by invasive tumor islands with multiple ''holes'' (pseudocysts or pseudolumina) punched out in a ''Swiss cheese'' or sieve-like pattern. The solid pattern (poorly differentiated or grade III) consists of large islands of carcinoma composed predominantly of myoepithelial cells with infrequent true lumina lined by cuboidal epithelial cells, with only occasional punctuation by pseudocysts. Perineural spread is a feature common to all patterns. Mitotic figures and apoptotic cells are occasionally present in intermediate-grade tumors and are common to high-grade tumors. Necrosis is seen usually only in the solid pattern.

Pathologists are often reluctant to diagnose AdCC on the basis of a limited biopsy, especially in the absence of definite tumor infiltration. The cribriform pattern so typical of AdCC may also be seen rarely in BCA, in mixed tumors, and in polymorphous low-grade adenocarcinomas. The diagnosis of minor salivary gland tumors based on limited biopsy material is especially challenging, as benign minor salivary tumors are rarely encapsulated but are well circumscribed.

On imaging, these tumors may appear either as a benign or a malignant process (Figs. 39-131 to 39-135). The parotid lesions tend to appear as benign, well-delineated tumors, while the minor salivary gland neoplasms usually have malignant infiltrative margins. Retrograde tumor extension to the skull base often occurs via the facial nerve or the mandibular nerve. Although this neural invasion may be demonstrated by CT, it is more consistently and more reliably identified on MR imaging. On contrast CT, a grossly

widened nerve may be seen in a widened bony neural canal and obliterating the normal fat present at the extracranial opening of these canals (see Chapter 13). MR imaging is more sensitive than CT in detecting lesser degrees of neural tumor invasion, and on contrast MR imaging, nerve enhancement can be identified, often in a minimally enlarged nerve (Fig. 39-134). MR imaging has proven to be especially useful when evaluating postoperative recurrences (Fig. 39-135). Clinically, these patients most often have had

a prior total parotidectomy and return with pain either in the postoperative bed or in the skull base. The examination of choice should be a contrast MR imaging study that at least includes coronal scans of the base of the skull.

Wide surgical resection with negative margins is the standard primary therapy. Adjuvant radiotherapy is usually indicated for most tumors; however, some would argue that well-resected T1 AdCC may not require adjuvant radiotherapy. Primary conventional radiotherapy has never been shown to provide sufficient local disease control. However, there are emerging data suggesting that neutron therapy, which involves larger particles of greater energy, can achieve reasonable local control as a primary therapeutic modality. Also, adoptive immunotherapy in combination with chemoradiotherapy has recently shown promising results. Larger series with more patients are necessary to confirm these preliminary data.

AdCC has been noted to have a greater local recurrence rate compared to other malignant salivary tumors (p = 0.0059). This propensity for local recurrence (up to 62%) is highest within the first 5 years, but a significant number of patients develop local recurrence after 10, 15, and 20 years.

FIGURE 39-132 Axial contrast-enhanced CT scan shows a necrotic mass in the right parotid gland with poorly defined margins. Multiple tumor nodules are seen along the wall of the lesion. This appearance suggests a high-grade tumor. This patient had an AdCC. This is a more aggressive tumor than most of these parotid adenoid cystic carcinomas.

Actuarial local control rates at 5, 10, and 15 years of 95%, 86%, and 79%, respectively, have been reported. Distant metastases are much more frequent than local lymph node metastases. The rate of development of distant metastases is 40% to 50% for all adenoid cystic carcinomas, and these metastases may occur 10 to 108 months (median, 96) after initial diagnosis. Approximately 3% to 8% of patients have metastases at initial presentation. Tumors most frequently metastasize to lung and, less frequently, to bone and soft tissues. Distant metastasis usually occurs in conjunction with local recurrence but may develop in the absence of locoregional disease; it was the most common type of treatment failure in one recent series.

Spiro reported disease-free intervals after adequate primary therapy ranging from 1 month to 19 years (median, 36 months) and disease-free intervals of more than 10 years in 9 of 113 patients (8%).[262] Survival with distant metastases was less than 3 years in 54% but more than 10 years (with a maximum of 16 years) in 10% of patients. A recent series from the MD Anderson Cancer Center of 160 patients using consistent surgery and radiation therapy in 87.5% of patients yielded survivals at 5, 10, and 15 years of 89.0%, 67.4%, and 39.6%, respectively. Treatment failure was documented in 37% of patients ranging from 2 months to 19 years. Eight percent failed locoregionally, 22% failed distantly, and 7% had both locoregional and distant failures. Major (named) nerve invasion, positive margins, and solid histologic features predicted treatment failures, while nodal metastases, major nerve involvement, solid histologic features, and four or more symptoms present at diagnosis were associated with increased disease mortality.

Surgical prognosticators in other series include tumor

grade, stage, site, nerve involvement, and resection margins. A number of studies confirm that the grading system, based on the pattern of differentiation and tumor stage, correlates with survival for adenoid cystic carcinoma. When grade is considered as a prognosticator, the cumulative survival at 5, 10, and 15 years is 92%, 65%, and 14%, respectively, for grade I tumors; 76%, 26%, and 5% for grade II tumors; and 39%, 26%, and 5% for grade III tumors. Tumor site is another important prognosticator: generally, major salivary gland sites have a more favorable outcome than minor salivary gland sites. AdCCs of the trachea have a better prognosis than their counterparts in the upper respiratory tract, with 5-year survival ranging between 66% and 100% and 10-year survival ranging between 50% and 75%. These data are summarized in a recent review by Azar and colleagues. Sites such as the sinonasal tract are inherently less resectable and have the worst prognosis. Spiro and Huvos have shown that tumor stage is a better prognostic discriminator than tumor grade. This fact has been underappreciated, as AdCCs are not commonly encountered as stage I tumors. Patients with stage I tumors had a lower rate of local recurrence (23%) than those with stage II to IV tumors (60%). Their cumulative 10-year survival rates per stage were 75% (stage I), 43% (stage II), and 15% (stage III/IV). Histologic grade did have an impact on survival early in the disease course; one third of recurrences were evident within 1 year for intermediate- and high-grade tumors, whereas only 14% of low-grade tumors recurred within 1 year.

VIEW IMAGE

FIGURE 39-135 Coronal T1-weighted MR image of a patient who previously had had a right parotidectomy. The recurrent tumor has grown from the parotid bed up along the auriculotemporal nerve to the third division of the trigeminal nerve and then via the foramen ovale it invades the right cavernous sinus (*arrow*). This patient had recurrent AdCC. (From Som PM, Braun IF, Shapiro MD, et al. Tumors of the parapharyngeal space and upper neck: MR imaging characteristics. Radiology 1987;164: 823–829.)

Garden et al. reported on 83 patients (42%) with microscopic positive margins and 55 patients (28%) with close margins (defined as 5 mm or less) or uncertain margins. Perineural spread was seen in 69% of cases, and invasion of a major (named) nerve occurred in 28% of patients. Local recurrences developed in 18% of patients with positive margins compared to 9% of patients with close or uncertain margins and 5% of patients with negative margins ($p = 0.02$). Patients with a major (named) nerve involvement had a crude failure rate of 18% (10 out of 55) compared to 9% (13 out of 143) for patients without major nerve involvement ($p = 0.02$).

DNA ploidy has shown promise as a prognosticator and may be especially helpful in the preoperative planning phase. Franzen et al. studied 51 AdCCs and found that 39 tumors were diploid and 12 were aneuploid. Grade III tumors were more often associated with aneuploidy than grade I and II tumors ($p = 0.011$), and ploidy also correlated with clinical stage ($p = 0.011$). The authors found that the combination of an S phase greater than 6% and aneuploidy is a sensitive predictor of treatment failure. Recently, Franchi et al. found that E-cadherin statement was a prognostic marker of the disease-free interval and survival in AdCC, independent of clinical stage and other histopathologic parameters. Reduced statement correlated with shorter disease-free intervals and actual survival rates.[257–267]

Acinic Cell Carcinoma

Acinic cell carcinoma (ACC) comprises 7% to 17.5% of all salivary malignancies and 10% to 30% of primary parotid malignancies. The vast majority (90%) of ACCs arise in the parotid gland. The minor salivary glands are the second most common site, usually the upper lip, buccal mucosa, and palate. ACC rarely affects the submandibular and sublingual glands. Given that ACC of the submandibular gland is rare, the surgeon should be directed to investigate the deep parotid lobe, where the primary tumor may be identified. The reported age range for patients with ACC is 3 to 91 years; the female:male ratio is approximately 2:1. Interestingly, the average age at diagnosis, 38 to 46 years, is nearly a decade younger than that of patients with other parotid malignancies. After MEC, ACC is the second most common malignant salivary gland neoplasm of childhood. ACC is the third most common bilateral salivary gland tumor after Warthin's tumor and pleomorphic adenoma. It is the most frequent malignant tumor to present bilaterally. Nearly all patients present with a mass; up to 50% also complain of facial pain. However, facial nerve involvement with paresis or paralysis is less common at presentation, seen in up to 7.5% of patients.

Grossly, the typical ACC appears as a circumscribed, tan-gray, rubbery mass and may be cystic. Recurrent tumors can be multinodular. There are four principal histologic patterns: solid, microcystic, papillary-cystic, and follicular; however, a mixture of patterns is common. Microscopically, ACCs characteristically grow as solid sheets of basophilic serous cells. The tumor cells recapitulate the serous acinar cells of the normal parotid gland and contain cytoplasmic zymogen granules, the packaged secretory product of acinar cells. These granules are responsible for the tumor's prominent cytoplasmic basophilia.

Surgical excision with negative margins is the goal of primary treatment. Superficial lobectomy is adequate for the majority of parotid tumors. However, for those involving the deep lobe, total parotidectomy is necessary. Elective neck dissection is not indicated. Recurrences tend to be multiple and require rigorous surgical reexcision.[40, 41] Most studies suggest that radiation therapy is of little utility in the treatment of ACC.

ACC is capable of a notoriously protracted clinical course. Disease-free and determinate survival curves do not level off for a decade. Five-year survival ranges from 76% to 90% and drops to 44% to 67% beyond 15 years. The expected rates of recurrence, metastasis, and mortality after adequate resection are approximately 30%, 13%, and 13%, respectively. Patients may succumb to progressive locoregional or metastatic disease. The latter may occur by either lymphatic and/or hematogenous lymphatic spread. Lung and bone are the most common sites of hematogenous spread. Long-term survival is possible after documentation of metastatic disease.[268–277]

The clinical stage at presentation gives the most prognostic information. Accordingly, metastases, large tumor size, deep lobe parotid involvement, and tumor multinodularity are all associated with a poor clinical outcome.

The imaging characteristics of these tumors are nonspecific, with most lesions having a generally benign appearance, often occurring on CT and MR imaging as a pleomorphic adenoma.

Polymorphous Low-Grade Adenocarcinoma and Low-Grade Papillary Adenocarcinoma of Salivary Origin

Polymorphous low-grade adenocarcinoma (PLGA) was first described in the 1980s by Freedman and Lumerman as lobular carcinoma, and by Batsakis and coworkers as terminal duct carcinoma. Evans and Batsakis subsequently coined the term polymorphous low-grade adenocarcinoma to describe this low-grade salivary malignancy, which usually occurs at minor salivary gland sites. It is the second most common intraoral malignant salivary gland neoplasm after MEC, accounting for 26% of carcinomas. Approximately 60% of the cases involve the palate, and most of the other cases occur at other intraoral sites. PLGA can rarely arise in the major salivary glands. There is a 2:1 female:male ratio, and most affected patients are in their fifth to eighth decade of life. Patients usually present with firm, elevated, painless, nonulcerated masses that range from 0.6 to 6 cm in maximum dimension.

Histologically, PLGA is characterized by an infiltrative growth pattern, histologic blandness, cytologic uniformity, and cellular organizational diversity, hence the descriptor *polymorphous*. PLGA is unencapsulated but is characterized by an infiltrative growth pattern. The tumor cells are arranged in varied patterns ranging from sheets, interconnecting cords, small tubules, solid islands, ducts, and cystic and cribriform areas to other foci having a characteristic infiltrating ''Indian file'' pattern (Fig. 39-136). Tumors commonly invade adjacent soft-tissue and salivary gland lobules and may infiltrate adjacent bone; perineural growth is common and is as frequent in PLGA as in AdCC. The overlying surface epithelium is usually intact but may be ulcerated. Mitoses may be present but are usually sparse. Atypical mitotic figures are usually not found, and necrosis is usually not seen. The absence of these two features aids in distinguishing PLGA from AdCC. Two recent studies have also shown that the proliferative rates (^{67}Ki) for PLGA and AdCC are quite different, with little or no overlap in their ranges, which may also be useful in distinguishing these two tumors.

Some authors consider low-grade papillary adenocarcinomas arising in the palate to be a subtype of PLGA. These tumors are histologically different and distinctive from PLGA because they lack the pleomorphic growth patterns and contain almost exclusively papillary and cystic structures (PLGA may have papillary-cystic foci, but the

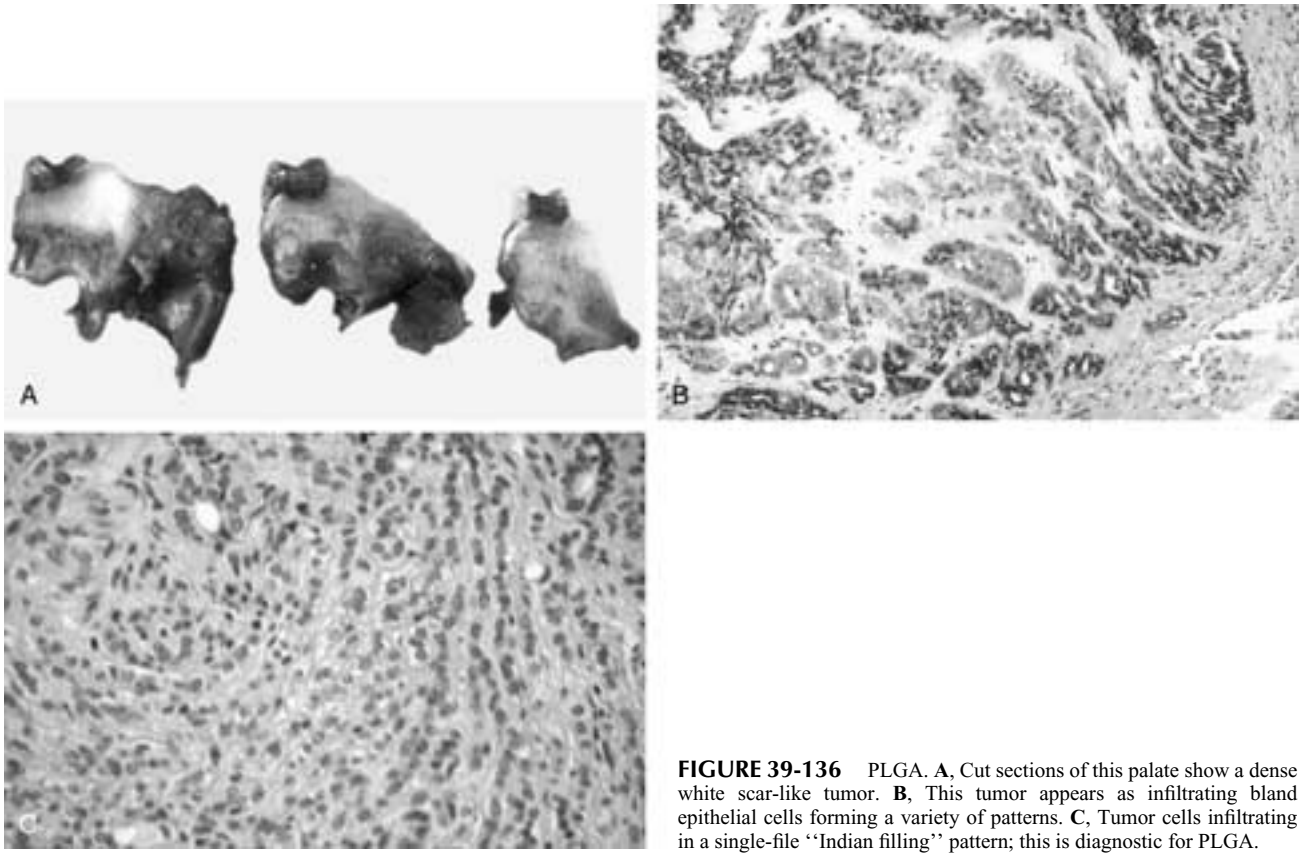

FIGURE 39-136 PLGA. **A**, Cut sections of this palate show a dense white scar-like tumor. **B**, This tumor appears as infiltrating bland epithelial cells forming a variety of patterns. **C**, Tumor cells infiltrating in a single-file ''Indian filling'' pattern; this is diagnostic for PLGA.

VIEW IMAGE

predominant growth pattern is not papillary.) They are also more aggressive biologically and therefore are more properly classified under the designation of papillary cystadenocarcinoma, which we prefer, or low-grade papillary adenocarcinoma.

Treatment consists of wide local surgical excision with possible adjuvant radiation therapy for insufficient margins or for recurrent tumors, although the literature indicates that the majority of recurrences are controlled by surgical reexcision alone. A lymph node dissection is indicated in the presence of cervical lymphadenopathy. Overall survival of patients with PLGA is excellent. The tumor behaves in an indolent fashion but may locally recur in 9% to 17% of patients. The rate of metastasis to cervical lymph nodes is low (varying from 0% to 9%). Two patients have been reported with pulmonary metastases, and to date, only three persons have died from PLGA.[278–287]

The imaging features are nonspecific and are similar to those of AdCC.

Salivary Duct Carcinoma (Plus Low-Grade Salivary Duct Carcinoma)

Salivary duct carcinoma (SDC) is a clinicopathologically distinct salivary tumor that gained wider recognition in the middle to late 1980s. Over 150 cases have been described, and some demographic features have emerged: there is a distinct male predominance (at least 4:1), most patients present after the age of 50 years, and the parotid gland is the most common site of origin. Occasionally SDC has been reported from the submandibular and sublingual glands and from minor salivary gland sites.

Grossly, tumors are usually firm, solid, tan, white, or gray, with a variable cystic component. Infiltration into the surrounding parenchyma is usually obvious, but occasional tumors may appear to be circumscribed. Microscopically, SDC can be subclassified as either high-grade or low-grade, infiltrative, or predominantly (>90%) intraductal.

The *high-grade* infiltrative tumor was the entity first recognized and reported, as it is the one most commonly encountered, representing more than 90% of cases. High-grade SDC resembles grade II and III intraductal and infiltrating breast ductal carcinoma both architecturally and cytologically. Comedonecrosis within ducts, a ''Roman bridge'' formation, and an intraductal cribriform pattern are typically seen. Perineural spread (60% of cases) and intravascular tumor emboli (31% of cases) are common. Cytologically, these cells have abundant light pink cytoplasm and large pleomorphic nuclei with prominent nucleoli and coarse chromatin. Mitotic figures are usually abundant (Fig. 39-137).

The cytologically *low-grade variant* was recognized and reported by Delgado and coauthors and by Tatemoto in 1996. Unlike the more frequent and familiar high-grade tumor, low-grade SDC has smaller cells with finely dispersed chromatin and small nucleoli, and may have apocrine-type cytoplasmic microvacuoles that may indent the nuclear contour. The cytoplasm may contain fine yellow to brown pigment, and the cytoplasmic membranes

FIGURE 39-137 **A**, SDC. This tumor is reminiscent of breast carcinoma in its tendency to form ''comedonecrotic'' foci (*N*). **B**, High- power view of pleomorphic epithelial tumor cells forming a ''sieve-like'' cribriform pattern (**C**).

may be indistinct. The papillae can contain fibrovascular cores. Mitotic figures are negligible, and necrosis is minimal.

There have also been some reports suggesting that purely *intraductal* or *minimally invasive SDC* might be associated with an improved prognosis. The intraductal lesions may be seen in multiple, enlarged, adjacent ducts, resulting in a crowded appearance. In a purely intraductal tumor, the surrounding basement membrane and fibrous tissue of the large ducts are still intact and discernible.

High-grade SDC is one of the most aggressive salivary malignancies, and therefore should be treated with wide surgical excision combined with radiation therapy and possibly with chemotherapy. In addition, because of the high risk of cervical nodal metastases (59%), the neck should be treated with a lymph node dissection or by radiation. Barnes et al. compiled 104 cases of SDC from the literature, concluding that 33% of reported patients developed local recurrence and 46% developed distant metastasis. Sites for distant metastasis (in decreasing order of occurrence) include lungs, bones, liver, brain, and skin. Sixty-five percent of patients die of disease between 5 months and 10 years of diagnosis, usually within 4 years. The clinical course is characterized by distant metastases early in the course of the disease.

For *low-grade, in situ*, or *minimally invasive tumors*, wide resection with negative margins is recommended. Adjuvant therapy can be withheld, with watchful waiting. Estrogen receptor positivity is an infrequent finding, so antiestrogen adjuvant therapy is generally not an option.

Of the six patients reported by Delgado et al. with low-grade SDC, all were disease-free at 2 to 12 years of follow-up (mean, 7 years). Of the two patients in Brandwein et al.'s original report with long disease-free survival, one could be classified as having low-grade SDC and was disease free after 5 1/2 years of follow-up. To date, the low-grade variant appears to have a much better prognosis than the higher-grade variant. However, data on additional cases are necessary to confirm this trend.[288–294]

The imaging picture, although nonspecific, is that of a high-grade, infiltrating mass.

Adenosquamous Carcinoma and Basaloid Squamous Carcinoma

Adenosquamous carcinoma (ASC) and basaloid squamous carcinoma (BSC) are actually variants of mucosa-based squamous cell carcinoma (SCC), with a predilection, in the upper aerodigestive tract, for the base of the tongue and the hypopharynx.[295] However, clinically, radiologically, and even histologically they bear a resemblence to salivary tumors; therefore, they are included in this discussion.

Their clinical appearance is distinct from that of SCC. The typical white to red, firm, exophytic mucosal component seen in the usual SCC is lacking in BSC and ASC. Rather, these tumors appear to be entirely submucosal and possibly ulcerated, just like a typical salivary malignancy.

Histologically, BSC is made up of small cells with a high nuclear/cytoplasmic ratio forming glands, either with a cribriform and pallisading (hence the term *basaloid*) appearance reminiscent of either an AdCC or a small cell–type carcinoma. The strong tendency toward perineural infiltration seen in AdCC is lacking in BSC. The other tumor, ASC, produces typical glands of adenocarcinoma without the features of MEC, SDC, or other salivary malignancies. Carcinoma-in-situ of the overlying mucosa, which would be consistent with squamous origin, is focal. Carcinoma-in-situ is not seen in the mucosa overlying a salivary malignancy. Sometimes many histologic sections are necessary to reveal this; at other times, one may assume that any in-situ changes have been abolished by the mucosal ulceration. Keratin pearls are also focally seen in these tumors and again point to squamous differentiation.

The tumors reported to date generally have been aggressive, and survival has been dismal.[296–298] The question has been raised as to whether these tumors may represent more aggressive variants of SCC. It appears, though, that when stage, tumor site, and treatment are matched with those of typical SCC, the prognoses of both are similarly poor. One can conclude, however, that BSC and ASC rarely present as T1 or T2 tumors.[299, 300]

Sebaceous Neoplasms of Salivary Gland Origin

Salivary sebaceous neoplasia can be classified into five categories: sebaceous adenoma, sebaceous lymphadenoma,

Copyright © 2003, Mosby, Inc. All rights reserved.

sebaceous carcinoma, sebaceous lymphadenocarcinoma, and finally, sebaceous differentiation within other tumors. Although benign sebaceous differentiation of the parotid and submandibular glands is relatively common, primary sebaceous tumors are extremely rare here. Approximately 149 primary sebaceous salivary tumors have been reported: 24 sebaceous adenomas, 40 sebaceous lymphadenomas, 29 sebaceous carcinomas, 3 sebaceous lymphadenocarcinomas, and 53 other tumors with sebaceous differentiation.[301–303]

Sebaceous adenomas are rare benign tumors, comprising less than 0.1% of all salivary gland neoplasms and less than 0.5% of all salivary adenomas. The mean age at initial clinical presentation is 58 years (range, 22 to 90 years); the male:female ratio is approximately 1.6:1. Half of the tumors reported originated in the parotid, two were from the submandibular gland, and seven were at minor salivary intraoral sites. These tumors are commonly encapsulated or circumscribed. Microscopically, they are composed of sebaceous cell nests with minimal atypia, pleomorphism, and no invasive tendency. Sebaceous cells are characterized by their small nuclei and abundant clear cytoplasm. The cytoplasm has tiny bubbles that indent the nuclei, which aid in the distinction from other salivary clear cells. Sebaceous adenomas are cured by surgical excision.

Sebaceous lymphadenomas are rare benign tumors composed of well-differentiated nests of sebaceous glands within a lymphoid background. As with adenomas, there is minimal atypia and no invasion. These tumors appear to arise from sebaceous nests within lymph nodes, analogous to the pathogenesis of Warthin's tumors. Most tumors arise in older individuals, with no gender predominance. The vast majority of cases reported arose in the parotid gland. Sebaceous lymphadenomas are usually encapsulated and can be solid or cystic. Cheesy sebum is commonly found in many cystic tumors. Complete surgical excision is curative.

Sebaceous carcinoma is the malignant counterpart of sebaceous adenoma. These tumors have been reported with a biphasic age distribution with a peak incidence (the third decade and the seventh and eighth decades), with no gender predominance. The majority of cases arise in the parotid gland. Patients most frequently present with a painful mass, with varying degrees of facial nerve paralysis and occasional fixation to the skin. Tumors can be well circumscribed or locally infiltrating. Histologically, there is more pronounced pleomorphism and atypia than in the benign counterparts, and necrosis and perineural invasion can be seen. The treatment of choice is complete surgical excision with negative margins when feasible. Adjunctive radiation therapy is recommended for higher-stage and high-grade tumors. The overall 5-year survival rate is 62%.[304]

Sebaceous lymphadenocarcinoma is the malignant counterpart of sebaceous lymphadenoma and is the rarest salivary sebaceous tumor. Only three cases have been reported.[301, 302, 305] These carcinomas are locally invasive. Histologically, one sees foci of sebaceous lymphadenoma intermixed with pleomorphic carcinoma. These tumors should be treated with wide local excision, with possible adjuvant radiation therapy. Available follow-up information is minimal, but pulmonary metastasis did occur in one patient.

Primary Squamous Cell Carcinoma

Primary squamous cell carcinoma (SCC) of the parotid and submandibular glands is extremely rare. The reported incidence of primary parotid SCC ranges from 0.3% to 8.9% of all parotid tumors and from 2.1% to 11.4% of all submandibular gland tumors.[306, 307] The diagnosis of primary parotid SCC requires the exclusion of possible metastases from skin of the upper face and scalp or from the upper aerodigestive tract. Direct extension from the external auditory canal or overlying skin SCC must also be excluded, as well as other primary parotid tumors with squamous elements (high-grade MEC and SDC). The diagnosis of primary submandibular SCC requires the exclusion of direct extension from SCC of the floor of the mouth or extension from metastasis to level I lymph nodes. Rarely, SCC arises in an accessory parotid duct, sublingual gland, or minor salivary ducts. These latter tumors have not received any attention in the literature and are treated as routine upper aerodigestive tract SCCs. Primary parotid SCC is much more common than primary submandibular SCC.[308, 309] Male predominance is seen, and most cases occur after the fifth decade. An association with previous irradiation has been noted.

Histologically, salivary SCC is similar to other upper aerodigestive tract SCCs. However, in situ ductal dysplasia can be seen and is helpful in establishing the diagnosis of a primary neoplasm. On the other hand, its absence does not obviate the possibility of a primary tumor. The pathologic differential diagnosis includes MEC, SDC, carcinoma ex pleomorphic adenoma, and carcinoma ex benign lymphoepithelial lesion (the Eskimo tumor; see the next section). We have recently seen a case of primary parotid SCC with extensive perineural spread. This man presented with a dermal SCC and slight facial nerve palsy. The dermatologist erroneously concluded that the dermal SCC was unrelated to the facial nerve palsy and commenced Mohs surgery. The patient underwent this surgery for 3 days without achieving negative margins. He was transferred to our institution, where a parotidectomy and temporal bone resection were performed. A 1-cm SCC was present in the deep lobe of the parotid gland. Extensive perineural spread was found, which explained the dermal satellite as well as the failure to obtain clear resection margins. Of note, the surrounding skin did not reveal actinic damage, which speaks against the possibility of a dermal primary.

Patients have been treated either with primary surgery or with combined surgery and radiation therapy. Disease course and survival are dictated, as with almost all salivary tumors, by tumor stage and grade. Elective neck dissection appears to be warranted, as there is a significant rate of lymphatic spread. Gaughan et al. reported a 50% survival rate at 5 years, while the Memorial Sloan Kettering group reported survival at 5, 10, 15, and 20 years to be 21%, 15%, 13%, and 10%, respectively.[306, 307]

On imaging, these are infiltrating, often partially necrotic tumors (Figs. 39-138 to 39-142). Like other high-grade tumors, they tend to have low T2-weighted signal intensity on MR imaging.

Lymphoepithelial Carcinoma

The topic of BLEL was previously addressed in the section on ''Autoimmune Diseases.'' The tendency of

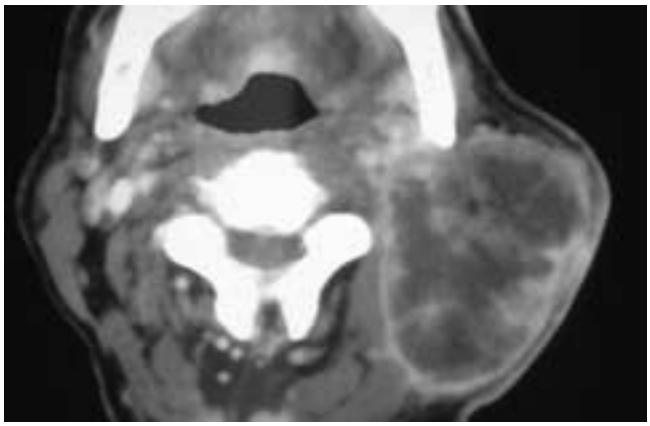

FIGURE 39-138 Axial contrast-enhanced CT scan shows a large necrotic mass in the left parotid gland. Some of the tumor borders are poorly defined. Clinically, this was a rapidly enlarging mass. This patient had an SCC of the parotid gland.

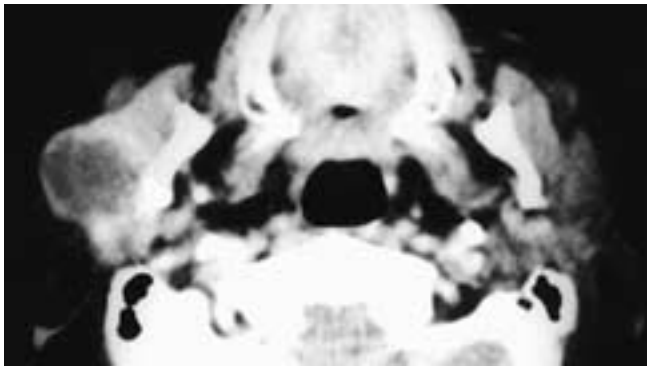

FIGURE 39-139 Axial contrast-enhanced CT scan shows a necrotic right parotid mass that has infiltrated the entire gland and the adjacent masseter muscle. This patient had an SCC of the parotid gland.

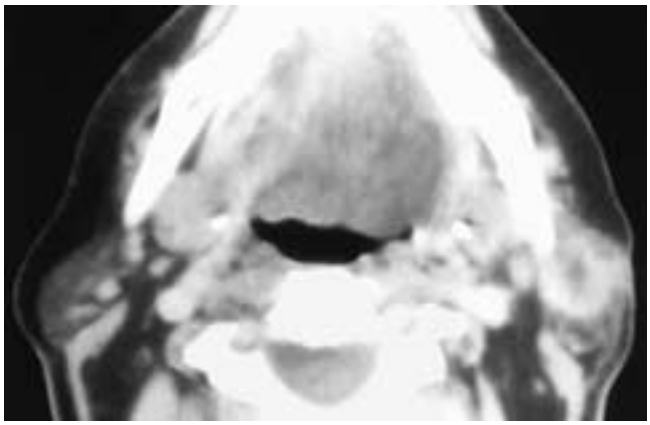

FIGURE 39-140 Axial contrast-enhanced CT scan shows a partially necrotic infiltrating mass in the left parotid gland in continuity with localized disease in the overlying skin. This patient had an SCC of the skin with extension to the parotid gland.

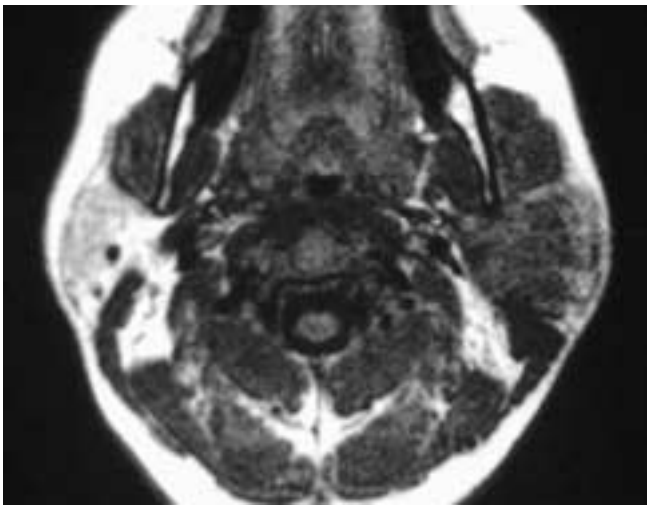

FIGURE 39-141 Axial T1-weighted MR image shows a poorly defined low signal intensity mass in the left parotid gland. The mass also had low T2-weighted signal intensity. The imaging appearance is that of a high-grade tumor. This patient had an SCC.

BLEL to undergo malignant transformation inspired the recommendation to change this diagnosis to myoepithelial sialoadenitis (MESA), a nosology that was never popularized. Most commonly, lymphoma will arise in BLEL in SS. The other possibility is that a carcinoma can develop; this is referred to as lymphoepithelial carcinoma (LEC), malignant lymphoepithelial lesion (MLEL), or undifferentiated carcinoma with lymphoid stroma (UCLS). Hilderman et al. initially described these tumors in 1962.[310]

The more colorful appellation ''Eskimo tumor'' is a reflection of the fact that this rarely encountered neoplasm has been described in patients from the Arctic region—Alaskan Eskimos, Aleuts, Greenland Inuits—as well as in oriental patients. LEC is very rare, accounting for 0.4% of

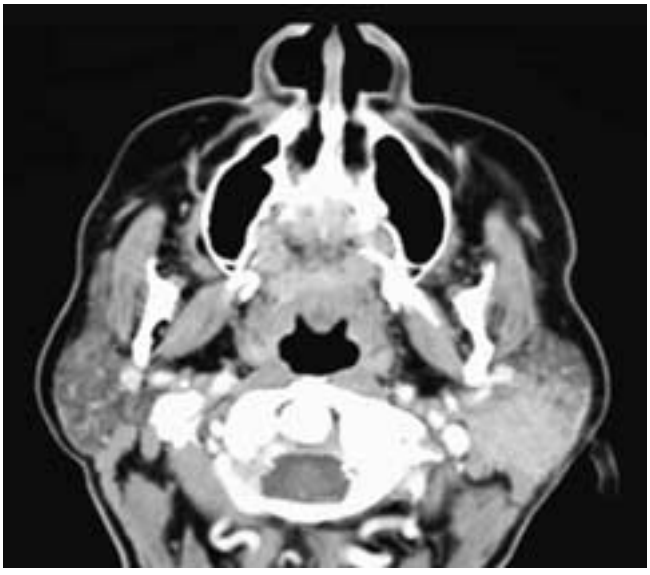

FIGURE 39-142 Axial CT scan shows an irregularly marginated, infiltrative mass in the left parotid gland. The tumor has started to extend beyond the parotid gland capsule. This patient had an SCC.

Copyright © 2003, Mosby, Inc. All rights reserved.

all salivary gland neoplasms in the Armed Forces Institute of Pathology Tumor Registry.[311] These tumors are histologically indistinguishable from the similarly named neoplasms of nasopharyngeal origin. Approximately 75% of reported cases have occurred in North American or Greenland Eskimos and southern Chinese individuals. A familial association has also been described, and the parotid gland is involved in over 90% of cases. The median age of affected persons is 39 years, and there is a 3:2 female predominance.[312–314]

These tumors may arise de novo, as well as within a BLEL. There is no association with SS or malignant lymphoma. As with LEC of nasopharyngeal origin, EBV has been strongly implicated in the oncogenesis of these tumors. In addition to elevated serum titers of anti-EBV antibodies in some patients, the EBV genome and mRNA have been demonstrated in tumor cells via in situ hybridization techniques. Most EBV-related tumors have been in patients of the Mongoloid race; however, occasional tumors in Caucasians may be associated with EBV. Conversely, epithelial cells in benign lymphoepithelial lesions appear negative for EBV infection.[315]

Patients present with an indurated mass of variable duration. Not uncommonly, the history is that of a long-standing mass with a recent rapid increase in size. Associated pain and discomfort are common, and facial nerve palsy is seen in up to 20% of cases. Cervical lymph node involvement is present in 41% of patients at presentation, although many of these nodal metastases are clinically occult.

Grossly, LEC may appear either encapsulated or infiltrative. Microscopically, these tumors are defined as undifferentiated carcinomas intimately intermingled with a dense lymphoid stroma. They are composed of sheets, strands, and/or irregular nests that may interconnect and are surrounded by a benign, dense lymphoid stroma. Tumor cells are large and polygonal or slightly spindled, with vesicular nuclei. Syncytial nests of tumor cells are typical, characterized by overlapping nuclei and indistinct cell borders. Perineural invasion is present in at half of LECs, and mitotic activity is variable. The differential diagnosis of LEC includes BLEL, metastatic tumors, and malignant lymphoma.

LEC is treated by complete surgical excision with negative surgical margins and adjuvant radiotherapy. Like LEC of nasopharyngeal origin, salivary LEC appears, at least in some cases, to be particularly radiosensitive. Given the high incidence of regional metastases, treatment of the cervical lymphatic chain with either surgery and/or radiotherapy is warranted in all cases. The prognosis correlates with the initial stage of disease. Advanced-stage disease has a poor prognosis. These tumors have been reported to have higher mitotic rates, necrosis, and greater anaplasia. Reported overall 5-year survival rates vary widely and are likely sullied by early reports of high mortality in patients who received suboptimal treatment. Five-year survival rates of 66% to 80% have been achieved with a combination of surgery and radiotherapy.[316–318] Nevertheless, up to 20% of patients develop local recurrence and/or distant metastases within 3 years of diagnosis.

Undifferentiated Carcinoma

Undifferentiated carcinomas of the salivary glands are rare tumors. Analogous to salivary adenocarcinoma, NOS, undifferentiated salivary carcinomas lack specific histologic features to allow for subclassification as other known salivary malignancies. Undifferentiated carcinomas are separated into two groups: small cell (undifferentiated) carcinoma and large cell undifferentiated carcinoma. LEC can be considered a subtype of undifferentiated large cell carcinoma, but it is unique in its resemblance to nasopharyngeal carcinoma, its association with EBV, and its marked predilection for southern Chinese and Eskimos. These features justify its distinct nosology.

Small Cell Undifferentiated Carcinoma

Small cell undifferentiated carcinoma has been reported to arise from major salivary glands (the majority within the parotid gland) and, less commonly, within the larynx, sinonasal cavity, oral cavity, pharynx, and upper esophagus. First reported by Koss et al. in 1972, it is remarkable for its resemblance to small cell carcinoma (oat cell carcinoma) of the lung.[319, 320] Importantly, the prognosis of salivary small cell carcinoma is better than the dismal one associated with pulmonary small cell carcinoma. Affected patients are usually in their fifth decade of life or older, and there is a slight male predominance.

Histologically, this tumor is composed of sheets, ribbons, and/or nests of tumor cells, which are as large as or slightly larger than lymphocytes. Appearing as small blue round cells, they have round to oval nuclei and scanty eosinophilic cytoplasm. Malignant features (infiltration, necrosis, pleomorphism, etc.) are seen. Vascular and perineural invasion are commonly found. Histologic, ultrastructural, and immunohistochemical studies have demonstrated the ductal and/or neuroendocrine characteristics of this tumor. The differential diagnosis includes tumors metastatic to the parotid gland such as pulmonary small cell carcinoma,[321] Merkel cell carcinoma from facial skin, metastatic BSC, malignant melanoma, and primary tumors such as solid-type AdCC and malignant lymphoma.

Wide local excision and lymph node dissection is indicated, and adjuvant chemotherapy and/or radiotherapy may be warranted. The 2- and 5-year survival rates for small cell carcinomas arising in the major salivary glands are 70% and 46%, respectively, while the rates for those arising in the larynx are only 16% and 5%, respectively.[320, 322]

Large Cell Undifferentiated Carcinoma

Large cell undifferentiated carcinoma (LCUC) represents a group of high-grade carcinomas that are too poorly differentiated to be classified as any other salivary carcinoma. As this tumor is extremely rare, little demographic data are available. The majority of patients with LCUC seen in consultation at the Armed Forces Institute of Pathology Tumor Registry presented in the seventh and eighth decades of life.[323] The majority of cases involve the parotid gland; up to 25% of cases arise in the submandibular gland. There is no gender predominance, and unlike LEC, there is no association with EBV and no racial predilection. Patients typically present with a rapidly growing, fixed parotid mass. Facial nerve palsy and palpable cervical adenopathy are common at presentation.

Microscopically, LCUC appears as a poorly differentiated carcinoma composed of large polygonal epithelioid tumor cells with brisk mitotic activity. There may be

Copyright © 2003, Mosby, Inc. All rights reserved.

ultrastructural evidence of squamous or glandular differentiation, but neuroendocrine differentiation is rare. The differential diagnosis includes metastatic tumors to the parotid gland (poorly differentiated adenocarcinoma, nasopharyngeal carcinoma, SCC, melanoma) and primary tumors such as poorly differentiated adenocarcinoma, MEC, and squamous carcinoma. LCUC can also occur as part of anaplastic progression of other tumors, either benign or malignant.

LCUC is best treated with wide local excision and aggressive radiotherapy. LCUC is aggressive: local recurrences, regional nodal metastases, and distant metastases develop in more than half of the patients, and over 60% of patients die of their disease.[324]

Hybrid Carcinoma

A salivary hybrid tumor is defined as a salivary tumor composed of two or more disparate patterns that are not included in each other's histologic realm. Tumors with features of both MEC and AdCC, or of ACC and cribriform SDC, are examples of hybrid tumors. There is presently no other nomenclature with which to adequately describe these types of tumors. The disparity inherent in hybrid tumors comes from the fact that either element differentiates toward distinctly different salivary elements: for example, excretory duct versus acini or excretory duct versus intercalated duct. Shared foci of phenotypic differentiation may be seen within salivary tumors; these cases would not be considered hybrid tumors. For instance, Grenko and colleagues have described AdCCs with foci of epithelial myoepithelial carcinoma–like differentiation, and vice versa. Both of these tumors are composed of ductal and myoepithelial elements, and presumably it is the degree of the local genetic statement that dictates the histologic phenotype. Therefore, these tumors would not be considered hybrid tumors, but rather variations in differentiation.[325, 326] By this definition, tumors with patterns of both canalicular adenoma and BCA, or AdCC and BCAC, would also not be considered hybrid tumors. Also, hybrid tumors would not show evidence of evolution from one entity to another. For instance, a tumor with features of MEC and pleomorphic adenoma is not a hybrid tumor and is better classified as MEC-ex-pleomorphic adenoma.

There are only a few acceptable examples of salivary hybrid tumors in the literature, and it has been estimated that they comprise less that 0.1% of all salivary tumors.[327–330] The reported combinations include parotid Warthin's tumor with sebaceous gland lymphadenoma; parotid cribriform SDC with ACC, sebaceous carcinoma with MEC, and palatal cribriform SDC with AdCC. More experience is necessary with salivary hybrid tumors before this group can be better characterized.

The treatment and prognosis should be based on the most poorly differentiated (highest-grade) component of the hybrid tumor.

Sialoblastoma

Salivary neoplasia is rare in children and adolescents. These patients comprise less than 3% of all patients with primary salivary tumors, and the majority of these tumors occur between the ages of 5 and 16 years. Tumors occurring in even younger patients are vanishingly rare. There is a 37% likelihood that a major salivary gland tumor in a child or adolescent will be malignant. By comparison, the rate of malignant tumors in the major salivary glands for all patients is generally between 15% and 20%. The most common tumors in the younger age group are pleomorphic adenoma, MEC, and ACC.

Sialoblastoma was first reported by Vawter and Tefft in 1966 as an *embryoma*.[331] Since that time, many terms have been used to describe this group of tumors, including congenital basal cell adenoma, basaloid adenoma, monomorphic adenoma, congenital hybrid basal cell adenoma–adenoid cystic carcinoma, low-grade basaloid carcinoma, adenoid cystic carcinoma, and sialoblastoma.[1, 4, 6] In his case report, Taylor drew an analogy between this tumor and others with a blastomatous appearance, suggesting the use of the term sialoblastoma.[332] To date, approximately 23 tumors have been reported that fit into the broad definition of sialoblastoma.[1–6]

Sialoblastomas arise almost exclusively in the major glands; over 80% involve the parotid gland and the remainder the submandibular gland. They are slightly more common in females than in males. Sialoblastomas arise almost exclusively in the perinatal period. Grossly, these tumors range up to 15 cm in greatest dimension[7] and are usually encapsulated or at least well circumscribed, but they may be locally infiltrative. Microscopically, these tumors try to recapitulate the embryonic development of the major salivary glands, with their histologic patterns reflecting the various stages of phenotypic expression and differentiation. Sialoblastomas frequently have variable histologic patterns within the same tumor and in different tumors. These patterns consist of solid multinodular nests and sheet-like collections of primitive-appearing epithelial cells with a basaloid morphology focally forming ducts and duct-like structures that may have peripheral palisading. The primitive nest-like pattern is frequently destructive and aids in separating this tumor from AdCC and BCA or BCAC. BCA does not exhibit destructive growth, while AdCC or BCAC grows in a less destructive pattern. Occasional acinar differentiation may also be seen. This latter feature helps to separate sialoblastoma from hamartoma, which usually has much more prominent acinar differentiation.

The nuclei in sialoblastoma are round to oval, usually with minimal to moderate amounts of cytoplasm. Nuclear pleomorphism is variable, as is the presence of nucleoli. Necrosis may be present and is more frequent in malignant tumors. Surrounding the nests and collections of epithelium is a loose mesenchyme that often has an embryonic appearance.[2] Mitoses are frequently found and may be plentiful; atypical mitoses are not usually seen. We have advocated the following grading subclassification scheme: well differentiated (grade 1) (including the basal cell subtype as well as tumors without cytologic atypia or invasive growth); moderately differentiated (grade 2) (including cases with invasive growth, greater cytologic atypia, and necrosis, but without definitive evidence of malignancy, i.e., no neural or vascular invasion or metastatic spread); and poorly differentiated tumors (grade 3) (which have definite evidence of malignancy).

Complete surgical excision with negative margins is the treatment of choice. Adjuvant chemotherapy and radiother-

apy have been tried; however, the limited number of cases hampers assessment of these modalities.[1, 4] The limited number of cases and short follow-up of reported cases also preclude drawing definitive conclusions about the tumor's biologic behavior; however, published data do indicate that sialoblastoma can be locally aggressive and malignant. Five of the 23 reported cases have recurred; several recurred multiple times or patients had local persistence of disease, and two patients developed regional lymph node metastases.[1, 4, 7, 10] Progression of tumor grade with recurrence and increasing mitotic rates has been seen.[4] One patient had four recurrences, with inoperative tumor extending into the skull at 43 months.[7] Low-grade tumors appear to be less aggressive than higher-grade tumors, with only one recurrence in eight tumors.[1]

MR imaging in one patient showed that the tumor was isointense with muscle on T1-weighted images, it had a high-intermediate signal intensity similar to that of fat on T2-weighted images, and it enhanced sparsely and nonhomogeneously (Fig. 39-143).[331–341]

Sclerosing Adenosis

Sclerosing polycystic adenosis is a recently described rare pseudoneoplastic reactive inflammatory process somewhat similar to sclerosing adenosis of the breast. It was first reported in 1996 by Smith and colleagues, who described a series of nine patients from the Armed Forces Institute of Pathology.[342] Since this initial report there have been only two other series, bringing the total number of cases in the literature to 18.[2, 3] Patients ranged in age from 12 to 63 years (mean, 29.4 years), with a male : female ratio of 2 : 7. Sixteen cases involved the parotid gland and two affected the submandibular gland. Presenting symptoms ranged from 10 days to 2 years. Patients typically presented with a slow-growing mass; three, in addition, had pain or a tingling sensation.

Grossly, most tumors were firm or rubbery, well circumscribed, and embedded in a normal salivary gland; five were multinodular. Tumors ranged in size from 1 to 7 cm in greatest dimension and had cut surfaces that were pale and glistening; a few had tiny visible cysts 1 to 2 mm in diameter. They were unencapsulated and consisted of multiple densely sclerotic, irregularly defined lobules composed of abundant hyalinized collagen surrounding areas of ductal cystic change. Hyperplasia of ductal and acinar elements with areas of apocrine-like metaplasia were typical. In addition, mucin-containing cells, squamous cells, and ballooned cells occasionally lined ducts and cystic spaces. The intraluminal epithelial proliferation infrequently formed a cribriform pattern, some of which was associated with nesting basement membrane–like material, similar to collagenous spherulosis of the breast. The differential diagnosis consists of polycystic (dysgenetic) disease, sclerosing sialadenitis, and carcinoma.

Until more cases with longer follow-up periods are available, treatment should consist of complete surgical excision with good surgical margins. Follow-up information is available in the Armed Forces Institute of Pathology series for six cases (mean, 43 months; range, 7 months to 9 years) and for two of the cases reported by Donath and Seifert.[3, 334]

FIGURE 39-144 Axial CT scan (**A**) shows a fat attenuation mass in the left parotid gland and the adjacent soft tissues. Axial T1-weighted (**B**), T2-weighted (**C**), and T1-weighted, fat-suppressed, contrast-enhanced (**D**) MR images show a mass with a high T1-weighted and a low T2-weighted signal intensity. There is faint enhancement. Within the mass are structures of low T1-weighted and high T2-weighted signal intensity. These structures do not enhance. This patient had sclerosing adenosis.

To date, four cases have recurred; one patient had a single recurrence at 4 years 8 months, a second had multiple recurrences over a 9-year period,[1] and two patients had recurrences at 8 years.[3] The other two patients reported in Donath and Seifert's series were alive without evidence of disease at unknown lengths of time.[3] In addition, none of the cases reported by Batsakis have recurred.[2, 343]

Radiographically, these tumors can appear similar to other benign solid and cystic salivary tumors. However, we have recently seen a case with a prominent adipose component mimicking a parotid lipoma, albeit with an atypical radiographic cystic component (Fig. 39-144).[342–344]

Adenocarcinoma, Not Otherwise Specified

Despite the scores of well-recognized diagnostic categories of salivary tumors, some tumors persist in eluding current classsification schemes. As some type of gland formation is common to most of these tumors, the group is referred to as adenocarcinoma, not otherwise specified (NOS). These tumors usually are painful, rapidly enlarging masses, but occasionally they may be painless, slow-growing swellings. In 1982, Spiro et al. reported on 204 cases of unclassifiable salivary adenocarcinomas, that is, adenocarcinoma NOS, which represented about 9% of their total salivary cases. The majority of tumors occur at minor

salivary gland sites (68%), followed by the parotid gland (28%), and the submandibular gland (4%). A review of 881 cases of adenocarcinoma NOS from the Armed Forces Institute of Pathology Tumor Registry revealed an almost opposite distribution of cases: 50% occurred in the parotid gland, 12% in the submandibular and sublingual glands, and 38% in minor salivary gland sites, most commonly the palate. The authors acknowledged that not all 881 cases were re-reviewed and that perhaps some could be reclassified currently as PLGA or BCAC. However, due to the relative rarity of these two tumors, they believed that the overall statistics would not have changed significantly.[345]

Adenocarcinoma can be subclassified according to cytologic and architectural grade: grade I tumors are circumscribed and minimally invasive, with mild features of pleomorphism; grade III tumors are more solid and pleomorphic, with a higher mitotic rate; and grade II tumors can be found between these two extremes. Tumor stage and site are important predictors of survival, as determined by the Memorial study.[345] The 5-, 10-, and 15-year survival rates for low-grade tumors were found to be 92%, 90%, and 82%, respectively. The 5-, 10-, and 15-year survival rates for high-grade tumors were predictably poorer: 49%, 42%, and 33%, respectively. Tumor site, as a reflection of tumor resectibility, was also an important prognosticator: patients with tumors of the paranasal sinuses had poorer survival. The 5-, 10-, and 15-year survival rates were 21%, 15%, and 10%, respectively. The Memorial data, albeit two decades old, represent the largest study correlating grade and stage with prognosis. However, because of improvements in surgical techniques, radiotherapeutic techniques, and chemotherapy protocols, one could hope for an improvement in survival even for patients with high-grade tumors. As more and more new salivary tumors are being recognized and categorized, the pool of NOS tumors may shrink, while the list of established salivary tumors will continue to grow. Radical surgery is the treatment of choice, and the imaging characteristics are those of a high-grade cellular infiltrating tumor (Figs. 39-145 to 39-150).[8, 345–349]

Carcinoma Metastatic to the Salivary Glands

Metastasis to the major salivary glands or adjacent lymph nodes is a frequent occurrence, accounting for one third of all metastases to the head and neck and comprising 4% of

salivary gland neoplasms in various series.[350, 351] The parotid glands contain 3 to 32 (average, 20) intraglandular lymph nodes connected by a plexus of lymphatics that drain the ipsilateral facial skin of the upper face and midface. In contrast, the submandibular and sublingual glands proper do not contain any intraparenchymal lymph nodes. Approximately 90% of metastases involve the parotid region; the remainder involve the submandibular gland. Metastases to the sublingual gland have not been reported to date. SCC and malignant melanoma are the most common neoplasms metastasizing to the major salivary gland area, accounting for 60% and 14.5% of diagnoses, respectively. The vast majority (85% to 88%) of parotid metastases from known primaries originate in the head and neck, and the majority of them (84% to 89%) arise from the skin. Regarding parotid metastases from known nonhead and nonneck primary sites, tumors most commonly originate from the lung, kidney, and

malignancies metastasizing to the submandibular gland originate in infraclavicular sites, most commonly the breast, kidney, and lung. The most frequent age at diagnosis for metastases to the major salivary glands is the seventh decade, and there is an approximately 2:1 male:female ratio. In most cases, the primary tumor is known; however, occasionally the metastasis is the initial presentation of disease and, rarely, bilateral involvement may be seen.[352, 353]

Appropriate treatment consists of complete surgical resection and cervical lymph node dissection if there is clinical or radiographic evidence of adenopathy. The addition of adjuvant radiotherapy is controversial, with varying recommendations. The primary location and tumor type will influence final therapeutic recommendations. Postoperative radiation therapy may also be warranted. It is difficult to generalize about the prognosis due to the different tumor types and variable primary locations encountered. For most tumors, metastatic disease implies a poorer prognosis for a given primary tumor. If the metastasis is from an infraclavicular primary and is only one of many metastatic deposits, the prognosis is usually poor. However, if the metastasis is only a single focus, local control of the primary and the metastasis is possible.

The prognosis for facial skin primaries that have metastasized to the parotid gland is better if the metastasis is confined to lymph nodes than if it infiltrates the parotid parenchyma (8% vs. 79% local recurrence rates).[354] The 5-year local disease control rate for facial squamous carcinoma metastatic to the parotid gland is 82%, and the overall 5-year survival is 54%.[355] Patients with head and neck mucosal primaries have a very poor prognosis, with only 1 of 10 patients alive and disease free at 5 years.[356] Ironically, patients with malignant melanoma of the parotid gland have a better prognosis if no primary site is found.[357] In a series of 19 patients, no primary tumor was found in 6 patients. Five of them were disease free (mean, 4.2 years; range, 14 months to 7.5 years), and one patient died of disease at 17 months. Extraparotid primary melanomas were found in the other 13 cases (10 cutaneous and 3 mucosal: sinonasal tract and occular). None of these patients were disease free at follow-up: nine died of melanoma (mean, 2.6 years; range, 10 months to 5 years), and three had metastatic disease (mean, 4.3 years, range, 3 to 6 years); only one patient was disease free at 2 years.

If a metastasis to the parotid gland is a solitary mass, it is indistinguishable from a primary high-grade salivary tumor. The typical imaging appearance of metastases to the parotid gland is that of multiple, invasive masses, often with some element of necrosis (Figs. 39-151 to 39-156).

Nonepithelial Tumors

Nonepithelial tumors of the salivary glands represent less than 5% of all salivary gland neoplasms. However, in children, they may comprise over 50% of the lesions.[7, 8] The only tumors of statistical consequence are hemangiomas, lymphangiomas, lymphomas, neurogenic lesions, lipomas, and sarcomas.

Hemangioma

Hemangiomas of the parotid gland represent 1% to 5% of all salivary gland tumors, but they are the most common salivary gland neoplasm in children.[7, 8, 358] Submandibular gland involvement is rare, and in these cases it has been difficult to distinguish between tumors that arose within the gland and those that arose in the soft tissues adjacent to the gland. Hemangiomas can be classified as capillary (composed of small capillary-sized vessels with plump endothelial cells) or cavernous (composed of large, thin-walled vessels with flattened endothelial cells). Congenital capillary hemangioma is the predominant tumor in the first year of life, representing 90% of parotid gland tumors in this age group. This lesion is usually discovered shortly after birth; it is unilateral, compressible, and soft. Rapid enlargement can occur and a bluish coloration can be seen in the overlying skin, especially when the infant is crying. There also may be an associated hemangioma in the overlying skin. These nonencapsulated and lobulated lesions are more common in girls than in boys. The differential diagnosis includes cystic lymphangioma and the rare malignant hemangioendothelioma, both of which can be distinguished histologically. If possible, surgery is to be avoided until adulthood since many of these tumors may regress spontaneously.[7] In addition, there are no known instances of malignant transformation of this lesion.[358] Cavernous hemangiomas occur in older children and adults, with most patients being older than 16 years of age. These tumors tend to be well circumscribed and involve the extralobular parotid tissues. Surgery is the treatment of choice since spontaneous regression is unlikely.[7]

Capillary hemangiomas (or vascular malformation: see Chapter 41 for a discussion of an alternate terminology) appear to be very rare in the parotid gland. For this reason, their characteristics have not been reported in sufficient numbers to allow any general conclusions.

On CT these tumors enhance, are often lobular in contour, may be seen to extend to the overlying skin, or have phleboliths within the tumor tissues (Figs. 39-157 to 39-159). Often, the mass effect of the tumor on the surrounding soft tissues is relatively small, reflecting the soft nature of these lesions. On MR imaging, the lesion can have sites of high signal intensity on both T1-weighted and T2-weighted images, which are caused by prior hemorrhage and slow flow. There also can be vascular flow voids, and the majority of the tumor has a low to intermediate, nonhomogeneous signal intensity on T1-weighted and proton density sequences. There usually is a high T2-weighted signal intensity (Figs. 39-160 and 39-161).

Lymphangioma

Lymphangiomas are benign tumors composed primarily of lymphatic vessels. These tumors are classified into three pathologic groups: lymphangioma simplex, cavernous lymphangioma, and cystic lymphangioma or cystic hygroma. Histologically, lymphangiomas consist of thin-walled spaces with flattened endothelium, without a significant erythrocyte component, as is seen in cavernous hemangiomas. All three pathologic types may coexist within the same tumor. Most of the lesions found in the head and neck are cystic hygromas. Lymphangiomas represent 5% to 6% of all benign tumors of infancy and childhood, with 50% to 60%

FIGURE 39-151 Axial T1-weighted MR images through the parotid gland (**A**) and the pinna of the left ear (**B**). There is a poorly defined low signal intensity mass in the left parotid gland. This mass also had low T2-weighted signal intensity. The imaging findings suggest a high-grade tumor. In **B**, there is a mass in the left ear pinna (*arrow*). This patient had metastatic disease to the parotid gland from a primary SCC of the ear. Axial contrast-enhanced CT scans (**C, D**) on another patient show multiple poorly defined masses in the right parotid gland. Some lesions are necrotic. This patient had metastatic SCC from a scalp primary.

VIEW IMAGE

FIGURE 39-152 Axial contrast-enhanced CT scan shows a necrotic mass with an enhancing rim within a swollen left ear pinna. The left parotid gland is dense and enlarged, and there are cellulitis-type changes overlying the gland. This patient had an abscess in the left pinna (secondary to an ear piercing) with cellulitis and parotitis. Compare this scan to Figure 39-151.

of the cases being present at birth. Between 80% and 90% of patients are diagnosed by the age of 2 years. This age range corresponds to the period of greatest lymphatic growth. It is uncommon for cystic hygromas to be reported in adults.[19, 187, 358–360]

Most commonly, these lesions arise in the posterior triangle of the neck. They can spread to invade the parotid and submandibular glands, muscles, and vessels. Most tumors are painless, soft or semifirm masses, and some fluctuation in size is common. Sudden enlargement is associated with infection or hemorrhage. Facial nerve paralysis can occur either secondary to nerve compression by a parotid lesion with hemorrhage or secondary to an acute otitis media caused by a lesion obstructing the eustachian tube.[360]

Cystic hygromas rarely occur in adults and usually develop as a solitary cyst either in the submandibular triangle or in the posterior triangle of the neck. Whether these lesions represent the congenital type of lymphangioma or a posttraumatic lesion is still unresolved.[187]

On CT, these lesions are usually cystic masses filled with homogeneous low-attenuation (10 to 20 HU) material. The

FIGURE 39-153 Axial contrast-enhanced CT scan (**A**) shows an infiltrating mass in the right infratemporal fossa, parotid gland, and parapharyngeal space. The mass has eroded the head of the mandible. In **B**, an axial proton density MR image, the mass has low to intermediate signal intensity. This patient had metastatic lung carcinoma.

cysts usually have thin walls that are often not clearly seen on the images. Most commonly there are multiple intercommunicating cystic components, although solitary cysts can occur, usually in adults in the submandibular triangle and deep to the sternocleidomastoid muscle (Figs. 39-162 and 39-163). Areas of higher attenuation within the cysts usually correspond to sites of hemorrhage.[360] Septation can occur within cysts even if they have not been previously aspirated. Infection is identified by an enhanced thickening of the cyst wall and infiltration of the adjacent soft tissues. In cases of multiple repeated infections, the attenuation of the cyst contents may approach that of muscle.

On MR imaging, the dominant water content of the cysts is revealed in their signal intensities, which are low on T1-weighted images and high on T2-weighted images. The multiple, intercommunicating nature of the cysts and any fluid-fluid levels are best seen on MR imaging, especially on T2-weighted scans (Figs. 39-163 and 39-164).

Lymphoma

Primary lymphoma of the salivary glands is a rare entity. The parotid gland is affected in 80% of the reported cases, and the submandibular gland is involved in nearly 20%. There are only isolated reports of primary lymphoma in the sublingual gland and the minor salivary glands. These lymphomas are classified as MALT (mucosa-associated lymphoid tissue) lymphomas in the classification schema (see Table 6-2). In the series of 33 patients with primary parotid lymphomas reported by Barnes et al., there were 15 men and 18 women aged 26 to 100 years (mean, 66 years). Patients invariably presented with enlarging painless masses. Autoimmune disease was associated with seven (21%) of these patients.[361]

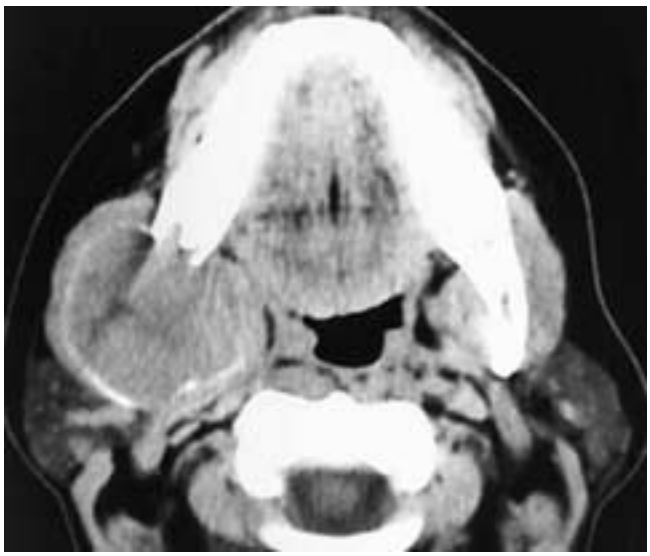

FIGURE 39-155 Axial CT scan shows an expansile and destructive mass of the right mandible, which clinically simulated a parotid tumor. This patient had metastatic meningioma. (From Som PM, Sacher M, Strenger SW, et al. ''Benign'' metastasizing meningiomas. AJNR 1987;8: 127–130.)

FIGURE 39-163 Axial T2-weighted MR scan shows multiple cystic components of varying size forming part of an overall bulky and infiltrating mass. The lesion involves the parotid gland, the adjacent superficial soft tissues in the face, and the deeper planes in the pharynx. This patient had a cystic lymphangioma.

The diagnosis of primary salivary gland MALT lymphoma is based on the demonstration of lymphocyte clonality (light chain restriction) and on morphology. Maltomas characteristically appear as infiltrates of small centrocytes and monocytoid B cells with variable plasma cell differentiation. These lymphocytes can invade parotid ductal and acinar tissue, which may be reflected in the radiographic imaging. The majority of MALT lymphomas type as B cells (L26, KiB3, LN2 positive) and are also low grade. However, some may be classified as intermediate- or high-grade lymphomas, which may also correlate with their imaging appearance, parotid infiltration, and tumor inhomogeneity. The differential diagnosis includes BLEL (or myoepithelial sialadenitis). Extensive sampling and immunohistochemistry may be required to make this distinction. Plasmacytoma and granulocytic sarcoma also enter into the differential diagnosis (see below).

If a diagnosis of parotid lymphoma is suspected, fine needle aspiration may be attempted, as this has the potential to establish the diagnosis. Systemic workup and bone marrow examination are necessary for staging. The majority of patients present with stage I_E disease (see Table 39-7).

Stage I and II MALT lymphomas are usually treated with either surgery or radiotherapy, with similar outcomes (see below). Parotidectomy may be initially performed for diagnostic purposes. If the MALT lymphoma is then found to be stage I or II, adjuvant therapy may not be necessary. The treatment choice between primary surgery and primary radiation therapy becomes important if the diagnosis is established preoperatively and the tumor is stage I or II. Surgery has an advantage since postirradiation xerostomia and mucositis are avoided. However, the cosmetic outcome is better with irradiation.

The overall prognosis of salivary MALT lymphomas is very good, as this is generally an indolent disease. Of 25 patients available for a minimal 2-year follow-up, 16 (64%) were alive with or without disease. Relapses are usually

Table 39-7
STAGE GROUPING OF THE AMERICAN JOINT COMMITTEE ON CANCER

Stage I	Involvement of a single lymph node region (I) or localized involvement of a single extralymphatic organ or site (I_E).
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of a single associated extralymphatic organ or site and its regional lymph node(s) with or without involvement of other lymph node regions on the same side of the diaphragm (II_E).
Note: The number of lymph node regions involved may be indicated by a subscript (e.g., II_3).	
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an associated extralymphatic organ or site (III_E), by involvement of the spleen (III_S), or both (III_{E+S}).
Stage IV	Disseminated (multifocal) involvement of one or more extralymphatic organs, with or without associated lymph node involvement, or isolated extralymphatic organ involvement with distant (nonregional) nodal involvement.

Source: AJCC Cancer Staging Manual 5th edition. Lippincott-Raven, Philadelphia 1997.

associated with a higher stage (stage II) or grade (intermediate or high grade) at initial presentation, and patients require additional radiotherapy combined with chemotherapy. Relapse may also be associated with progression in grade.

Lymphoma may also involve the salivary glands (usually parotid) secondary to diffuse disease. This secondary parotid involvement is not classified as MALT lymphoma. It occurs in 1% to 8% of lymphomas and is most commonly seen with high-grade, diffuse large cell lymphoma. Parotid lymphomas presenting in HIV patients usually can be classified as high-grade and secondary rather than MALT lymphoma. The prognosis is usually poor due to presentation with a high-stage and high-grade tumor.

The association of lymphoma and BLEL has been previously discussed (see the section on Autoimmune Diseases).

Solitary extramedullary plasmacytomas have a propensity for the upper respiratory tract but occur rarely in the parotid gland. This diagnosis requires a clinical workup to exclude multiple myeloma. The treatment of choice should be surgical excision followed by radiotherapy. The prognosis of solitary extramedullary plasmacytoma is generally good.

Granulocytic sarcoma represents the tissue manifestation of myeloid leukemia. It has been reported in the head and neck, and rarely may also be localized to the parotid gland. It is often misdiagnosed as a malignant lymphoma, which may delay proper treatment. The appearance of granulocytic sarcoma often precedes systemic relapse or progression from the chronic to the acute blastic form.[361–369]

The CT appearance of secondary lymphoma of the parotid gland varies with the pathologic distribution of the disease. Most commonly, the parotid disease is confined to the intraparotid lymph nodes, and one to six benign-appearing masses are identified within the gland. Usually, each node is homogeneous and may enhance slightly on postcontrast CT scans; however, nodal necrosis can occur (Figs. 39-165 to 39-167). If the parenchyma is involved, a diffuse infiltration will be seen either with poorly defined margins or involving the entire gland. The identification of extraparotid nodal disease can be helpful in suggesting the diagnosis. On MR imaging, the lymphoma tends to have a homogeneous intermediate signal intensity on all imaging sequences. There is also a tendency for the mass to ''fade'' into the signal intensity of the parotid gland on T2-weighted and contrast-enhanced, fat-suppressed, T1-weighted MR images (Figs. 39-168 to 39-171). In the uncommon patient with Hodgkin's disease involving the parotid gland, on both CT and MR imaging the nodes usually are nonhomogeneous.[358] Primary parotid lymphoma usually has a nodular, diffuse infiltrative pattern of the gland. As such, it is nonspecific and can mimic some cases of chronic sialadenitis. By definition, there are no affected parotid lymph nodes.

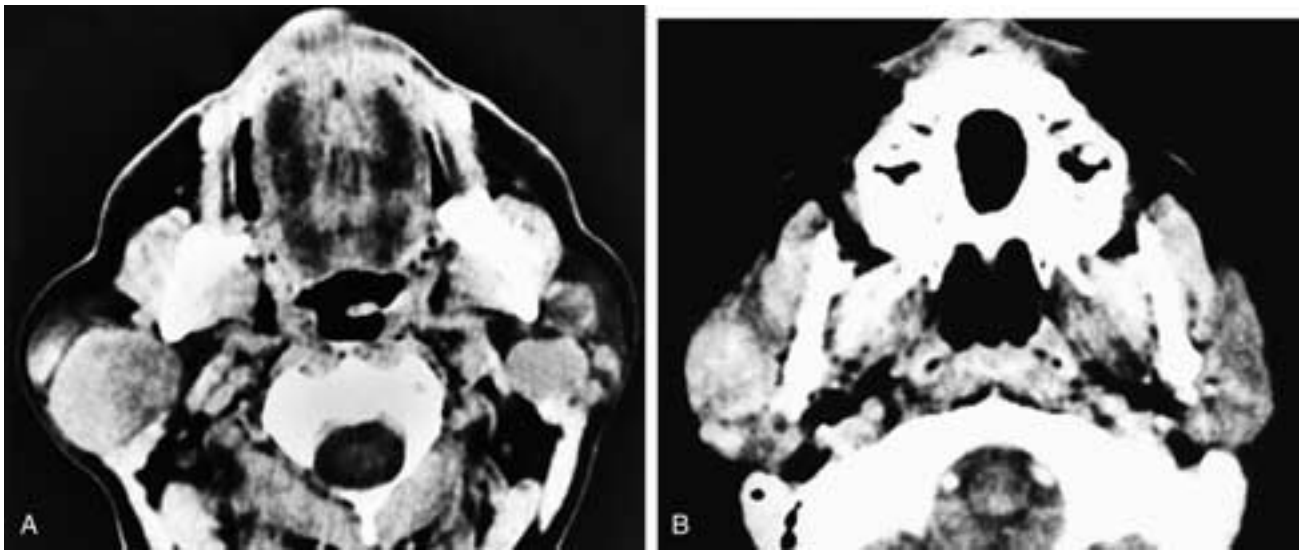

FIGURE 39-165 Axial CT scan (**A**) shows multiple benign-appearing masses in both parotid glands; the largest mass is in the right parotid gland. This patient had lymphoma. Axial contrast-enhanced CT scan (**B**) shows a slightly enhancing, benign-appearing mass in the right parotid gland. This was a hyperplastic lymph node. Note the similarity to **A**. These cases reinforce the fact that histology cannot be determined by imaging alone.

VIEW IMAGE

FIGURE 39-166 Axial contrast-enhanced CT scan shows a necrotic, irregularly walled, infiltrating mass in the right parotid gland. Edematous changes are also present in the overlying skin. This patient had systemic large cell lymphoma with involvement of the parotid gland.

Intraparotid Lymphadenopathy

Enlargement of intraparotid lymph nodes can occur from a variety of causes, most of which have already been discussed: acute viral or bacterial adenopathy, lymphoma, chronic infectious disease, and metastatic disease from the scalp, midface, or infraclavicular sites. Reactive hyperplastic lymphadenopathy can also involve periparotid lymph nodes and may be the result of an adjacent inflammatory process, the first stages of a systemic process (e.g., acute HIV infection), or of unknown etiology. Rapid, painful lymph node enlargement may simulate a parotid malignancy, especially in children. If facial nerve paralysis is present, this may further mimic malignancy. However, acute otitis media (AOM), a common pediatric event, can present with reactive lymphadenopathy of periparotid lymph nodes and facial nerve paralysis: about 5% of facial nerve paralysis is caused by AOM. Clinically, the child presents with a tender, rapidly growing parotid mass and accompanying facial nerve paralysis, bringing suspicions of rhabdomyosarcoma to mind. If MR imaging is performed, the lymph node usually has a fairly high T2-weighted signal intensity, whereas the high-grade malignancies tend to have low to intermediate T2-weighted signal intensities. This information can be helpful in distinguishing these entities, but in most cases needle aspiration or surgery will be necessary to establish the diagnosis. Such inflammatory nodes may enhance on postcontrast CT scans and have a slightly irregular margin due to the inflammatory reaction, further simulating a malignancy (Fig. 39-165B).

Heerfordt's syndrome consists of an enlarged parotid lymph node, facial nerve paralysis, and uveitis due to sarcoidosis. However, the clinical presentation of a parotid mass with a facial nerve paralysis has been misdiagnosed many times as a parotid gland malignancy.

Even when a parotid node is enlarged with metastatic disease, the mass may simulate a benign lesion on imaging. This is especially true in cases of metastatic melanoma from a facial or scalp primary. In such cases, the node usually has a well-delineated margin and is homogeneously enhanced.

Lipoma

Lipomas can arise either within the parotid gland or in the immediate periparotid region. At times, it may be clinically and radiographically impossible to distinguish the true site of origin. Series of parotid region lipomas reveal that 57% arose within the gland and 43% were of periparotid origin. Lipomas represent about 1% of parotid gland tumors, and approximately 90% of the cases are ordinary lipomas. The remaining lesions are either infiltrating lipomas or occurred as part of a lipomatosis syndrome.[19, 192, 370]

The ordinary lipomas are discrete lesions that usually have a homogeneously low attenuation (−65 to −125 HU). They have no definable capsule on imaging, yet they are easily delineated from the adjacent soft tissues (Fig. 39-172). The infiltrating lipoma is similar in appearance to the ordinary lipoma, except that it has poorly defined margins (Fig. 39-173). Actual infiltration of adjacent muscles may be demonstrated on imaging. Hemorrhage and

However, in **B** and **C**, the mass is poorly seen. These findings are highly suggestive of lymphoma. This patient had large cell lymphoma.

VIEW IMAGE

fibrotic changes can occur within lipomas, and on CT these changes may cause increased attenuation approaching that of muscle. Usually these changes are focal within the lipoma; however, the entire lesion may be hemorrhagic, rendering impossible the CT diagnosis of a lipoma. On MR imaging, lipomas have a high T1-weighted and an intermediate T2-weighted signal intensity, which may be minimally heterogeneous. An important diagnostic point to note is that whenever a lipomatous mass has an overall heterogeneously dense matrix, it may represent a liposarcoma.[19, 370]

Neurogenic Tumors

Neurogenic tumors of the parotid gland are the second most common benign mesenchymal neoplasm after vascular/lymphatic tumors. They may be either schwannomas or neurofibromas. Both lesions are usually ovoid, sharply delineated masses that arise primarily from the facial nerve trunk or its branches. Schwannomas are solitary, whereas neurofibromas often are multiple and associated with other manifestations of von Recklinghausen's disease. On CT these tumors can enhance, be cystic, or be isodense with muscle. The cystic changes usually are small and multiple. Neurofibromas may have a low, almost fatty attenuation that may simulate a lipoma. On MR imaging, these tumors in general have a low to intermediate T1-weighted and a high T2-weighted signal intensity. However, nonhomogeneous regions of higher and lower signal intensity can occur, making these lesions on MR imaging indistinguishable from a pleomorphic adenoma (Figs. 39-174 and 39-175).[371, 372]

The histologic distinction between these two benign peripheral nerve sheath tumors can be made as follows: a neurofibroma arises from actual neuronal and perineuronal tissue. A fairly uniform distribution of thin, wavy spindle cells is seen within a myoid-type stroma. To excise a neurofibroma is to sacrifice the nerve from which it arises. By contrast, a schwannoma arises from neural supporting elements, not from the actual neuronal elements. It arises eccentrically to the nerve and can theoretically be ''peeled'' off from the nerve. Histologically, one sees the classic yin/yang of the cellular (Antoni A) and paucicellular (Antoni B) areas. The wavy spindle cells have a tendency to palisade and form rows of palisading cells called Verocay bodies.

Solitary neurofibromas affecting the major salivary gland are uncommon. They are usually seen in the setting of von Recklinghausen's disease but may occur in the absence of manifestations of this disease.[373] Large and long-standing plexiform neurofibromas in patients with von Recklinghausen's disease are at risk for malignant transformation (malignant peripheral nerve sheath tumor). Histologically, malignant transformation is seen as an increase in tumor cellularity, mitotic figures, pleomorphism, and necrosis.

Primitive neuroectodermal tumor (PNET) is a rare tumor found in children and young adults, commonly in the gluteal

Copyright © 2003, Mosby, Inc. All rights reserved.

region, thighs, shoulder, and arms. Isolated cases of PNET have been reported in visceral sites such as the kidney, uterus, ovary, testis, urinary bladder, and pancreas. In the head and neck area, these tumors have been described in the maxilla, orbit, and soft tissues of the neck. PNET has rarely been reported to involve the parotid region.[374]

Histologically, tumor cells are small and round or oval, with minimal cytoplasm and clumped chromatin. Rosettes are frequently found, and mitoses vary from moderate to numerous. The differential diagnosis includes small cell carcinoma and BSA. Prominent rosette formation and MIC2 positivity support a diagnosis of PNET. PNETs are, in general, highly aggressive tumors requiring a combined approach consisting of surgery, radiation therapy, and chemotherapy.[375]

Fibrous Tissue Lesions

A number of benign lesions of fibroblastic origin may affect the periparotid region, including fibromatosis (or desmoid tumor), nodular fasciitis, myofibromatosis, fibrous histiocytoma, and plexiform fibrous histiocytoma. Fibromatosis, or desmoid tumor, is a histologically bland proliferation of fibroblasts in a collagenous background. The significance of this tumor lies in its insidiously infiltrative nature. For this reason, fibromatosis is considered a low-grade fibrosarcoma. The surgeon is never assurred that he or she is beyond the lesion, and resection margins have a tendency to be positive. A high rate of recurrence after surgery is not surprising. Surgical resection is the mainstay of therapy. Radiation therapy has been utilized in recurrent cases, but there have been cases of high-grade malignant transformation occurring after irradiation. Antiestrogen therapy (Tamoxifen) has resulted in some regression of unresectable recurrences.[376] The differential diagnosis includes nodular fasciitis, benign peripheral nerve sheath tumor (neurofibroma or schwannoma), fibrous histiocytoma, and myofibromatosis. Infantile myofibromatosis may be present as an isolated single tumor or, less commonly, as

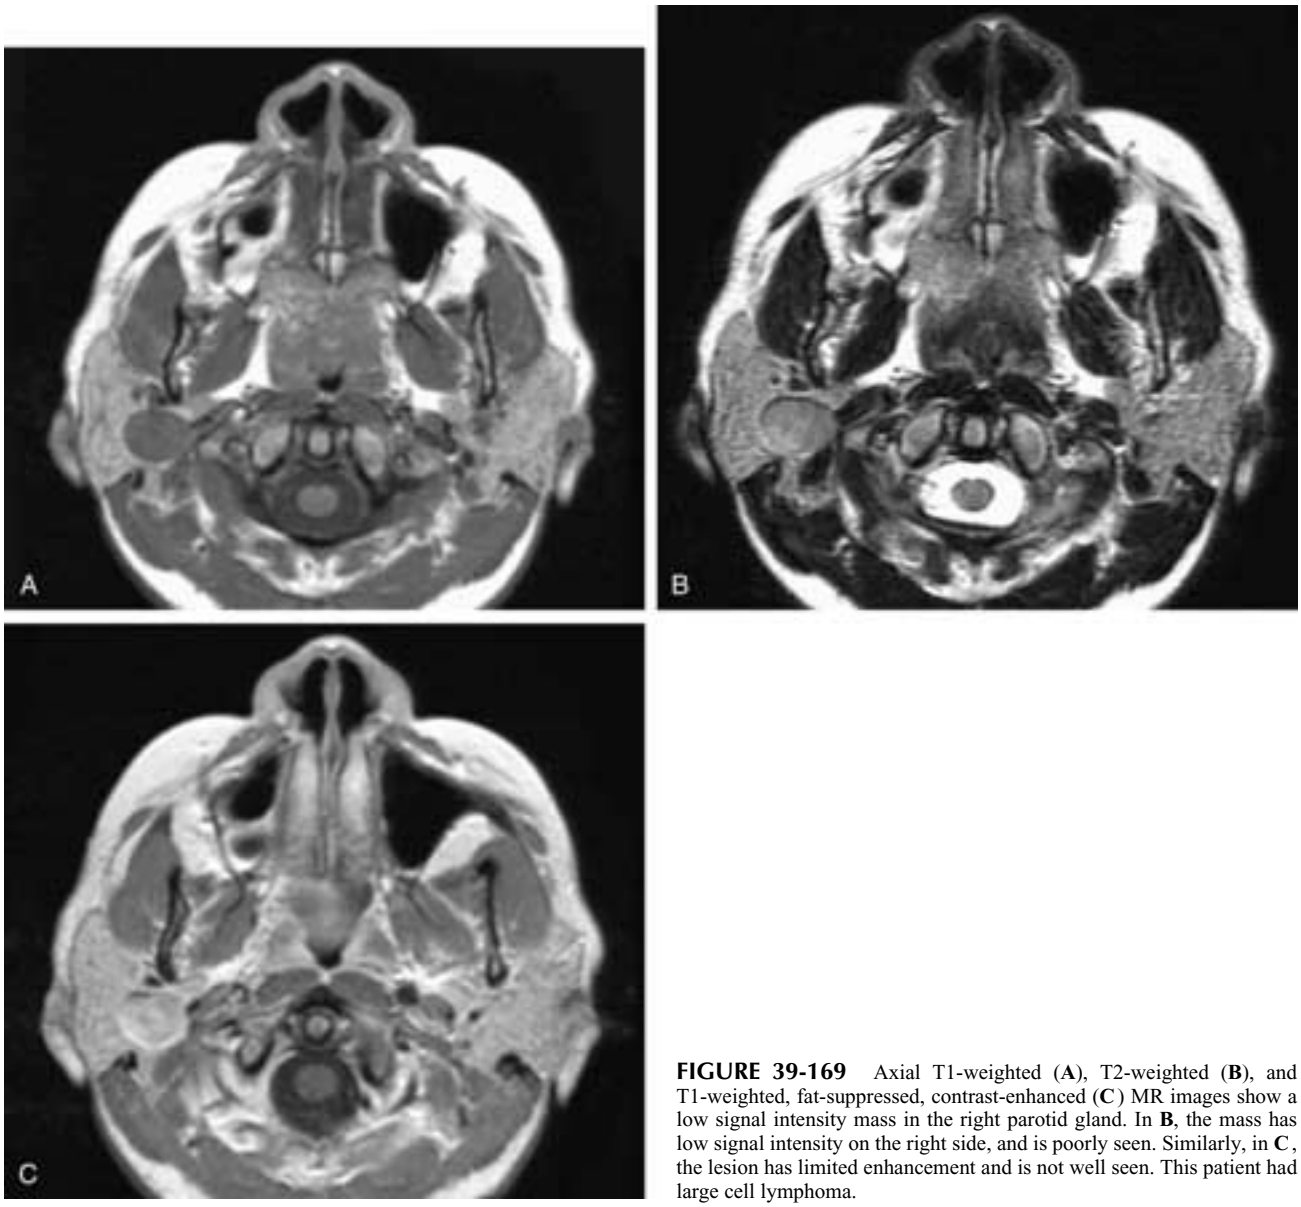

FIGURE 39-169 Axial T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, fat-suppressed, contrast-enhanced (**C**) MR images show a low signal intensity mass in the right parotid gland. VIEW IMAGE

multiple tumor masses. The important clinical distinction between this entity and fibromatosis is that myofibromatosis is circumscribed, amenable to resection, and may occasionally regress spontaneously.

Nodular fasciitis is a benign reactive lesion of fibroblasts. Commonly, it presents as a rapidly growing, tender mass. Unlike fibromatosis, it is circumscribed, without an infiltrative growth pattern, and recurs uncommonly after excision, 7% in a series of 54 cases.[377] Histologically, one may see zones of necrosis and degeneration bordered by ''wild''-looking immature reactive fibroblasts. A tendency toward maturation with zones of whorled, bland fibroblasts may be seen.

Fibrous histiocytoma is a benign tumoral proliferation of fibroblasts and histiocytes. It is usually seen as a subcutaneous neoplasm but may occasionally arise in periparotid tissue (Fig. 39-176). Histologically, it enters the differential diagnosis with fibromatosis and nodular fasciitis.

Plexiform fibrohistiocytic tumor (PFT), a relatively newly described entity, is a soft-tissue neoplasm with low malignant potential that most commonly affects children and young adults and rarely occurs in the head and neck region. In the original description by Enzinger and Zhang, two thirds of patients were under 20 years of age, and there was a clear female predominance. The majority of PFTs occur in the superficial subcutaneous tissues of the upper extremities. Less frequently, they present in the lower extremities or trunk. PFTs affect the head and neck rarely: 10% of the cases reported by Enzinger and Zhang, 7% of the cases reported by Hollowood et al., and none of the cases reported by Remstein et al.[378–380]

Clinically, PFTs almost invariably present as slow-growing superficial masses, usually measuring less than 3 cm, which are painless and firm or rubbery. Generally, PFT can be asymptomatic, although one study reported a lower extremity lesion with an associated foot drop and contractures. The lesions may be raised and sometimes show a

Copyright © 2003, Mosby, Inc. All rights reserved.

central depression, but usually show little discoloration and no ulceration. Most often, the tumors are located in subcutaneous adipose tissue and may extend into dermis or skeletal muscle.

PFTs are characterized by a plexiform proliferation of mononuclear histiocyte-like cells, multinucleated osteoclast-like cells, epithelioid mononuclear cells, and spindle fibroblast-like cells in variable proportions. The stroma consists of a variable admixture of collagen or loose stroma. Cellular atypia and pleomorphism are usually minimal or absent. Mitoses are frequent, and atypical mitoses can also be seen.

PFT should be treated with complete resection and negative margins. Enzinger and Zhang originally emphasized the benign nature of these tumors, citing a low metastatic rate to regional lymph nodes and no distant metastasis. However, there is a significant local recurrence rate after surgical resection, indicating that PFTs are in fact locally aggressive and require complete excision. We have recently seen a 17-year-old boy with a cheek PFT that was initially treated only by shave biopsy. The tumor subsequently recurred, infiltrated the parotid gland, and metastasized to the cervical lymph nodes 3 years after initial biopsy. Distant pulmonary metastasis and a mortality reported by Remstein et al. indicate that PFT is capable of presenting with or progressing to systemic metastatic disease. However, the overall mortality rate for PFT is low (3 of 63 patients or 4.7%), and it appears more likely that patients will survive their disease.

Miscellaneous Lesions

Masseteric Hypertrophy

Masseteric hypertrophy is the most common form of an uncommon entity that is more accurately called masticator hypertrophy, since all of the muscles of mastication may be involved. Usually the condition occurs bilaterally, but it may be unilateral. Muscle enlargement may vary from minimal to up to three times the normal size.[372] Flaring of the mandibular angle(s) can occur. The process usually starts in adolescence or early adulthood, and there is a history of slowly progressive muscle growth. The facial fullness is located anterior to the usual location of a parotid mass and enlarges when the patient's teeth are clenched. The mass feels like muscle on palpation, and the muscle is nontender and not painful. Excessive gum chewing or bruxism has been suggested as playing an etiologic role, but many cases have no known cause. Plain films may show an exostosis of the lateral aspect of the angle of the mandible at the line of attachment of the masseter muscle. A sialogram demonstrates lateral bowing of Stensen's duct around the enlarged masseter muscle. Computed sectional imaging demonstrates the enlarged muscle mass(es), which otherwise appears as normal muscle tissue (Figs. 39-177 and 39-178). Surgery is performed only for cosmesis, and microscopic examination of resected muscle demonstrates either normal muscle or muscle with true work hypertrophy.[381]

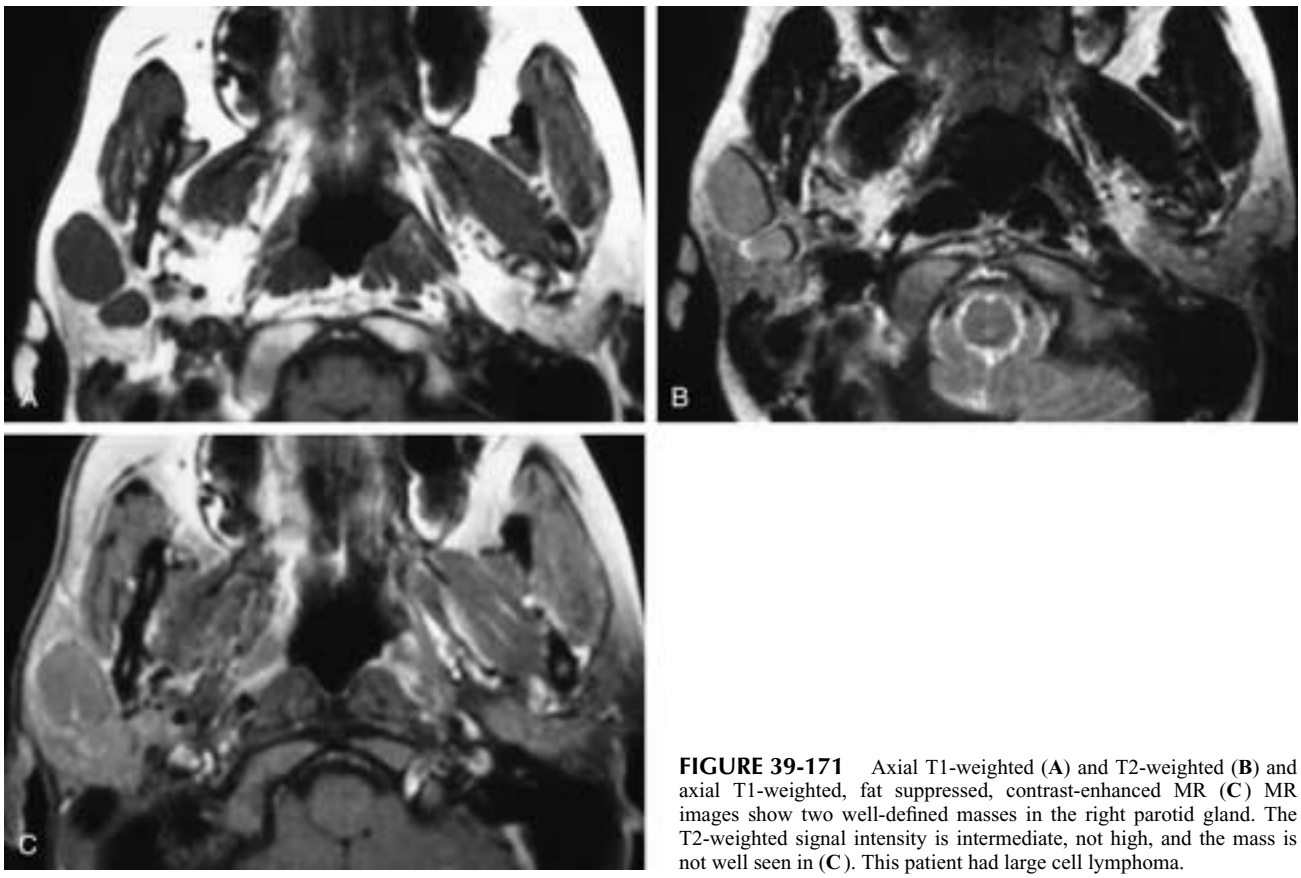

FIGURE 39-171 Axial T1-weighted (**A**) and T2-weighted (**B**) and axial T1-weighted, fat suppressed, contrast-enhanced MR (**C**) MR images show two well-defined masses in the right parotid gland. The T2-weighted signal intensity is intermediate, not high, and the mass is not well seen in (**C**). This patient had large cell lymphoma.

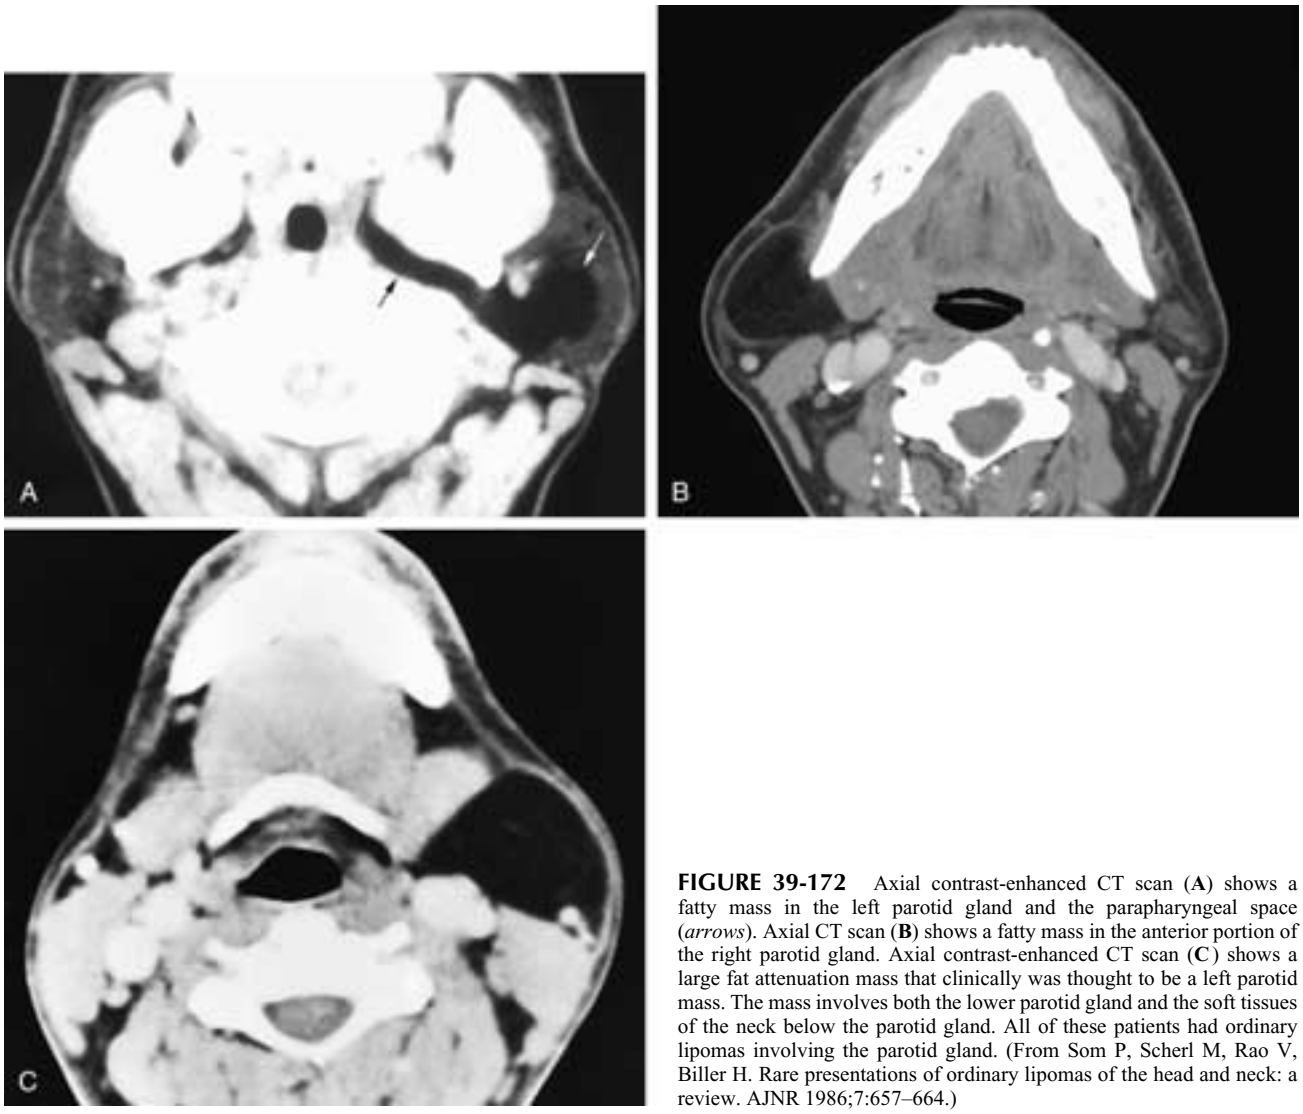

FIGURE 39-172 Axial contrast-enhanced CT scan (**A**) shows a fatty mass in the left parotid gland and the parapharyngeal space (*arrows*). Axial CT scan (**B**) shows a fatty mass in the anterior portion of the right parotid gland. Axial contrast-enhanced CT scan (**C**) shows a large fat attenuation mass that clinically was thought to be a left parotid mass. The mass involves both the lower parotid gland and the soft tissues of the neck below the parotid gland. All of these patients had ordinary lipomas involving the parotid gland. (From Som P, Scherl M, Rao V, Biller H. Rare presentations of ordinary lipomas of the head and neck: a review. AJNR 1986;7:657–664.)

VIEW IMAGE

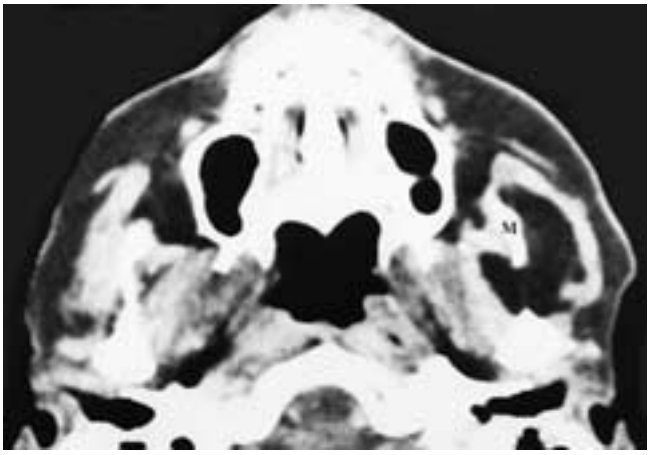

FIGURE 39-173 Axial CT scan shows a fat attenuation mass that has extended from the superficial portion of the left parotid gland back around the mandible (*M*) into the deep portion of the gland. The masseter muscle was also involved. This was an infiltrating lipoma. (From Som P, Scherl M, Rao V, Biller H. Rare presentations of ordinary lipomas of the head and neck: a review. AJNR 1986;7:657–664.)

VIEW IMAGE

Temporomandibular Joint and Mandibular Lesions

A variety of lesions can occur within the region of the temporomandibular joint (TMJ) that may clinically mimic parotid gland disease. Usually degenerative changes and internal joint derangements can be identified clinically as being of primary TMJ origin. However, fibroosseous lesions and exuberant degenerative productive changes involving the TMJ can occasionally present clinically as a mass in the parotid region, as can joint diseases such as synovial chondromatosis (Fig. 39-179). Similarly, in some circumstances, mandibular cysts and odontogenic masses in the mandibular ramus (i.e., dentigerous cysts and ameloblastomas) may be confused clinically with parotid lesions. Metastases to the mandibular ramus and TMJ region may also mimic salivary masses (Figs. 39-180 and 39-181). In these patients, computed sectional imaging provides the most accurate assessment of the true anatomic origin of the process. Metastases often have a cystic, destructive appearance, and the primary tumor usually arises in the lungs, breast, kidneys, or gastrointestinal tract.

VIEW IMAGE

FIGURE 39-178 Axial T2-weighted MR image shows bilateral enlargement of the masseter muscles. The internal pterygoid muscles may also be slightly enlarged. This patient had bilateral masseteric (masticator) muscle hypertrophy.

Other Miscellaneous Conditions

Frey's syndrome, also known as auricular temporal syndrome or gustatory sweating, is an unusual entity that results from an injury to the auriculotemporal nerve. Clinically, sweating and flushing of the skin occur in the area of this nerve's distribution when the patient has a stimulus to salivate. Its true incidence is unknown, but it is estimated to occur in as many as 35% to 60% of postparotidectomy patients. It probably results from a communication between the postganglionic parasympathetic fibers from the otic ganglion and the sympathetic nerves from the superior cervical ganglion. Most patients are not bothered sufficiently to seek medical treatment. If the gland has not been removed, the sialogram and computed sectional imaging studies are normal.[26, 382]

Rarely, skin or subcutaneous lesions such as sebaceous cysts or dermoid cysts overlying the parotid gland may clinically mimic a parotid tumor. By comparison, a prominent transverse process of the second cervical vertebra may be clinically confused on palpation with a deep parotid mass. Tumors arising in the soft tissues around the parotid gland and masseter muscles rarely may also clinically simulate a parotid mass. These lesions include schwannomas, Merkel cell tumors, and rare carcinomas and sarcomas.[192] (See Chapter 41 for a discussion of these lesions (Figs. 39-184 and 39-185).)

Kimura's Disease

Kimura's disease occurs in Orientals, primarily of Chinese or Japanese extraction. The disease has a male predominance (87%), and most cases occur in patients in their second and third decades of life. Lesions can be solitary or multiple, localized or disseminated. Most lesions occur in the head and neck, with the majority of patients having disease in the major salivary glands and regional lymph nodes. The tumoral masses may range in size from 2 to 11 cm, and many reported patients have had these lesions for one to two decades.[383, 384] Histologically, one sees a

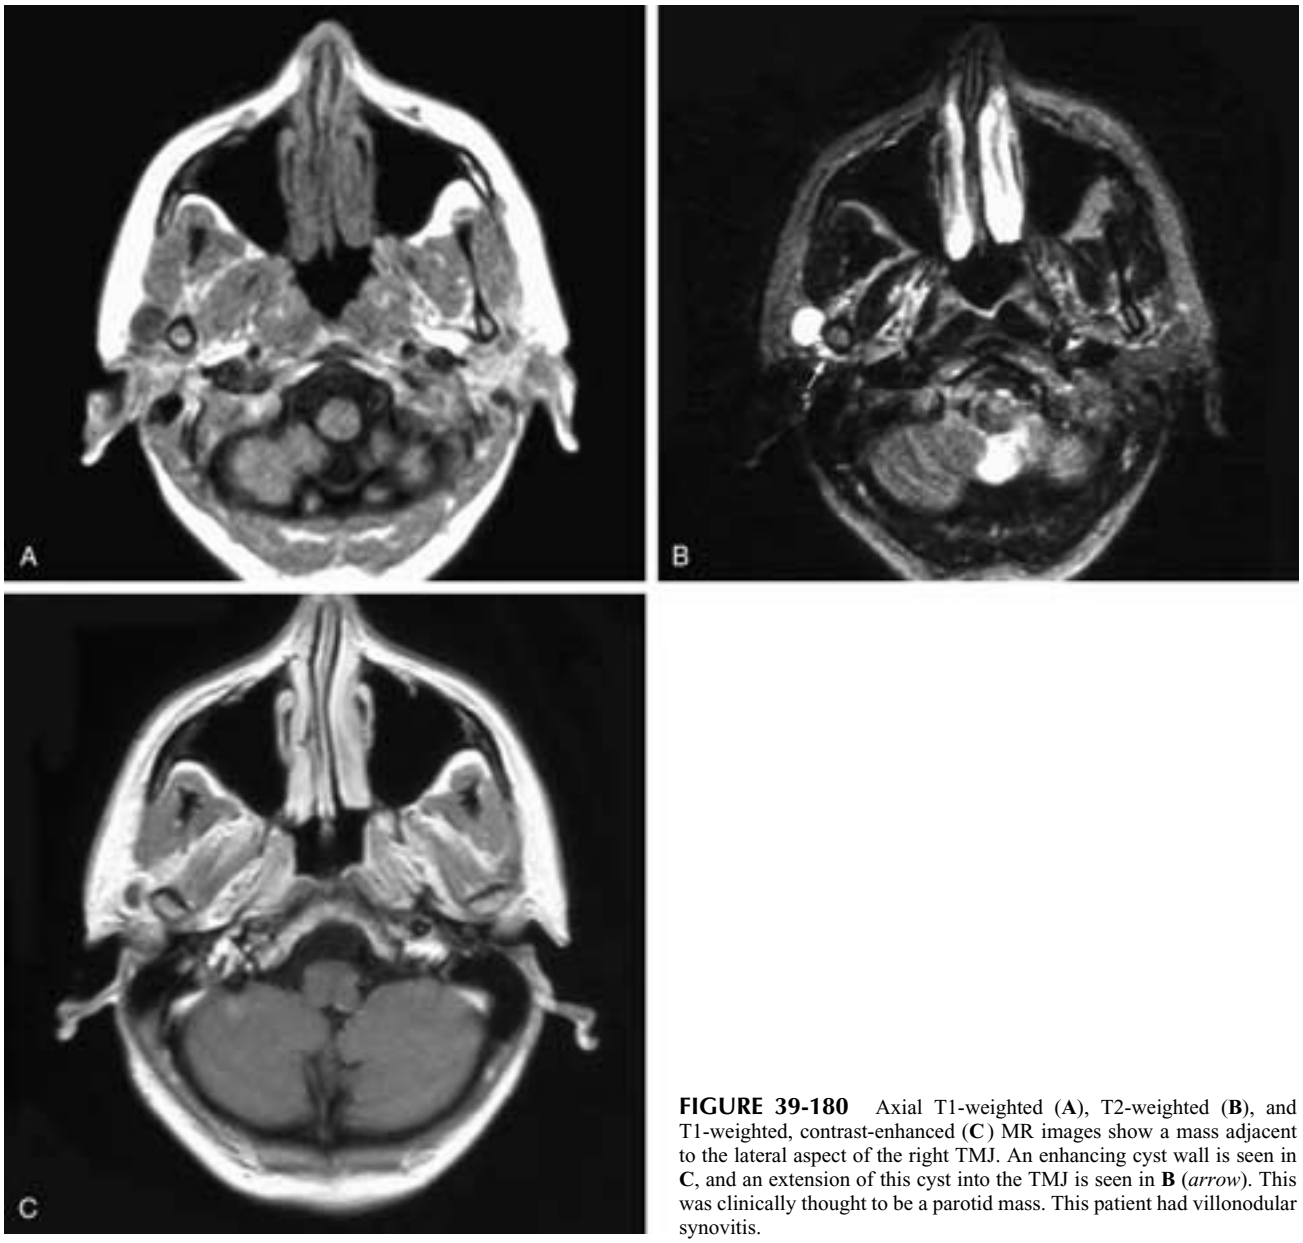

FIGURE 39-180 Axial T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, contrast-enhanced (**C**) MR images show a mass adjacent to the lateral aspect of the right TMJ. An enhancing cyst wall is seen in **C**, and an extension of this cyst into the TMJ is seen in **B** (*arrow*). This was clinically thought to be a parotid mass. This patient had villonodular synovitis.

VIEW IMAGE

vascular and lymphoid proliferation with eosinophilia. The cause of this lesion is unknown. There often is associated blood eosinophilia (10% to 70%) and elevated serum IgE (800 to 35,000 U/ml). Treatment is usually surgical excision. Irradiation has been reported to produce a local control rate of 80%; however, many clinicians are reluctant to irradiate young patients. On CT, the lesions enhance intensely, while on MR imaging, the lesions may have variable T1-weighted signal intensity and usually high T2-weighted signal intensity. Occasionally, flow voids may be present (Figs. 39-182 and 39-183).[383, 384]

Two cases of Kimura's disease with parotid gland and postauricular lymph node involvement were reported. Elevated Tl-201 single photon emission computed tomography (SPECT) uptake was noted on both early and delayed images, and it was concluded that Kimura's disease should be included in the differential diagnosis when increased Tl-201 uptake in head and neck mass lesions is noted.[385]

The clinical differential diagnosis of bilateral parotid swelling includes sialadenosis, mumps, benign lymphoepithelial lesions, Warthin's tumors, clear cell oncocytosis, sarcoidosis, Wegener's granulomatosis, SS, amyloidosis, and polycystic (dysgenetic) disease. The last, an extremely rare condition, has rarely been reported in the literature. It has been reported exclusively in females, in almost all cases is bilateral, and may have its clinical onset either in childhood or in adulthood. Histologically, the parotid gland is entirely replaced by a honeycomb-type meshwork of cysts containing inspissated material with spheroliths. The cysts are the result of dilated ductoacinar units, and very few normal residual acini are seen. Despite its histologic similarity to cystic transformation of other organs such as polycystic kidney

FIGURE 39-181 Coronal (**A**) and axial (**B**) T1-weighted, fat-suppressed, contrast-enhanced MR images show a destructive mass in the left TMJ and skull base. In **A**, there is a mass (*arrow*) in the lower left parotid gland that was a metastatic lymph node. This patient had a synovial sarcoma with metastasis to the parotid nodes.

disease, no other associated parenchymal involvement has been reported.[172, 386]

SUMMARY OF DISEASE PATTERNS

A history of recurrent parotid swelling, with or without associated pain, suggests an inflammatory process. A CT scan may identify a calcified sialolith, show the sialadenitis with or without adjacent inflammation, or suggest SS or sialosis. A sialogram can help determine the amount of damage that has occurred to either the parotid or submandibular gland by showing whether the acinar regions can be visualized. If the acini are not seen, it is unlikely that there will be normal saliva formation and surgery to remove the gland should be performed. On the sialogram, scattered collections of contrast material usually indicate abscesses. Multiple collections of contrast material that are uniform in size and distribution throughout the gland suggest SS. MR can also identify SS in its more advanced stages. An enlarged gland with an otherwise normal sialogram makes sialosis most likely.

Salivary tumors in children are uncommon and represent less than 5% of tumors in all age groups. Hemangioma is the

FIGURE 39-185 Axial contrast-enhanced CT scans (**A** and **B**) show a mass arising in the soft tissues overlying the right parotid gland. The tumor invades the parotid gland and the masseter muscle. Clinically, this was thought to be a parotid malignancy. This patient had a Merkel cell carcinoma.

most common tumor, representing over 50% of all lesions. Next in decreasing frequency are pleomorphic adenomas, MEC, lymphangiomas, and ACC. Rarely, undifferentiated carcinomas, adenocarcinomas, and AdCC can occur. About 30% to 35% of the cases are malignant, a higher percentage than found in adults.[8, 192, 197, 387] Masses that result from autoimmune disease and chronic sialadenitis may on occasion simulate a parotid tumor, and intraparotid lymphadenopathy may also mimic a parotid neoplasm.

A solitary benign-appearing mass in a pediatric patient is probably a lymph node, an hemangioma, a benign mixed tumor, a low-grade MEC, or a lymphangioma.

A solitary benign-appearing mass in an adult patient is probably a benign mixed tumor, a Warthin's tumor, a lymph node, an ACC, a low-grade MEC, a carcinoma ex pleomorphic adenoma, or an AdCC. A solitary malignant-appearing mass is most likely to be a high-grade MEC, an adenocarcinoma, or an undifferentiated carcinoma. Multiple masses suggest Warthin's tumors, acinic cell tumors, lymphoma, chronic inflammatory disease, oncocytic tumors, pleomorphic adenomas, or metastases. Multiple cystic masses, especially in association with benign cervical adenopathy, suggest that the patient is HIV positive.

If a cyst is present within a salivary gland, the limited differential diagnosis includes Warthin's tumor, lymphoepithelial cyst, branchial cleft cyst, sialocele, low-grade MEC, the papillocystic variant of ACC, and oncocystic cystadenoma. CT is the best modality for consistently evaluating the presence of a cyst and any cyst wall characteristics. On MR imaging, it is often difficult to distinguish a solid mass from a cyst unless there are contrast-enhanced images. This is because the watery cyst fluid gives the same signal intensities as the high water content of most benign and low-grade tumors. After contrast administration, the cyst wall enhances but the cyst contents do not. By comparison, the entire tumor usually enhances.

CT and MR imaging findings were reported on two patients with known HIV infection, bilateral parotid lymphoepithelial cysts, and bilateral multiple submandibular gland cysts with no evidence of obstructive glandular disease, autoimmune disease, or other organ system cysts. These cases of presumed submandibular gland lymphoepithelial cysts are rare in the literature.[388]

All salivary masses are probably better identified on MR imaging than on CT. However, calcifications are better seen on CT.

If the tumor accumulates ^{99m}Tc pertechnetate, a Warthin's tumor or oncocytoma is present.

If a tumor mass has low to intermediate signal intensity on all MR imaging sequences, a high-grade malignancy may be present. Although other entities can give these signal intensities, the high-grade lesion is the most important one to rule out of the differential diagnosis.

Calcifications may also be useful in generating a differential diagnosis. Solitary or multiple calcifications usually indicate the presence of chronic sialoadenitis. If calcification is seen within a salivary gland mass, most often the lesion is a pleomorphic adenoma. Less often, calcification can be seen within a schwannoma or an MEC. Parotid lymph node calcifications may occur in such conditions as posttreatment lymphoma and long-standing amyloidosis. Calcification may also occur within chronic hemorrhage. Ossification within a parotid mass is rare, the most common lesion being a pleomorphic adenoma. Phleboliths indicate a hemangioma. The inability of MR imaging to detect such small calcifications is one of the major limitations of this modality when imaging the major salivary glands.

When a solid salivary mass is present, MR imaging usually shows the margins more sharply than CT. What may appear on CT as a vague fullness in the parotid gland or a mass with unsharp margins will usually be seen as a discrete mass on MR. What may appear to be possibly several adjacent masses on CT can be seen either as a highly lobulated solitary mass or as several discrete adjacent

Copyright © 2003, Mosby, Inc. All rights reserved.

masses on MR imaging. Thus, in most cases, MR imaging better resolves the borders of such lesions. Evaluation of tumor extension outside the gland can be well achieved by either CT or MR imaging, as can gross erosion of the mandible or skull base. However, focal bone erosion or subtle bone sclerosis must be evaluated with CT.

With regard to the floor of the mouth and the sublingual glands, a study reported that the T1-weighted signal intensity of carcinomas in and near the sublingual space was lower than that of the sublingual glands, but the T2-weighted signal intensity of carcinomas may exceed that of the glands. Gadolinium enhancement occasionally diminished the contrast between invading carcinomas and the glands. T1-weighted MR imaging shows that sublingual glands affected by SS exhibit features analogous to those of the other major salivary glands; however, the sublingual glands seem to be less severely involved overall in this syndrome than the other major glands. Lastly, fat suppression and short time inversion recovery are useful for assessment of sialadenitis of the sublingual gland.[75]

SECTION ONE

THE THYROID GLAND

The thyroid gland plays a critical role in the regulation of several metabolic functions including cardiac rate and output, lipid catabolism, and skeletal growth, as well as oxygen and heat production. As a result, patients with hormonally active thyroid abnormalities (hypothyroidism or hyperthyroidism) present with a wide range of symptoms. The evaluation of such patients requires an understanding of the hormonal functions carried out by the thyroid gland.

In addition to the pathophysiology resulting from abnormal thyroid function, cross-sectional imaging to assess the morphologic features of the thyroid gland may be necessary for comprehensive patient care. Nuclear scintigraphy reveals functional information about the thyroid gland,

FIGURE 40-1 Normal thyroid gland on MR imaging. **A**, Unenhanced axial T1-weighted MR image shows the normal appearance of the thyroid gland (*T*), which is homogeneously hyperintense to the neck musculature (*m*). The normal anatomic relationship of the gland to the jugular vein (*J*), carotid artery (*c*), esophagus (*e*), and musculature (*m*) is shown. **B**, Axial T2-weighted image at the same level as **A** shows the normal gland to be hyperintense relative to the neck musculature.

while imaging including ultrasound, computed tomography (CT), and magnetic resonance (MR) imaging provide important adjunctive anatomic information. In addition to evaluating the intrinsic structure of the thyroid gland, these modalities provide important information about the related structures in the neck, including the presence of lymphadenopathy, and extension of disease into adjacent soft tissues of the neck such as the mediastinum, trachea, and carotid sheath.

The anatomy and physiology of the thyroid gland will be reviewed. Congenital, autoimmune, inflammatory, metabolic, and neoplastic diseases of the thyroid will then be discussed, and the diagnostic utility of radiologic imaging to evaluate each of these thyroid abnormalities will be addressed.

ANATOMY OF THE THYROID GLAND

The thyroid gland is shield-shaped in the majority of patients. It consists of right and left lobes that are usually joined by the isthmus, though occasionally the isthmus may be absent. The thyroid isthmus is anterior to the trachea, usually overlying the first through third tracheal rings. Uncommonly, it may be more cranial, positioned at or just caudal to the anterior cricoid cartilage arch. The right and left lobes of the thyroid gland are on either side of the trachea, and each lobe has a superior and an inferior pole. The normal thyroid gland is situated with its upper margin near the oblique line on the thyroid cartilage and its lower margin at the level of the fourth or fifth tracheal cartilage; a region referred to as the thyroid bed. The normal thyroid gland weighs between 15 and 35 grams and in males the average thyroid volume is 19.6 ml, while in females it is 18.6 ml. The gland size varies with patient weight, age, and gender and the thyroid gland is enlarged in females during menstruation and pregnancy. The average thyroid lobe measures 3 cm in greatest anteroposterior dimension and 2 cm in width. The thyroid is anterior to the prevertebral (longus colli) and paraspinal musculature and posterior (deep) to the sternothyroid and sternohyoid muscles (Fig. 40-1). Usually, the entire thyroid gland is in the neck above the level of the clavicles; however, substernal extension into the superior mediastinum may occur. An accessory lobe, referred to as the pyramidal lobe, may be present in 50% to 70% of people. It usually arises from the isthmus of the gland and extends superiorly along the course of the distal thyroglossal duct.[1] The pyramidal lobe may be attached to the hyoid bone or, uncommonly, it may arise from the medial aspect of the right or left thyroid lobe. A pyramidal lobe is most commonly recognized in patients with Graves' disease because it is enlarged and readily identified on nuclear scintigraphy (Fig. 40-2).

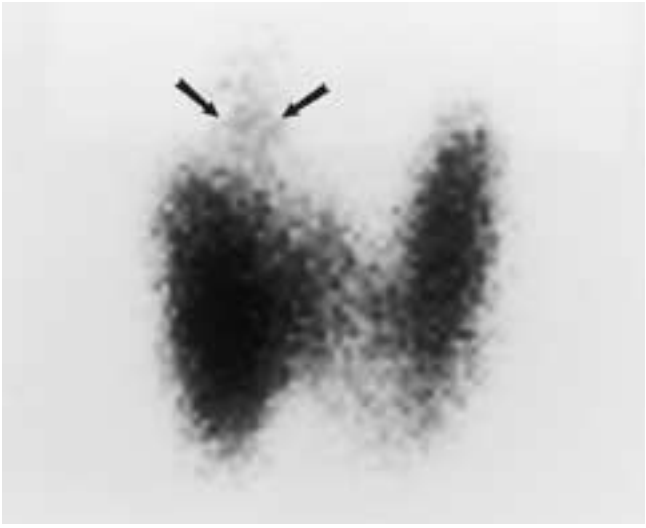

FIGURE 40-2 Iodine-131 scan in a patient with Graves' disease. There is diffuse enlargement and uptake of I-131 by the thyroid gland. A pyramidal lobe is noted (*arrows*). The 24-hour uptake was 48% (normal, 10% to 30%).

As discussed in Chapter 34, the pharynx and cervical esophagus are surrounded posteriorly and along their lateral margins by the retrovisceral space. At the level of the pharynx, this space is often referred to as the retropharyngeal space, while at the level of the cervical esophagus, this same space is usually referred to as the retroesophageal space. At the level of the thyroid cartilage and the attachment of the inferior pharyngeal constrictor muscles to this cartilage, the retrovisceral space has an anterior projection that extends around the sides of the cervical esophagus to encompass the larynx, trachea, thyroid gland, and parathyroid glands. This ventral extension is often referred to as the visceral compartment. This fascia thus attaches the thyroid gland to the larynx and trachea. As a result, the thyroid gland moves with the larynx during swallowing. The thyroid gland is encapsulated, and from this capsule septae extend into the substance of the gland.

Projecting up into the lower aspect of this visceral compartment is a fold of fascia containing the inferior thyroid artery. As a result, this fascial fold divides the lower visceral compartment into anterior and posterior sections. The anterior section, or pretracheal space, extends down behind the sternum to the level of the innominate vessels (sternoclavicular joint) in the anterior mediastinum. The posterior section of the visceral compartment is the retroesophageal space, which extends behind the esophagus down into the posterior mediastinum to approximately the level of the carina. Thus, the entire visceral space is a single, somewhat complex-shaped common space that contains in its anterior portion the larynx, trachea, thyroid gland, and parathyroid glands and surrounds the cervical esophagus and pharyngeal constrictor muscles.

The superior mediastinum is defined as being separated from inferior mediastinum by a plane connecting the joint between the manubrium and the body of the sternum (second costal cartilage) and the lower border of the fourth thoracic vertebra. The inferior mediastinum is further subdivided into anterior (in front of pericardium), middle (pericardium and heart and roots of the great vessels), and posterior (behind the pericardium) compartments. The anterior mediastinum is continuous with the pretracheal space while, as mentioned, the posterior mediastinum is continuous with the retropharyngeal space and the spaces lateral to the esophagus and trachea, between the carotid sheaths.[3]

If a thyroid gland enlarges sufficiently, it will extend outside the normal volume of the thyroid bed. Direct caudal growth is downward into the pretracheal space. As such, the thyroid extension lies in the retrosternal region, anterior to the common carotid arteries and the internal jugular veins. In this location, the thyroid enlargement is usually referred to as a retrosternal or substernal goiter. These goiters are usually resected via a cervical approach, without the need for a sternotomy. If the caudal thyroid gland enlargement is posteriorly directed, the goiter can grow along the sides of the esophagus and eventually extend behind the esophagus. Once behind the esophagus, the goiter can project either down into the posterior mediastinum or up behind the pharynx. If the thyroid growth is into the posterior mediastinum, the goiter is referred to as a mediastinal goiter and it lies dorsal to the great vessels. In this location, many surgeons prefer to resect the goiter via a sternectomy approach. Cranial extension behind the pharynx is resected via a cervical approach.

The thyroid gland has a rich vascular supply. There are paired superior and inferior thyroidal arteries. The right and left superior thyroidal arteries are the first branches off of the respective external carotid arteries, and travel inferiorly from their origin to the thyroid gland. The thyrocervical trunks, which originate from the subclavian arteries, each give rise to an inferior thyroidal artery. The thyroidea ima is an inconstant vessel that, when present, arises directly from the aortic arch and helps supply the inferior thyroid gland. The venous drainage of the thyroid gland is via the superior and middle thyroidal veins, which empty into the internal jugular vein, and an inferior vein, which drains into the innominate vein. The thyroid gland is innervated by the tenth cranial (vagus) nerve and the cervical sympathetic neural plexus. The sympathetic fibers descend from the ganglia of the sympathetic trunk, while the parasympathetic fibers course along with the vagus nerve. This autonomic innervation is believed to strongly influence thyroid gland perfusion.

The thyroid gland contains multiple lobules, each of which is composed of multiple follicles. Thyroglobulin is stored within colloid in these follicles, and the follicular cells secrete thyroid hormones. Parafollicular (C) cells are also dispersed throughout the stroma of the gland and secrete thyrocalcitonin.

ENDOCRINOLOGY OF THE THYROID GLAND

The primary function of the thyroid gland is to synthesize hormones that play a vital role in the regulation of a variety of metabolic functions. Two hormones, triiodothyronine (T3) and thyroxine (T4), are synthesized within the thyroid. They are released from the thyroid in response to a feedback mechanism with the pituitary-hypothalamic axis. Ultimately, the secretion of thyroid hormones is mediated by thyrotropin-stimulating hormone (TSH) secreted by the anterior lobe of the pituitary gland. Pituitary secretion of TSH is in turn regulated by thyrotropin-releasing hormone (TRH) secreted by the hypothalamus.

The synthesis of hormones within the thyroid is a regulated, systematic process. The first step involves trapping of iodide, in which iodide from the circulating plasma is actively transported into the thyroid gland and concentrated within follicular cells. This active transport mechanism traps iodine to a concentration of approximately 100 times more than that in the serum. Iodide is then oxidized by *thyroid peroxidase* into its chemically active form. Subsequently, organification, a process in which tyrosine residues on thyroglobulin molecules are iodinated to form monoiodotyrosine (MIT) and diiodotyrosine (DIT), occurs. The coupling of MIT and DIT forms T3, and the coupling of two molecules of DIT forms T4. Next, T3 and T4 are released from thyroglobulin and secreted into the circulation in free and bound forms.[2] Simultaneously, deiodination of free MIT and DIT occurs for iodide salvage and recycling within the thyroid gland. Aberrant organification usually results from enzymatic defects that interfere

Copyright © 2003, Mosby, Inc. All rights reserved.

with the oxidation of iodide or the iodination of tyrosine. Rarely, there may be failure of iodide trapping.

In the circulation, several carrier proteins transport thyroid hormones. Thyroxine-binding globulin carries approximately 70% of T3 and T4, thyroxine-binding preglobulin carries about 5% of T3 and 25% of T4, and albumin carries the remaining hormones. The active form of T3 and T4 is the free or unbound form, representing only 0.3% of T3 and 0.03% of T4. T3 is approximately three to four times more active physiologically than T4. T4 is synthesized entirely within the thyroid, while 80% to 95% of T3 is synthesized by peripheral conversion of T4.

Temporary interference with the organification of iodide may occur with several medications and with the iodinated contrast materials that are frequently used in CT studies (Table 40-1). The result is altered (decreased) radioactive iodine uptake measurements. Hence, these medications and contrast CT studies should be discontinued prior to nuclear scintigraphy (see below).

CLINICAL MANIFESTATIONS OF THYROID DISEASE

Thyrotoxicosis refers to a clinical syndrome that develops when circulating levels of T4 and T3 are increased (TSH is usually suppressed). Hyperthyroidism refers to sustained thyroid hyperfunction with increased thyroid hormone synthesis and release. Thyrotoxicosis is manifested by a variety of symptoms including warmth and flushing reflecting peripheral vasodilatation, increased heat loss, weight loss, myopathy, and increased appetite. Patients, especially children, may be hyperactive. Cardiac manifestations are more common in older patients and include tachycardia, palpitations, arrhythmias, and cardiomegaly.

Thyrotoxicosis associated with hyperthyroidism is most frequently seen with Graves' disease but may also be seen with toxic multinodular goiter or a hyperfunctioning adenoma. Toxic multinodular goiter associated with hyperthyroidism (Plummer's disease) commonly develops in patients over the age of 50 years and is related to a hyperfunctioning thyroid nodule.[3] Rarely, thyrotoxicosis may be associated with a TSH-secreting pituitary adenoma or thyroid neoplasms. Thyrotoxicosis not associated with hyperthyroidism (low radioactive iodine uptake) may be related to inflammatory thyroid disease or ectopic thyroid tissue (ovarian strumii), or it may be factitious (exogenous hormone use or Munchausen syndrome) (Table 40-2).

RAIU, 24-hour radioactive iodine uptake (normal, 10% to 30%); *TFTs*, thyroid function tests.

Thyroid storm characterized by hypertension, tachycardia, and fever may present as a clinical emergency in patients with unrecognized or inadequately treated thyrotoxicosis. If unrecognized, it may result in death.

Thyroid ophthalmopathy, more common in women, is characterized by proptosis usually secondary to enlargement of the extraocular muscle bellies, with sparing of their tendinous insertions. Although most commonly seen in Graves'disease and hyperthyroidism, thyroid ophthalmopathy may occur in euthyroid and even hypothyroid patients. The most common patterns of extraocular muscle involvement are enlargement of the inferior rectus muscle, enlargement of both the inferior and medial rectus muscles, and enlargement of all of the muscles (Fig. 40-3).[4] There usually is relative sparing of the lateral rectus muscles, and isolated involvement of this muscle should raise the suspicion of a different disease process such as myositis or pseudotumor. Proptosis may also be related to an increase in orbital fat secondary to edema and lymphocytic infiltration, as well as due to an increase in the volume of the extraocular muscles. Although most commonly symmetric, exophthalmos (proptosis) may be asymmetric or even unilateral.[4] Clinical signs and symptoms include proptosis, lid retraction, decreased ocular range of motion, and corneal exposure caused by eyelid retraction. Extraocular muscle enlargement may result in compression of the optic nerve at the orbital

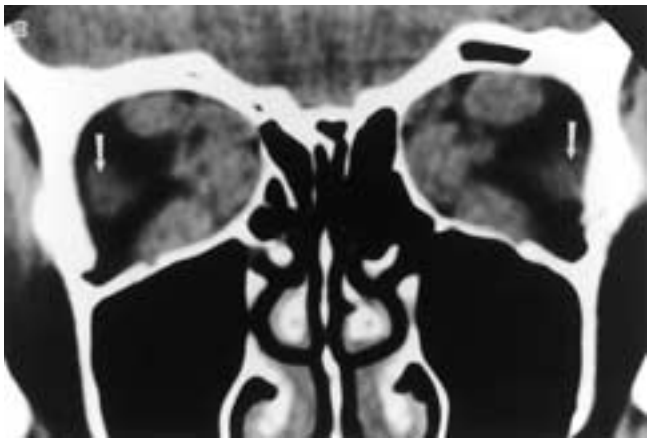

FIGURE 40-3 Thyroid ophthalmopathy in a 43-year-old woman with Graves' disease. Coronal CT scan shows bilaterally symmetric enlargement of the bellies of the extraocular muscles, with relative sparing of the lateral rectus muscles (*arrows*).

FIGURE 40-4 Enhanced CT scan of a multinodular goiter with substernal extension and compression of the trachea and esophagus. **A**, Axial CT scan at the level of the upper trachea shows diffuse nodular enlargement of the thyroid gland that is heterogeneous in density. There is marked displacement of the trachea (*T*) and esophagus (*e*) from left to right. **B**, There is extension of goiter (*arrows*) behind the trachea into the middle mediastinum.

apex, resulting in visual loss. Surgical decompression of the orbit is frequently necessary to preserve vision. Late in the disease, contractures and fibrosis of the extraocular muscles may lead to abnormal eye movements (see Chapter 9).

Hypothyroidism refers to decreased thyroid hormone synthesis (serum TSH is high, while T3 and T4 levels are low). Primary hypothyroidism may be secondary to structural or functional derangements of the thyroid gland, and in adults it most often results from processes that destroy thyroid tissue such as autoimmune disease or iodine-131 (^{131}I) treatment. In children it may be related to enzyme deficiencies, defects in organification, or congenital anomalies such as lingual thyroid or thyroid agenesis.[5] Central hypothyroidism refers to decreased thyroid stimulation by TSH related to pituitary disease (secondary hypothyroidism) or hypothalamic TRH deficiency (tertiary hypothyroidism). Unless readily identified and managed, hypothyroidism occurring prenatally or during infancy will result in cretinism. Hypothyroidism occurring in older children and adults is termed *myxedema*. Clinical manifestations are extremely variable, ranging from fatigue to coma.

Many of the secondary manifestations of thyroid disease are frequently responsible for the clinical presentation of such patients. Any condition that causes marked enlargement of the thyroid gland, most commonly multinodular goiters, but also neoplastic and inflammatory processes, may compress the adjacent esophagus and trachea, causing dysphagia and respiratory distress, respectively (Fig. 40-4). Similarly, there may be compression and displacement of the jugular vein and carotid artery. Because the recurrent laryngeal nerve travels in the tracheoesophageal groove, thyroid lesions that extend to this area may present with vocal cord paralysis. Cervical lymphadenopathy in the presence of a thyroid mass, violation of the thyroid gland capsule's integrity, or direct extension of a thyroid lesion into the trachea or carotid sheath structures are findings highly suggestive of a thyroid malignancy.

THYROID IMAGING

Nuclear scintigraphy and ultrasonography are frequently the first imaging modalities used to assess patients with suspected thyroid disorders. CT and MR imaging are frequently utilized to address specific issues regarding thyroid disease such as the extent of thyroid goiter or extension of neoplasm outside the thyroid capsule and into adjacent structures in the neck. They are used in assessing for regional nodal metastases in the setting of thyroid cancer and in the evaluation of recurrent disease following treatment for thyroid cancer.

Nuclear Scintigraphy

Nuclear scintigraphy provides excellent functional information about the thyroid because the radionuclides used to image the gland do so by utilizing some step of hormone synthesis within the thyroid. The primary role of scintigraphy in the evaluation of a focal thyroid mass is to determine whether a lesion is ''hot'' (low incidence of malignancy) or ''cold'' (higher incidence of malignancy).[6, 7] Nuclear imaging of the thyroid gland is performed with a gamma scintillation camera. The patient is usually placed in a hyperextended supine position. Images are typically obtained from the chin to the sternal notch in multiple views including anterior, posterior, and bilateral oblique projec-

Copyright © 2003, Mosby, Inc. All rights reserved.

tions. Findings on imaging are correlated with those on palpation of the gland.

Currently, morphologic detail of the thyroid gland is obtained using technetium (Tc-99m) pertechnetate, iodine 123 (I-123), and iodine 131 (I-131). Routes of administration, doses, and some physical properties of these agents are reviewed in Table 40-3. Imaging is performed approximately 20 minutes following administration of Tc-99m pertechnetate, 4 to 24 hours following oral ingestion of I-123, and 24 to 72 hours following administration of I-131. The normal thyroid gland shows homogeneous radionuclide uptake and distribution. The isthmus of the thyroid gland may demonstrate slightly less activity than the right and left thyroid lobes.

I-131 is used for determining 24-hour thyroid iodine uptake, measured with a dedicated probe centered 1 inch above the sternal notch. Thyroid uptake reflects the percentage of the dose given to the patient that is accumulated within the thyroid gland, corrected for radioactive decay. Normal 24-hour uptake ranges from 10% to 30%. Several medications such as propylthiouracil, methimazole, and iodine-containing contrast agents used for imaging may temporarily interfere with the organification of iodide, altering radioactive iodine uptake measurements for as long as 6 weeks (Table 40-1).[8–11] The uptake of I-131 may be reduced by as much as one half 1 week following injection of iodinated agents for CT examination.[8–10] Furthermore, in over one third of patients with underlying thyroid disease, temporary changes in thyroid function may occur following injection of iodinated contrast material.[8] Therefore, if CT imaging is believed to be necessary in a patient who will also be studied with nuclear scans using iodinated radionuclides, it should be performed without contrast administration. If contrast is desired, then CT should be performed after nuclear scintigraphy. Medications that interfere with thyroid function should be withdrawn for adequate periods of time prior to nuclear scanning. In general, if CT contrast is administered, one should wait at least 6 weeks before performing nuclear scintigraphy.

I-131 is used in both the evaluation and treatment of patients with thyroid cancers that concentrate iodine. It is particularly useful in the follow-up of patients after thyroidectomy to evaluate for residual thyroid tissue in the operative bed as well as to assess for distant metastatic disease (see Neoplasms of the Thyroid Gland).

More recently, fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) has played an increasingly important role in the follow-up of patients with thyroid cancer due to increased glucose metabolism by malignant tumors. It may be particularly useful in assessing metastatic thyroid tumors that do not concentrate radioiodine [12, 13]. It is frequently used in evaluating patients with rising thyroglobulin levels following thyroidectomy.[14] Whole body scans are obtained to identify regions of FDG uptake (Fig. 40-5). Potential pitfalls include indolent or well-differentiated thyroid tumors that take up FDG poorly and FDG uptake in areas that are not related to metastatic thyroid cancer.

Cross-Sectional Imaging

While scintigraphy provides functional information about the thyroid, CT and MR imaging provide important adjunctive anatomic information that is superior to that of nuclear imaging. These modalities not only provide better delineation of lesions within the thyroid, but also play a critical role in the detection of lymph node metastases, as well as extension of thyroid disease to adjacent tissues in the neck. Specifically, invasion of the paraspinal musculature, esophagus, trachea, and carotid sheath structures may be assessed [15] (Fig. 40-6). The detailed anatomic information provided by CT and MR imaging is also valuable in guiding the surgical approach.

For CT and MR examinations, patients are typically scanned in the supine position with the neck mildly hyperextended so that the hard palate is roughly perpendicular to the tabletop. When possible, the patient is scanned with quiet breathing and swallowing suspended. Contiguous 3 mm thick axial sections are obtained from the level of the cavernous sinuses (upper level of the external auditory canal) to the superior mediastinum, including the aortic arch. In cases where small lesions are being evaluated, thinner sections (1 to 2 mm) may be obtained.

The normal thyroid gland (due to its iodide content) has a density of approximately 80 to 100 HU on CT. That is, since the thyroid gland normally concentrates iodine approximately100 times over the iodine concentration in the serum, and since iodine is the basis of the CT contrast agents, the radiodensity of the thyroid gland on noncontrast CT images correlates well with thyroid function. Thus, a well-seen thyroid gland usually indicates a normally functioning

Table 40-3
RADIONUCLIDES COMMONLY USED IN IMAGING THE THYROID GLAND

Radionuclide	Administration	Dose	Half-life	Energy
Tc-99m	Intravenous	2–10 mCi	6.02 hr	140 keV
I-123	Oral	200–400 µCi	13.6 hr	159 keV
I-131 (diagnostic)	Oral	30–100 µCi	8.05 days	364 keV
I-131 (whole body)*	Oral	2–5 mCi		
I-123 (whole body)*	Oral	1–2.5 mCi		
I-131 (treatment)†	Oral	100 mCi		
I-131 (treatment)‡	Oral	100–200 mCi		

*Diagnostic whole body scan following thyroidectomy to evaluate for residual thyroid tissue in the thyroid bed or to detect distant metastases; to detect ectopic thyroid tissue such as struma ovarii; in hyperthyroid patients with no demonstrable iodine uptake in the thyroid.
† Cancer treatment following thyroidectomy with the goal of ablating residual thyroid tissue (may require hospital admission, depending on the dose).
‡ Cancer treatment with the goal of ablating thyroid metastases (may require hospital admission, depending on the dose).

thyroid. Conversely, a poorly seen gland, or portion of a gland, correlates with poor thyroid function. The injection of iodinated contrast material intravenously usually increases the density of the gland diffusely. While iodinated contrast material may provide additional information about lesions within the thyroid, as mentioned, such contrast will alter radioactive iodine uptake measurements for up to 6 weeks following the study. Therefore, in patients in whom nuclear scintigraphy will also be performed, either contrast should not be administered for the CT study or the nuclear imaging

should be performed prior to CT. Alternatively, MR with contrast material (gadolinium) may be used in conjunction with scintigraphy, as this contrast agent does not interfere with iodide uptake or organification by the thyroid. Another advantage of MR imaging is that it readily identifies blood vessels (signal voids) that on CT may be confused with lymph nodes.

MR imaging is performed with an anterior neck coil centered over the thyroid gland, which provides high-quality images with a high signal-to-noise ratio and the best soft-tissue resolution. Nodules as small as 4 mm may be detected.[16] Multiple pulse sequences should be obtained including noncontrast sagittal and axial T1-weighted images, as well as axial fast spin-echo T2-weighted images with the application of fat saturation. Following intravenous contrast administration, axial T1-weighted images with the application of fat saturation are usually acquired. On T1-weighted images, the normal thyroid gland shows homogeneous signal intensity slightly greater than that of the musculature in the neck. On T2-weighted images, the thyroid gland is hyperintense relative to the neck musculature (Fig. 40-1). Following contrast administration, the normal gland enhances diffusely and homogeneously.

Ultrasonography

Real-time ultrasound of the thyroid gland is usually performed with high-resolution linear array transducers ranging from 7.5 to 10 MHz.[17] The neck is mildly hyperextended, and the thyroid gland is imaged in its entirety in both the transverse and longitudinal planes. The carotid arteries and jugular veins are posterior and lateral to the thyroid lobes, respectively, and provide excellent anatomic markers during the examination. The thyroid gland is normally uniformly hyperechoic.[17] The more hypoechoic a focal lesion is relative to the normal thyroid gland, the higher the likelihood of malignancy.[18]

The advantages of ultrasound are three: it is accessible, inexpensive, and noninvasive. It is a quick and highly sensitive modality for distinguishing cystic from solid lesions. Focal lesions meeting all of the criteria for a simple cyst (thin wall with smooth margins, anechoic, distinct back wall, and enhanced through transmission) are usually benign. However, any complicated cyst may represent a carcinoma. When calcifications are present, they appear as foci of increase echogenicity with distal acoustic shadowing. Calcifications are nonspecific and may be seen in benign as well as malignant lesions.[18] Ultrasound may also be used to guide fine needle aspiration of nodular disease within the thyroid or to guide aspiration of suspicious cervical lymph nodes in the setting of thyroid cancer (Fig. 40-7).[19–21]

Drawbacks of ultrasound are that the quality of the images as well as their interpretation are dependent on the expertise of the examiner. Another limitation is that ultrasound is not as good as cross-sectional imaging techniques in identifying lymphadenopathy or in evaluating for extension of thyroid disease into the soft tissues of the neck, chest, or air-filled structures.

PATHOLOGY OF THE THYROID GLAND

Congenital Anomalies

The thyroid gland develops in the first trimester of pregnancy, beginning around the fifth week of gestation, and its development is completed by the tenth week of gestation. It develops from median and paired lateral anlages. The median anlage arises in the midline oropharynx at the fourth to fifth gestational week and gives rise to follicular thyroid tissue, which will ultimately secrete hormones.[22] The lateral anlages are believed to arise from the ultimobranchial bodies, which in turn are derived from the fourth and fifth branchial pharyngeal pouches at around the fifth week of gestation. They give rise to the parafollicular C cells that are thought to derive from the neural crest.[22] The parafollicular cells ultimately secrete calcitonin. By the tenth week in utero, the right and left lateral anlages fuse with the median anlage, resulting in the bilobed thyroid gland (see also Chapter 33).[22, 23]

During fetal development, the thyroid gland must descend from its place of origin, the foramen cecum, located at the anterior, midline base of the tongue, to its final adult destination in the lower neck both anterior and lateral to the trachea. The thyroid is attached to the tongue base by the thyroglossal duct, which is lined by squamous epithelium. During the caudal descent of the gland, this duct elongates and subsequently degenerates and atrophies.

Abnormal development or aberrant caudal descent of the thyroid gland results in a variety of congenital anomalies. Arrest of descent can occur anywhere from the tongue down to the lower neck. Ectopic thyroid has rarely been reported in the submandibular and lateral neck regions.[24] In these cases, these ectopias may be misinterpreted as metastatic disease. Failure of descent of the median thyroid anlage, or complete failure of descent of the thyroid, results in a lingual thyroid gland at the base of the tongue, the most common type of functioning ectopic thyroid tissue (Fig. 40-8). In

such cases, up to 75% of patients may have no functioning thyroid tissue in the neck.[25–27] As a result, if tissue at the base of the tongue is not recognized as thyroid and is resected, the patient may become acutely and severely hypothyroid.[28] Nuclear imaging plays the major role in establishing the diagnosis of a lingual thyroid gland as well as in determining whether there is normal functioning thyroid tissue in the neck. On noncontrast CT, lingual thyroid is hyperdense due to its iodine content, and on MR imaging it has high signal intensity on T1-weighted and T2-weighted images compared to the tongue musculature. Avid enhancement is seen following contrast administration.

Overdescent of the thyroid may result in ectopic normal thyroid in the lower neck or mediastinum. On rare occasions, thyroid tissue may be found in remote locations, such as within the heart and within ovarian teratomas (struma ovarii).[29, 30] In the handful of reported cases of intracardiac thyroid tissue, all arose from the right ventricular aspect of the interventricular septum, and none were associated with abnormalities of thyroid function.[30] Intratracheal thyroid ectopia may also occur, with aberrant thyroid tissue most often located at or just below the cricoid cartilage.[31] The overwhelming majority of patients with this condition are female, and most present with respiratory distress that may be acute or chronic. The intratracheal thyroid tissue may be contiguous with the thyroid lobe by a bridge of tissue or a thin fibrous strand.[31]

Any pathology that may arise within normally located thyroid may also arise in ectopic tissue. Though extremely rare, carcinoma has been described in ectopic tissue.[27, 32] Scintigraphy using Tc-99m pertechnetate or I-131 should be performed when ectopic thyroid is suspected.[33]

Other developmental anomalies of the thyroid gland include agenesis or hemiagenesis of one lobe, with normal formation of the contralateral lobe and isthmus.[6, 33, 34]

Incomplete degeneration of the thyroglossal duct may result in a persistent fistulous tract or in a thyroglossal duct cyst along the path of migration of the thyroid gland from the foramen cecum at the tongue base to the anterior lower neck. Thyroglossal duct cysts most often are anterior midline neck masses, although they may be located in a paramedian location especially when infrahyoid. Over half of these cysts have normal thyroid follicular tissue in their walls.[35] Approximately 65% of thyroglossal duct cysts are infrahyoid in location and are encased by the thyroid strap muscles (Fig. 40-9). Cysts may also occur in the suprahyoid region (20%) at the tongue base/floor of the mouth (Fig. 40-10) or in the hyoid region (15%) above the strap muscles.

On cross-sectional imaging, uncomplicated thyroglossal duct cysts are usually well demarcated. On CT, they most often are isodense to water; however, they may be hyperdense when there is high protein content. On MR imaging, they typically have low T1-weighted and high T2-weighted signal intensities. However, when the contents of the cyst are proteinaceous, the cysts may be hyperintense on T1-weighted images (Fig. 40-11) and usually remain intermediate to hyperintense on T2-weighted images. Thick peripheral enhancement is unusual unless a cyst is secondarily infected. On sonography, these lesions have typical features of a cyst. They may also demonstrate internal echoes when proteinaceous or infected, similar to other complicated cysts. Nuclear scintigraphy is usually not necessary in the evaluation of thyroglossal duct cysts. The one exception is a cyst in a child without a palpable thyroid gland; in this case, nuclear scintigraphy may be necessary to determine if the cyst contains the patient's only functional thyroid tissue.

When large, these cysts are clinically detected as palpable midline or near-midline neck masses. A highly suggestive clinical finding of a thyroid origin is vertical motion of the mass with swallowing or tongue protrusion. These larger

cysts may have multiple septations on imaging (Fig. 40-12). Small thyroglossal duct cysts are usually clinically occult and may be recognized only if they become secondarily infected or traumatized, or if they are incidentally noted on imaging studies of the neck being performed for unrelated reasons. Rarely, thyroglossal duct cysts may undergo malignant degeneration, usually into papillary carcinoma. This should be suspected when a soft-tissue component or nodule exists within or around the cyst or if the cyst has calcifications.[36]

Thyroglossal duct cysts may be excised for a variety of indications including secondary infection, a mass effect resulting in pain or dysphagia, or for cosmesis. Acutely infected cysts should be treated with a full course of antibiotics prior to surgical excision. In cases where a cyst is associated with a sinus tract, excision of the entire tract is necessary. The general operation for a thyroglossal duct cyst is the Sistrunk procedure. Sistrunk proposed that the body of the hyoid bone should be removed during surgical resection of a thyroglossal duct cyst. In so doing, recurrences were reduced from nearly 50% to less than 4%.

In cases of small thyroglossal duct cysts with carcinoma, surgical resection alone may be considered adequate therapy when there is no evidence of angio-invasion, the surgical margins are clear, the remainder of the thyroid gland is normal on ultrasound, and the patient is young and has no significant risk factors. Otherwise, in a patient of advanced age, or with unfavorable pathologic findings or nodularity in the thyroid gland, management may require surgical resection of the cyst accompanied by total thyroidectomy and/or radioiodide therapy.

Autoimmune Disease and Thyroiditis

Thyroiditis is infiltration of the thyroid gland with inflammatory cells. This may be seen in a diverse group of autoimmune, inflammatory, and infectious processes. Thyroiditis may be acute and self-limiting or chronic and progressive.

Several autoimmune disorders may affect the thyroid gland including Graves' disease, Hashimoto's thyroiditis, and silent/postpartum thyroiditis. Each differs in pathophysiology and clinical presentation. Graves' disease and silent thyroiditis are usually associated with thyroid hyperfunction, while Hashimoto's disease (chronic lymphocytic thyroiditis) is typically associated with hypofunction. As will be discussed later, the term *goiter* simply refers to a clinically evident enlargement of the thyroid gland.

Graves' Disease

Graves' disease is the most common of the autoimmune disorders, occurring in approximately 0.4% of the U.S. population.[2] The peak incidence is in the third to fourth decades of life, with a female predominance. There is a familial predisposition. In Graves' disease the thyrotropin receptor on the follicular cells is the target for thyroid autoantibodies, which bind to these receptors, stimulating them as though TSH triggered the receptor. This results in constant autonomous function of the thyroid resulting in hyperthyroidism. Serologic tests for specific autoimmune markers may be elevated, confirming the diagnosis. Marked enlargement of the thyroid gland without focal nodules referred to as diffuse toxic goiter results. There may be prominent enlargement of a pyramidal lobe (Fig. 40-2). Pathologically, in the thyroid gland there is diffuse hyperplasia of the follicular epithelial cells and depletion of

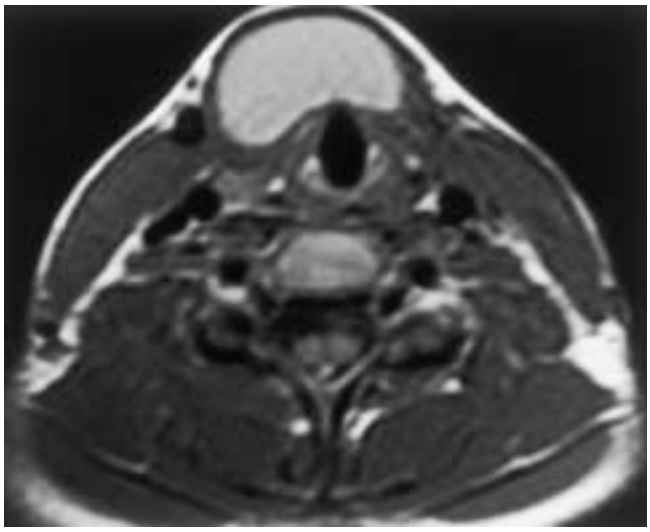

FIGURE 40-11 Thyroglossal duct cyst containing proteinaceous material. Unenhanced axial T1-weighted image shows a midline cyst that is hyperintense due to its proteinaceous contents.

colloid. Vascularity is increased. Graves' disease is associated with other autoimmune diseases of the thyroid including Hashimoto's thyroiditis.

Radionuclide scintigraphy may be useful in evaluating a patient with suspected Graves' disease as well as in differentiating it from acute thyroiditis. Typically in Graves' disease, the thyroid gland is diffusely enlarged with intense radiotracer uptake, often as high as 80% in 24 hours (Fig. 40-13).

The differential diagnosis includes thyroiditis, toxic multinodular goiter, and toxic adenoma. In contrast to Graves' disease, where there is concordance between the clinical presentation of thyrotoxicosis and the radionuclide uptake, in the acute phase of thyroiditis when the patient is clinically hyperthyroid, the gland may be so impaired that there is little observable radionuclide uptake (Fig. 40-14), which is usually less than 10% (normal, 10% to 30%). On scintigraphy, tracer uptake is often inhomogeneous and reduced. During the subacute phase of thyroiditis, the radiotracer uptake usually returns to normal if the gland recovers and the patient reverts to a euthyroid state. Differentiation between Graves' disease and subacute thyroiditis is important for appropriate patient management, as patients with Graves' disease often require medication to

VIEW IMAGE

treat the secondary manifestations of hyperthyroidism (beta blockers for tachycardia) as well as thyroid medication, radioiodine ablation of the thyroid gland, or surgery when required. Subacute thyroiditis is treated conservatively.

In toxic multinodular goiter, there are areas of both increased and decreased uptake within an enlarged gland (Fig. 40-15) distinct from the homogeneous uptake seen in Graves' disease, and the overall uptake is not as avid as that in Graves' disease. In toxic adenoma, there is focal uptake in a single nodule. If the nodule is autonomous, suppression of the normal glandular tissue may be observed.

On cross-sectional imaging, the findings in Graves' disease are nonspecific. The thyroid is enlarged. On ultrasound, the gland is often diffusely hyperechoic, without discrete nodules. A characteristic increase in thyroid vascularity is observed on color Doppler studies in both systole and diastole, particularly in patients with active hyperthyroidism.[37, 38] On CT and MR imaging, the enlarged thyroid demonstrates avid enhancement. The noncontrast CT density is actually decreased, reflecting a decrease in iodine concentration even though there is an overall increase in the iodine content of the gland. Even after treatment, density values may not return to normal.[39]

Hashimoto's Thyroiditis

Hashimoto's thyroiditis (chronic lymphocytic thyroiditis) is the prototype autoimmune thyroiditis. Pathologically, the thyroid gland is enlarged and demonstrates lymphocytic and plasma cell infiltration, follicular cell atrophy, and interlobular fibrosis.[40] Additionally, the normal follicular epithelial cells may be altered, being replaced with pink oxyphilic epithelium (Hurthle or Askanazy cells).[41] It is usually associated with a goiter. The pathogenesis of Hashimoto's thyroiditis involves both cellular and humoral mechanisms. Autoantibodies have been identified against thyroglobulin, thyroperoxidase, and TSH receptors. In reported cases, when TSH receptor-blocking antibodies disappeared, normal thyroid function returned.[42] Hashimoto's thyroiditis is

associated with other autoimmune disorders including lupus, Graves' disease, and pernicious anemia.

Hashimoto's thyroiditis occurs predominantly in women, most commonly presenting in the fourth and fifth decades of life. It may also present in children, in whom it is the most common thyroiditis.[43] The clinical presentation is frequently that of hypothyroidism.[44] Antibody titers are markedly elevated during the acute phase. In the acute phase of glandular destruction and hormone release, symptoms of hyperthyroidism may be evident. However, ultimately, hypothyroidism usually prevails.

The diagnosis of thyroiditis in general is based on the clinical presentation, and laboratory analysis of thyroid function and imaging is not a critical component of the initial workup of these patients. Although the radiologic findings are nonspecific, imaging can be useful, especially in patient follow-up and monitoring of disease.

On scintigraphy, there is no typical pattern in Hashimoto's thyroiditis. Uptake of radioiodine or Tc-99m pertechnetate is most commonly heterogeneous and patchy, and may be uniformly increased or mildly to severely decreased.[41, 45] In children, a homogeneous distribution of tracer is more common.[43]

Ultrasonography demonstrates a variety of patterns. The thyroid may be normal or enlarged in size and is diffusely abnormal, with heterogeneous echogenicity (Fig. 40-16). There may be numerous poorly defined, hypoechoic regions separated by fibrous strands.[19] Large nodules within the gland raise the possibility of superimposed non-Hodgkin's lymphoma. In end-stage disease, the thyroid gland may be atrophied and fibrotic, resulting in a heterogeneous echotexture.

On CT, there is an inhomogeneous distribution of iodine. With MR imaging, T2-weighted images may show areas of increased signal intensity. Linear, septated, low-intensity bands thought to represent fibrosis have been described.[16] Following contrast administration, there may be regions that enhance more than the remainder of the gland (Fig. 40-17).

Ultrasound may be used to follow patients with Hashimoto's thyroiditis to detect occult malignancy because there is a well-known increase in the incidence of non-Hodgkin's lymphoma in this setting.[46–49] Thyroid lymphoma may produce solitary or multiple focal hypoechoic lesions or diffuse disease that may be difficult to distinguish from Hashimoto's thyroiditis.[46, 47] The presence of cervical lymphadenopathy raises the suspicion of lymphoma. Primary thyroid carcinoma is unusual but has been reported.[50]

Silent, Painless Thyroiditis and Postpartum Thyroiditis

Silent, painless thyroiditis and postpartum thyroiditis are two different types of subacute lymphocytic thyroiditis, which are usually self-limited. When this inflammatory process occurs in the absence of pregnancy, it is termed *painless thyroiditis*. Low-titer antithyroid antibodies may be present, and the disorders are thought to be autoimmune.

During the early phase of lymphocytic infiltration, follicular disruption with hormone release usually causes patients to present with thyrotoxicosis. As the disease progresses, patients may be hypothyroid transiently before returning to a euthyroid state.[51] Patients may or may not have glandular

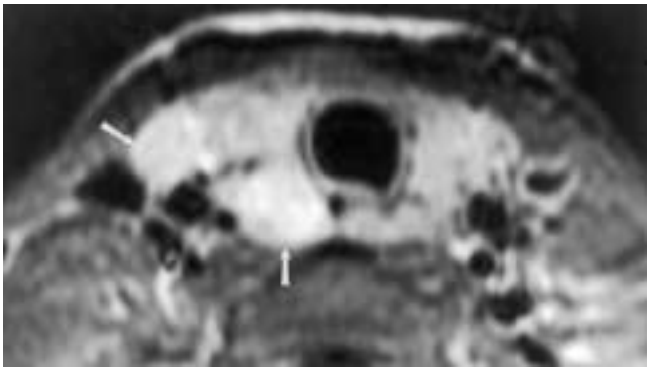

FIGURE 40-17 Hashimoto's thyroiditis. Enhanced axial T1-weighted MR image shows two nodules (*arrows*) in the right lobe of the thyroid gland that enhance more than the remainder of the gland.

Copyright © 2003, Mosby, Inc. All rights reserved.

enlargement. Radioactive iodine uptake is low, and the pattern on scintigraphy varies from no tracer uptake to diffuse or heterogeneous uptake.[34] Nuclear scans may return to normal in conjunction with resolution of the process.

Postpartum thyroiditis typically occurs 4 to 6 weeks following delivery. It occurs in up to 5% of postpartum women and may recur with subsequent pregnancy.[52] As with silent thyroiditis, women may present with goiter, thyrotoxicosis, and antithyroid antibodies. The process usually resolves after transient hypothyroidism; however, some patients progress to chronic lymphocytic thyroiditis.

De Quervain's Thyroiditis (Subacute Granulomatous Thyroiditis)

De Quervain's thyroiditis is a self-limited inflammatory process that usually occurs following a viral upper respiratory tract infection.[2, 22] The viral infections that have been associated with subacute thyroiditis include coxsackievirus and the mumps.[53] The peak incidence is in the second to fifth decades of life, with an occurrence three times more frequent in women. Early in the inflammatory process, follicles may be replaced with neutrophils forming microabscesses. Later, macrophages and multinucleated giant cells surround the damaged follicles, stimulating a granulomatous process.[2] Viral inclusions have not been found in the inflamed gland. With healing, there is regeneration of the follicles. The clinical presentation may include painful enlargement of the thyroid gland, fever, and thyrotoxicosis with low radioactive iodine uptake. Scintigraphy shows a variable pattern that usually reverts to normal as the patient returns to a euthyroid state.[6] On non-contrast CT, the gland is slightly enlarged and has a lower than normal attenuation.

Acute Suppurative Thyroiditis

Acute suppurative thyroiditis is uncommon and typically occurs due to seeding of the thyroid gland by bacterial, and occasionally fungal, organisms in immunocompromised or debilitated patients.[22] It may be associated with a fourth branchial cleft abnormality, and one of the roles of imaging is to exclude a fistula (from the pyriform sinus apex) as an etiology of the thyroiditis.[54] On cross-sectional imaging, the affected portion of the gland (lobe[s] and/or isthmus) will be enlarged and heterogeneous in CT density and MR signal intensity. With disease progression, focal abscesses may develop and there may be obliteration of the adjacent soft tissues in the neck resulting from associated myositis and cellulitis.[55]

Riedel's Thyroiditis (Struma)

Riedel's thyroiditis (struma) is a rare form of chronic thyroiditis characterized by a fibrosing reaction similar to that seen in retroperitoneal fibrosis, which destroys the thyroid and extends into the adjacent soft tissues of the neck. Within the fibrosing tissue is a lymphocytic and plasma cell infiltration and a vasculitis (phlebitis).[56] As a result, stridor, dysphagia, and vocal cord paralysis may result from recurrent laryngeal nerve involvement. In fact, Reidel's thyroiditis is one of the few nonmalignant thyroid causes of recurrent laryngeal nerve paralysis. The cause of Reidel's thyroiditis is unknown. It is more common in women and usually occurs in the fourth to seventh decades of life. On palpation, the thyroid is frequently firm, which may be confused with a malignancy.[57] One-third of patients will develop hypothyroidism. On ultrasound the thyroid may be hypoechoic, and on CT the involved thyroid may be hypodense compared to normal thyroid (Fig. 40-18).[17, 58] The characteristic MR appearance includes decreased signal intensity on T1-weighted and T2-weighted images believed to correspond to fibrosis, as well as infiltration of adjacent soft tissues in the neck.[57] Riedel's thyroiditis may be associated with mediastinal or retroperitoneal fibrosis as well as sclerosing cholangitis.

Thyroid Goiter

As mentioned, the term *goiter* refers to any clinical enlargement of the thyroid gland. A goiter develops because as the thyroid gland compensates for inadequate thyroid hormone output, the follicular epithelium undergoes compensatory hypertrophy to achieve a euthyroid state. As a result, either hypothyroidism or hyperthyroidism may develop. Although initially the goitrous enlargement is diffuse, with time it usually becomes nodular. If the impediment to thyroid hormone output abates, the thyroid gland may revert to normal during the diffuse state.

Diffuse nontoxic goiter is a diffuse nonnodular enlargement of the thyroid associated with a euthyroid state. There are two stages in its development. The first stage is hyperplasia (follicular cell growth) characterized by diffuse glandular enlargement and hyperemia. The second stage is colloid involution, which occurs when a euthyroid state is maintained. Endemic goiters are prevalent in iodine-deficient areas. In simple sporadic goiter, there is a female predominance and a peak incidence at puberty.[2] With time, most simple goiters progress to multinodular goiters that may remain nontoxic or may induce thyrotoxicosis.

Multinodular goiter is characterized by nodularity, focal hemorrhage, focal calcifications, cyst formation, and scarring. Glandular enlargement may be asymmetric, involving

one lobe more than the other and/or involving the isthmus. Thyroid goiters may extend substernally and into the anterior mediastinum.

Multiple patterns may be identified with nuclear scintigraphy (Fig. 40-15). Radioactive iodine or Tc-99m pertechnetate may accumulate in multiple foci throughout the gland or, less typically, in only a few nodules. Some nodules may demonstrate autonomous function. In patients with thyrotoxicosis, therapeutic doses of I-131 may be required to reduce thyroid function. Although it was previously thought that a solitary cold nodule in a multinodular goiter was less likely to be malignant than a solitary cold nodule in a normal gland, recent studies have demonstrated similar rates of malignancy.[58–60] A dominant or enlarging mass within a goitrous thyroid should be biopsied (Fig. 40-19).[61]

On ultrasonography, a simple goiter demonstrates diffuse glandular enlargement with uniform or irregular echogenicity that may be increased or decreased. A multinodular goiter is often irregular, showing diffuse inhomogeneous echogenicity or multiple focal hypoechoic nodules. On CT evaluation of multinodular goiter, the gland is asymmetric, with multiple low-density areas reflecting regions of hemorrhage, cyst formation, or necrosis (Fig. 40-20). More focal regions of hyperdensity are common, reflecting calcifications present in over one half of patients, hemorrhage, or colloid (Fig. 40-21). On MR imaging, multinodular goiter may show a wide spectrum of appearances.[62] On T1-weighted images, multiple foci of high signal intensity may represent cysts containing colloid or hemorrhage (methemoglobin). On T2-weighted images, diffuse heterogeneity may be present,[62] and nodules as small as 3 to 5 mm can be visualized.[16] Alternatively, multiple large, heterogeneous nodules may be present. Enhancement is usually inhomogeneous. Unlike CT, calcifications may be difficult to detect and, when visualized, may appear as low-intensity foci on T1- and T2-weighted sequences.

CT and MR imaging are useful in evaluating secondary manifestations of goiter including compression and displacement of the trachea, esophagus, and adjacent vessels (Fig. 40-4). Importantly, substernal and mediastinal extension is readily detected (Figs. 40-4 and 40-21). In contrast, nuclear scintigraphy and ultrasound may fail to

show continuity between a cervical and a mediastinal goiter. When symptoms related to compression of the aerodigestive tract or vessels occur in elderly patients, nonsurgical candidates, or those refusing surgery, therapy with I-131 may be effective in reducing thyroid volume.[63]

Specifically on CT and MR reports, the radiologist must mention any shift in the axis of the trachea, the location of any tracheal narrowing, the degree of this narrowing, and the length of the stenotic segment. The location of the tracheal narrowing should be given with reference to the bottom of the cricoid cartilage, as this is an easily recognizable endoscopic landmark. The length of the segment in centimeters should then be mentioned. Finally, the percentage of the tracheal cross-sectional area reduction should be estimated. If the patient has normal pulmonary function, a 50% reduction in tracheal cross-sectional area usually is associated with dyspnea at rest. In addition, the greatest dimension of the enlarged thyroid gland and the most cranial and caudal levels of the gland should be noted. Thus, a typical report might mention that ''there is a large multinodular goiter of 9 cm in greatest dimension. The most cranial level of the gland is at the level of the true vocal cords, and the most caudal level is 1 cm below the level of the top of the manubrium. The tracheal axis is shifted to the right, and starting 2 cm below the level of the cricoid cartilage and extending over a 3 cm length of trachea, there is an approximately 30% narrowing of the cross-sectional tracheal area.'' Such a report provides all of the necessary information to the clinicians in order for them to make an appropriate treatment decision. The extension of a goiter outside of the normal thyroid bed occurs into the substernal area in 5.7% –20% of the cases. Extension into the posterior mediastinum occurs in 9.8%–12% of cases, and this always occurs in conjunction with extension into the anterior mediastinum. There are also (7.4%) of goiters that extend up behind or along the side of the pharynx.

Nodular Thyroid Disease

Palpable nodules in the thyroid gland are common, occurring in approximately 4% to 7% of the population, or an estimated 10 to 18 million people in the United States.[64] Furthermore, on CT and MR imaging studies of the neck performed for other reasons, as many as 14.5% of patients may be found to have incidental thyroid nodules.[65] Most represent follicular nodules that develop in adenomatous goiters following cycles of hyperplasia and colloid involution. However, since any nodule could represent a thyroid carcinoma, the challenge lies in identifying those lesions that are malignant in the most cost-effective, noninvasive manner.

It is difficult to distinguish benign from malignant nodules. Findings on ultrasound, CT, and MR imaging are nonspecific. A sonolucent halo around a thyroid nodule or a solid, hyperechoic lesion favors a benign process (Fig. 40-22).[18] The presence of calcification is nonspecific, seen in 10% to 15% of all benign and malignant lesions.[18] Similarly, malignant and benign lesions may be cystic, solid, or mixed.[18] Clinical factors that increase the likelihood of a nodule's representing a carcinoma include age (less than 20 or more than 60 years), male gender, low-dose irradiation during childhood for benign conditions, a family history of thyroid carcinoma or multiple endocrine neoplasia, ipsilateral lymph nodes, and longstanding goiter.[6, 66] However, most thyroid nodules occur sporadically and are not associated with these conditions.

Radionuclide scintigraphy plays an important role in distinguishing cold nodules (those that do not demonstrate radioactive iodine uptake relative to the normal gland) from hot or hyperfunctioning nodules (those that demonstrate increased uptake compared to the surrounding thyroid). Cold nodules have a higher incidence of malignancy (Fig. 40-23). The risk of cancer in cold nodules is approximately 20%, compared to less than 5% in hot nodules.[6, 67] The dy-

FIGURE 40-24 A 60-year-old woman presented with hyperthyroidism. The 24 hour uptake was 46% (upper limit of normal is 30%), and scintigraphy showed a hot nodule with suppression of the remainder of the gland consistent with an autonomous nodule. (Courtesy of Dr. Joseph Sam, Department of Radiology, Ultrasound Division, University of Pennsylvania Medical Center.)

namic phase in Tc-99m pertechnetate thyroid imaging may be useful in evaluating cold nodules, with studies suggesting that malignant nodules have a perfusion equal to or greater than that of the surrounding normal thyroid gland.[68]

Functioning or hot nodules in over 90% of cases reflect benign conditions, most commonly adenomas or hyperplasia.[6] If the adjacent normal thyroid tissue is suppressed on scintigraphy, and if, in turn, the nodule cannot be suppressed with exogenous thyroid hormone, it is considered to have autonomous function (Fig. 40-24). Because the incidence of carcinoma in hot nodules is low, these lesions are frequently managed conservatively with close follow-up.

While the majority of cold nodules are benign (adenomas, cysts, inflammation), because of their higher incidence of malignancy, they usually require biopsy or surgical removal.[7] Fine needle aspiration with palpation, CT or ultrasound guidance that ensures positioning of the needle within the lesion has gained wide acceptance as an accurate diagnostic method for evaluating thyroid nodules.[18, 69, 70] Specimens may be obtained with 22- to 25-gauge needles. Typically, on average, three separate passes are made to ensure the most adequate specimen possible. Interpretation requires a skilled cytopathologist. Benign nodules may be followed, and malignant or suspicious nodules are usually surgically resected. In instances where fine needle aspiration is nondiagnostic, repeat aspiration or surgical excision may be necessary.[70]

NEOPLASMS OF THE THYROID GLAND

Adenomas

Thyroid adenomas are true benign neoplasms distinctly separate from the adjacent thyroid tissue and encased by a

Copyright © 2003, Mosby, Inc. All rights reserved.

fibrous capsule. They are usually solitary and nonfunctioning, most commonly detected in young and middle-aged adults. Autonomously functioning adenomas are not usually associated with hyperthyroidism.[71] Toxicity is most commonly seen with large lesions and advanced age. Follicular adenomas slowly increase in size, usually not exceeding 4 cm.[2] Sudden enlargement of a follicular adenoma is usually related to spontaneous hemorrhage within the lesion.[72] Spontaneous degeneration of an adenoma may occur, and in fact, most thyroid cysts represent degeneration of adenomas. The presence of carcinoma within an adenoma is rare.[72] Hurthle cell adenomas are rare neoplasms composed of granular cells and pink-staining cytoplasm. Unlike follicular adenomas, these are not well circumscribed, and some believe they are malignant.

If an adenoma is autonomous (independent of TSH), ablation with I-131 may be performed, as the short-acting beta radiation will deposit preferentially in the nodule. Alternatively, the nodule may be surgically removed. In either case, the risk of postprocedural hypothyroidism is small. The previously suppressed normal thyroid tissue resumes normal function following treatment.

Recent reports describe successful treatment of autonomous thyroid and parathyroid adenomas with 95% ethanol injection. Results vary but generally show resolution of the hyperthyroid state without development of hypothyroidism.[73–78] A potential complication is inadvertent injection of ethanol into the recurrent laryngeal nerve at the level of the tracheoesophageal groove, which may result in vocal cord paralysis.[79]

Malignant Neoplasms

The incidence of thyroid cancer in men and women increased up to 1975. This increase was believed to reflect the use of low-dose radiation to treat the head and neck, particularly in children for benign diseases such as thymic enlargement and adenoidal hypertrophy.[80] There is a linear dose-response relationship between 100 and 2000 rads.[6, 81] Approximately 15% to 30% of patients who received radiation in this dose range will develop a thyroid nodule, and 6% to 8% will develop thyroid cancer. Long-term follow-up is necessary, as the latent period for the development of cancer may be as long as 30 years. Early detection is essential since carcinoma in this population is more aggressive and may require extensive surgical management to achieve a cure rate equivalent to that of nonirradiated patients.[66] Thyroid carcinoma following high-dose irradiation (greater than 2000 rads) is rare, likely because irradiation at these doses destroys thyroid tissue.[6] Individuals at increased risk (low-dose radiation exposure, genetic predisposition) of developing thyroid cancer may be screened and followed by obtaining serum calcitonin levels, as calcitonin serves as a sensitive marker for tumor development.

Approximately 12,000 new cases of thyroid carcinoma are diagnosed in the United States each year, and the annual death rate is approximately 1000.[82] Of interest, the prevalence of incidental thyroid carcinomas identified at autopsy is 3.9%[83] and at surgery it is 10.5%.[84] Differentiated thyroid carcinomas including papillary and follicular subtypes are most common and have a favorable prognosis.

Thyroid carcinoma arises from both follicular and parafollicular C cells. Malignant potential and behavior ranges from low-grade (papillary carcinoma) to aggressive (anaplastic carcinoma) and is reflected by mortality rates: papillary carcinoma 8% to 11%, follicular carcinoma 24% to 33%, medullary carcinoma 50%, and anaplastic carcinoma 75% to 90%.[66] The prognosis is dependent upon the biological behavior, the tumor size, and the tendency for hematogenous or lymphatic metastases. The major histologic classification of thyroid carcinoma includes papillary, follicular, medullary, and anaplastic types. The majority of carcinomas (60% to 80%) are papillary, while follicular, medullary, and anaplastic types each account for approximately 5% to 20% of thyroid cancers.[6, 85]

The major role of scintigraphy in assessing a dominant, palpable thyroid mass is to determine whether the lesion is hot or cold (Figs. 40-23 and 40-24). The risk of cancer in a cold nodule is four times that of a hot nodule.[6, 67] Ultrasonography, because of its availability, is frequently the first imaging modality used to assess a thyroid mass. It is useful in distinguishing solid from cystic lesions. Ultrasound also plays a significant role in the follow-up of patients treated for papillary carcinoma. Its main utility in this regard is in identifying cervical lymph nodes suspicious for regional metastases that can be biopsied with ultrasound guidance (Fig. 40-22). It should be remembered that the main role of cross-sectional imaging (ultrasound, CT, and MR) is not in the characterization of an intrathyroidal lesion, as there are no imaging findings that are histologically specific. The role of the radiologist is to assess the findings related to a thyroid mass, including invasion through the thyroid capsule and infiltration of adjacent tissues and structures in the neck, and to identify the presence of cervical lymph node metastases.

Papillary Carcinoma

Papillary carcinoma is a low-grade malignancy occurring most commonly in female adolescents and young adults. It comprises up to 80% to 90% of all thyroid cancers. However, despite being the most common thyroid carcinoma, it constitutes only about 1% of all malignancies diagnosed in the United States. Histologically, papillary carcinoma may have a spectrum of findings and may be purely papillary, mixed papillary and follicular, or completely follicular.[86–88] The mixed papillary subtype behaves like papillary carcinoma.[86] The completely follicular variant is also included under papillary carcinomas because, both biologically and clinically, it behaves like these tumors.[23, 89] Frequently, papillary carcinoma is multifocal and microscopic in the thyroid gland. This condition is believed to represent intraglandular lymphatic spread rather than multiple synchronous tumors. However, other patterns of papillary cancer are also common, including occult cancers (less than 1.5 cm), intrathyroidal encapsulated, and extrathyroidal cancers.[90, 91] In goiter belt areas of the world, not only is there a prevalence of goiter, but there is also a higher than average rate of anaplastic carcinoma. In the regions of the world that have introduced iodine into

the diet to decrease the incidence of goiter, there has also been a decrease in the frequency of anaplastic thyroid carcinoma. However, an increase in the incidence of papillary carcinomas in these same regions has been noted.

At gross pathology these tumors are firm, and they may have calcium, hemorrhage, necrosis, and/or cysts. Histologically, papillary cancer is characterized by the presence of papillae (epithelial cells encasing a fibrovascular core) and clear nuclei.[87, 88] Psammoma bodies (microscopic calcified remnants of papillae) are present in over one third of papillary cancers.

Uncommon histologic subtypes of papillary cancer have been noted to behave more aggressively, including tall cell and columnar cell variants.[92] The tall cell variant is composed of oxyphilic (pink) cells.[92] At presentation these malignancies are frequently extrathyroidal, with vascular invasion, and they have a poorer prognosis than other papillary carcinomas.

The imaging appearance of papillary carcinoma is variable and may include a dominant nodule (Fig. 40-25), multifocal nodules (Fig. 40-26), diffuse infiltration of the gland that is manifest as heterogeneous hypodensity, or a normal-appearing gland on CT (Fig. 40-27). Thus, although not commonly reported, infiltrative papillary carcinoma may not be detected in the thyroid gland on imaging (Fig. 40-28). Papillary carcinoma has the highest incidence of the thyroid malignancies for cervical lymph node spread, seen in up to 50% of cases. Metastatic lymph nodes are not uncommonly normal in size (Fig. 40-27) and may be calcified (Fig. 40-29), cystic, hemorrhagic, or may contain colloid.[93] Cystic nodal metastases are characterized by a thin or imperceptible wall (Fig. 40-30), and they can be mistaken for benign cysts. Cystic nodes are different from the necrotic nodes frequently seen with metastatic squamous cell carcinoma that have central low density but retain a thick rind of residual lymphatic tissue. Hemorrhagic or colloid-containing nodes may be hyperintense on unenhanced T1-weighted MR images (Fig. 40-31). Although in the vast majority of cases regional nodal metastases from thyroid cancer occur in the anterior and posterior cervical lymph chains, occasionally (2%) metastases occur in retropharyngeal nodes (Fig. 40-32). Any lymph node seen in a patient with papillary carcinoma should raise the suspicion of metastatic disease because of the high rate of lymphatic spread. This is

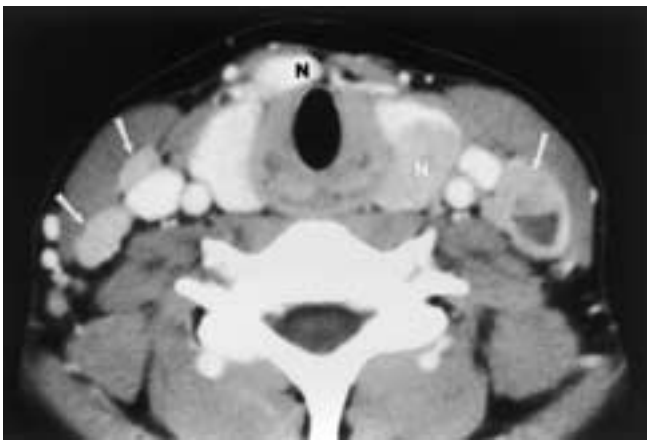

FIGURE 40-26 Papillary carcinoma presenting with multiple nodules. Enhanced axial CT scan shows a focal nodule (*N*) in the left thyroid lobe, as well as a focal nodule in the isthmus on the right (*N*). Both were found to be papillary carcinoma at histologic evaluation. Also note the bilateral cervical lymph node metastases (*arrows*).

especially true if the node enhances, as these tumors are highly vascular.

Hematogenous spread to the lungs, bones (Fig. 40-33), and central nervous system may occur; however, this is less common (approximately 5%), especially in the absence of nodal disease. Since papillary carcinomas concentrate radioiodine, scanning with I-131 following thyroidectomy may be valuable in identifying recurrent/residual thyroid disease in the operative bed of the neck as well as in detecting distant metastases (Fig. 40-34). Subsequently, treatment with I-131 may be performed (Table 40-3). The prognosis for papillary thyroid carcinoma is excellent, with a 20-year survival rate of over 90%.[87, 88, 90, 91] The most important prognostic factors appear to be (1) age, as patients older than 50 years have a poorer prognosis than younger patients; (2) tumor size; (3) extrathyroidal extension (violation of the thyroid capsule); and (4) histologic subtype. In males, the age at presentation and the absence of gross nodal metastasis are predictors of survival. In females, in addition, tumor size and the number of structures adherent to the gland are predictors.

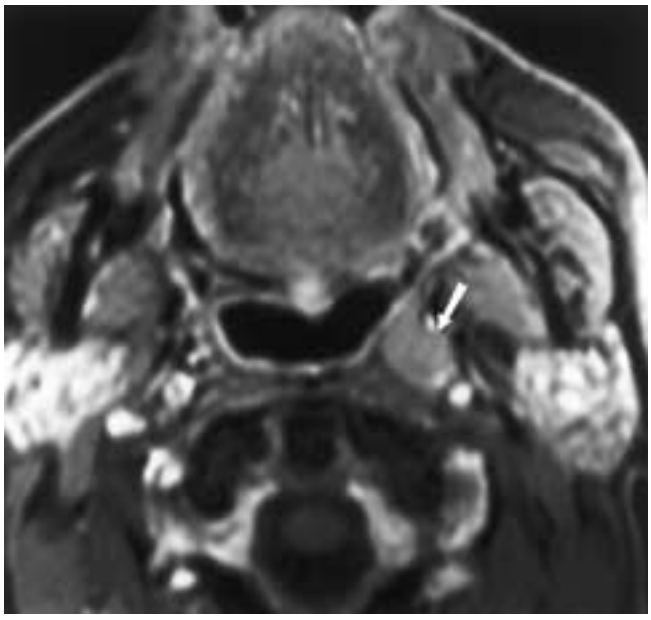

FIGURE 40-32 Metastatic papillary carcinoma in a retropharyngeal node. Enhanced fat-suppressed axial T1-weighted MR image shows a metastatic retropharyngeal lymph node (*arrow*).

Follicular Carcinoma

True follicular carcinomas of the thyroid gland constitute only 5% of all thyroid cancers. Follicular carcinomas are well-differentiated, relatively low-grade malignancies that are reportedly more common in the setting of iodine deficiency. They are slightly more aggressive than papillary carcinomas. On gross evaluation, they are either encapsulated or invasive. Pathologically, they are characterized by capsular and vascular invasion and are usually solitary lesions. Distant metastases to the lung and bone related to hematogenous seeding are more common than lymph node spread; the latter is seen in less than 8% of cases.[94] The 5-year survival rate for encapsulated variants is approximately 90%; however, invasive variants have a poorer prognosis. Like papillary carcinoma, follicular cancers concentrate iodine, and I-131 imaging may be useful in the follow-up of these patients.

Hurthle Cell Tumors

Hurthle cells are derived from follicular epithelium.[95] A Hurthle cell neoplasm must meet specific criteria including that of an isolated thyroid mass composed predominantly of Hurthle cells in the absence of inflammatory cells.[95, 96] These tumors are diagnosed according to the criterion of malignancy used for follicular neoplasms of the thyroid gland. Regional nodal metastases in addition to hematogenous dissemination may occur.

Medullary Carcinoma

Medullary carcinoma arises from parafollicular C cells that are believed to be derived from neural crest tissue in the ultimobranchial bodies. It is relatively uncommon and has a

higher mortality rate than well-differentiated papillary and follicular malignancies. Medullary carcinomas are usually solitary lesions. They may invade locally (Fig. 40-35), may spread to regional cervical lymph nodes,[97] and may result in hematogenous seeding with distant metastases most commonly to the lungs, bones, and liver. Because of their origin from parafollicular C cells that secrete calcitonin (up to 90% of medullary carcinomas secrete calcitonin), calcitonin provides a specific hormonal marker for following these patients.[48, 98]

Medullary carcinoma occurs sporadically, but may also be inherited as an autosomal dominant trait (approximately 15% of cases are familial) and comprises a component of the multiple endocrine neoplasia (MEN) syndromes, types IIA and IIB, which include medullary thyroid carcinoma and adrenal pheochromocytomas.[99, 100] Hyperparathyroidism is common in MEN type IIA (Sipple's syndrome) due to hyperplasia of the parathyroid glands.[99, 100]

Medullary carcinomas may be encapsulated or infiltrative on gross pathology.[99, 100] Well-described patterns of medullary carcinoma include amyloid-containing, classic, trabecular, and epithelial types.[100] There is a broad spectrum of histologic and biochemical subtypes. The prognosis for medullary thyroid cancer is variable. Patients with thyroid cancer in the setting of MEN type IIB tend to have very aggressive, often fatal tumors that frequently occur at a young age, while those in association with MEN type IIA have favorable outcomes.[101] Sporadic tumors may behave in an indolent manner or may be aggressive.[101] Serum levels of calcitonin and carcinoembryonic antigen, as well as immunostaining of resected tumor, may help predict the tumor's behavior.[102]

Unlike papillary and follicular subtypes, medullary carcinoma does not concentrate radioiodine. However, radionuclides specific for neuroendocrine tissue such as I-131 meta-iodobenzylguanidine (MIBG) and the somato-

statin analog I-111 pentetreotide have been used with some success to evaluate primary as well as metastatic medullary thyroid carcinoma.[103–106] These neoplasms may also take up gallium or thallium.

Anaplastic Carcinoma

Anaplastic carcinoma usually presents in elderly women (over the age of 60 years), and is highly aggressive and rapidly fatal. Life expectancy is measured in months. Approximately 10% of all thyroid malignancies are anaplastic. They commonly occur in patients with long-standing goiter. Anaplastic carcinoma actually comprises a group of high-grade thyroid neoplasms that are characterized by undifferentiated histology and a highly aggressive course. Other terms include *undifferentiated*, *dedifferentiated*, and *sarcomatoid carcinoma*. These cancers grow rapidly, and typically compress and invade the aerodigestive tract and vessels (Fig. 40-36). Lymphatic metastases occur in the majority of patients and are necrotic in approximately one half of cases (Fig. 40-36).[48, 107] These neoplasms do not concentrate radioiodine. On ultrasound they are frequently hypoechoic (Fig. 40-37).[17, 18, 97] On CT, punctate calcifications and necrosis are frequently present.[107]

Primary Lymphoma

Primary lymphoma of the thyroid gland is uncommon, representing less than 5% of all lymphomas arising in extranodal sites and approximately 1% to 3% of all thyroid malignancies. It usually presents in elderly women with a long history of goiter. In addition, patients with Hashimoto's thyroiditis have an increased incidence of developing lymphoma of the thyroid, usually the non-Hodgkin's type.[46, 47] The thyroid gland may also be involved secondarily by lymphoma.

Imaging, including MR imaging, cannot reliably distinguish lymphoma from thyroiditis in patients with Hashimoto's thyroiditis.[1, 108] Patients usually present with a rapidly enlarging thyroid mass and symptoms of obstruction related to compression of the aerodigestive tract.[1, 46] Thyroid lymphoma may present as multiple nodules, but more commonly (80%) it presents as a solitary mass.[1, 46] Usually it is hypoechoic on ultrasound[17, 18] and hypodense on CT.[46] While lymphoma is typically cold on iodine and technetium nuclear scintigraphy, it may show increased uptake on gallium scans. Necrosis and calcification are uncommon.[46] On MR imaging, lymphoma is usually hyperintense on T2-weighted images and isointense to normal thyroid on T1-weighted images.[1, 108]

Rare Malignancies

Primary squamous cell carcinoma of the thyroid gland is rare and may result from squamous metaplasia of epithelial cells. Similarly, rare sporadic cases of mucoepidermoid carcinoma may occur (Fig. 40-38). These are typically seen in patients with a long history of goiter and have a poor prognosis. There are no diagnostic imaging findings to distinguish these from other neoplasms. Primary sarcomas of the thyroid gland are extremely rare, can be radiation induced, and have a poor prognosis. Such lesions include liposarcomas, fibrosarcomas, leiomyosarcomas, chondrosarcomas, osteosarcomas, and angiosarcomas.

Teratomas in infants, and rarely in adults, may involve the thyroid gland. Thymus-related lesions may also rarely occur. About 1.5% of thyroid glands contain thymic tissue, and intrathyroidal thymomas can occur. Similarly, spindle and epithelial thymus-like tumors (SETTLE) and carcinoma with thymus-like features (CASTLE) have been reported. Even a very rare intrathyroidal paraganglioma has been reported.

Metastatic Disease

Metastatic disease to the thyroid gland is uncommon. Lung and breast carcinomas are the most common causes of thyroid metastases found at autopsy, while renal carcinoma is the most common metastasis detected clinically.[109] Metastatic melanoma and colon carcinoma metastatic to the thyroid gland have also been reported.[110] Multiple thyroid masses are usually present in the setting of metastatic disease (Fig. 40-39). When atypical histology of a resected thyroid mass is detected, metastatic disease should be considered. Testing to establish the presence of thyroglobulin and/or calcitonin supporting the belief that the neoplasm is thyroidal in origin may be extremely useful, and the absence of these markers favors metastatic disease.

SECTION TWO

THE PARATHYROID GLANDS

Primary hyperparathyroidism resulting in hypercalcemia is the most common presentation of parathyroid pathology and is usually related to a parathyroid adenoma, although less commonly it may be secondary to gland hyperplasia. Imaging of the parathyroid glands primarily focuses on the detection of adenomas in patients with primary hyperparathyroidism. A second focus is the detection of an unrecognized adenoma in a patient with persistent or recurrent hypercalcemia after prior surgery for hyperparathyroidism. The role of imaging (as well as which modality to use) for preoperative localization of the parathyroid glands continues to be a controversial issue, with practices differing from institution to institution.

The anatomy, physiology, and pathology of the parathyroid glands will be reviewed. The diagnostic utility of radiologic imaging including ultrasonography, CT, MR imaging, and nuclear scintigraphy will be discussed, particularly as it pertains to the evaluation of primary hyperparathyroidism.

ANATOMY OF THE PARATHYROID GLANDS

The parathyroid glands arise from the third and fourth branchial pouches. The upper or superior parathyroid glands arise from the fourth branchial pouch along with the lateral anlages of the thyroid gland. Because the superior parathyroid glands are closely related to the thyroid gland and have minimal descent, their positions are relatively constant along the dorsal aspect of the upper thyroid. Less than 2% of the superior parathyroid glands are ectopic in location. The lower or inferior parathyroid glands and thymus are derived from the third branchial pouch, and in contrast to the upper glands, the lower parathyroid glands descend a variable distance with the thymic anlage. As a result, the position of the inferior parathyroid glands, is more variable than that of the superior parathyroid glands, and the inferior glands may descend into the anterior mediastinum as far as the pericardium. On either side of the neck, a branch of the superior thyroidal artery usually supplies the upper parathyroid gland, while the inferior thyroidal artery supplies the lower parathyroid gland. Drainage from the glands is usually to the thyroidal veins. The cervical sympathetic plexus innervates the parathyroid glands.

The number of parathyroid glands ranges from 1 to 12, although most individuals (over 80%) have 4.[1] The most common anatomic location of the upper parathyroid glands is posterior to the middle one third of the thyroid gland (75% of the time). The majority of the remainder of the upper parathyroids are located behind the upper or lower one third of the thyroid, with approximately 7% found below the inferior thyroidal artery.[1] The upper glands may also be located behind the pharynx or esophagus.[2] The most common anatomic location of the lower parathyroid glands is lateral to the lower pole of the thyroid gland (50% of the time). The next most common location encompasses an area 1 cm below the lower thyroid pole (15%). The position of the remaining one third is variable along the thyrothymic tract, extending anywhere from the angle of the mandible to the lower anterior mediastinum. Intrathyroidal parathyroid glands are uncommon, occurring in 2% of cases. It is not possible with current imaging techniques to distinguish an intrathyroidal parathyroid adenoma from a primary thyroid lesion.[3–5]

The variability in number and location of the parathyroid glands can create problems for the surgeon exploring the neck for diseased glands in patients with primary hyperthyroidism. In addition, in patients having neck surgery for other reasons such as thyroid disease, the parathyroid gland(s) may accidentally be injured or removed.

ENDOCRINOLOGY OF THE PARATHYROID GLANDS

The normal parathyroid glands are each less than 9 mm in maximal dimension, and are composed of chief cells and oxyphil cells embedded within a fibrous capsule and intermixed with adipose tissue.[6] The role of the oxyphil cells is unknown. They appear at around puberty and increase with age. Chief cells secrete parathormone (PTH), which regulates the concentration of calcium in interstitial fluids. Serum calcium levels in turn regulate the secretion of PTH. Parathormone acts predominantly in three regions: (1) the skeleton to mobilize calcium into the plasma, (2) the kidneys to reduce calcium excretion, and (3) the gastrointestinal tract to increase calcium absorption.[7] Parathormone enhances the synthesis of 1,25-$(OH)D_3$ (vitamin D), which promotes the absorption of calcium by the intestines. In patients with elevated serum calcium concentrations, PTH should be suppressed. When a normal PTH level is encountered in the setting of hypercalcemia, it is referred to as hyperparathyroidism. In primary hyperparathyroidism, hypercalcemia is the result of excessive secretion of PTH from one or more of the parathyroid glands.

CLINICAL MANIFESTATIONS OF PARATHYROID DISEASE

Hyperparathyroidism

Primary hyperparathyroidism is common, more common in women, occurring in approximately 1 in 700 adults.[8] In most cases, patients are asymptomatic and the condition is detected by routine screening blood tests for serum calcium that individuals frequently have as part of their yearly checkup. It occurs secondary to hypersecretion of PTH, resulting in hypercalcemia. The causes of primary hyperparathyroidism include a single 1 to 3 cm parathyroid adenoma (75% to 85% of cases), parathyroid hyperplasia (10% to 15%), multiple parathyroid adenomas (2% to 3%), and, rarely, parathyroid carcinomas (less than 1%).[3, 9–11] Solitary adenomas vary widely in size, being very small (less than 1 cm) as well as very large (several centimeters).

VIEW IMAGE

FIGURE 40-40 Patient with recurrent primary hyperparathyroidism. **A**, Enhanced axial CT scan shows a hypodense mass (*arrows*) just posterior to the inferior pole of the left lobe of the thyroid gland. At surgery this was found to be a parathyroid adenoma separate from the thyroid. A clip in the right tracheoesophageal groove is from prior neck exploration. **B**, Bone scan showing markedly increased uptake in the calvarium and nonvisualization of the kidneys that has been described in association with hyperparathyroidism. **C**, Lateral plain film radiograph demonstrating the classic ''salt and pepper'' skull.

Hyperplasia typically involves multiple parathyroid glands. The classic clinical features of hypercalcemia include bone pain related to osseous demineralization, abdominal pain secondary to renal calculi, and occasional psychiatric disturbances (Fig. 40-40). Hypercalcemia left untreated can also result in pancreatitis, peptic ulcer disease, and musculoskeletal dysfunction.

The treatment of primary hyperparathyroidism is surgical excision of the abnormal parathyroid gland(s). Surgeons continue to debate over the ideal operative approach to cure primary hyperparathyroidism while limiting morbidity and controlling costs. Most surgeons still perform bilateral neck explorations since very small lesions or hyperplasia may be overlooked with current imaging techniques. Although the need for preoperative imaging localization remains a topic of debate, many surgeons report fewer complications and shorter operating times when abnormal parathyroid glands are identified prior to surgery.[3, 12–14] Importantly, preoperative imaging in many cases has allowed the surgeon to treat hyperparathyroidism successfully with only a unilateral neck exploration.[14, 15]

Nonetheless, there are clearly certain situations in which all would agree that imaging plays a very useful role. This includes high-risk surgery patients where imaging may permit the surgeon to resect the abnormal gland with only a unilateral neck exploration. Alternatively, percutaneous injection of absolute ethanol to ablate adenomas may be performed under ultrasound guidance in patients who are poor surgical candidates due to underlying medical illness.[16, 17] The success of treatment is monitored with serum calcium levels, which are followed until levels approach near-normal values. Also, when hyperparathyroidism recurs following surgery, imaging is indicated, as ectopic glands are prevalent in this group of patients.

Copyright © 2003, Mosby, Inc. All rights reserved.

There are also secondary and tertiary forms of hyperparathyroidism. Secondary hyperparathyroidism occurs in patients with long-standing renal failure leading to changes in calcium metabolism, which in turn results in enlargement of the parathyroid glands. In tertiary hyperparathyroidism, hypercalcemia occurs as a sequela of secondary hyperparathyroidism due to the autonomous secretion of PTH from chronically overstimulated parathyroid glands.

Hypoparathyroidism

Hypoparathyroidism is mainly a functional clinical disorder characterized by hypocalcemia and hyperphosphatemia secondary to a deficiency of PTH. The clinical manifestation may be subtle and include facial contractions brought on by tapping the facial nerve (Chvostek's sign), or carpal contractions initiated by applying a blood pressure cuff (Trousseau's sign). Hypoparathyroidism may be acute and transient, usually following parathyroid or thyroid surgery. Chronic hypoparathyroidism may be iatrogenic (surgery), developmental (agenesis is rare), autoimmune, infiltrative (secondary to cancers, amyloid, etc.), or part of a group of disorders called pseudohypoparathyroidism in which there is a resistance in the kidneys and skeleton to the physiologic effects of PTH. There is a group of patients that exhibit the characteristic phenotypical appearance of pseudohypoparathyroidism (short, round facies, brachydactyly), but lack the unresponsiveness to PTH (normal calcium and phosphate levels). These patients are said to have pseudopseudohypoparathyroidism.

IMAGING OF PATHOLOGY OF THE PARATHYROID GLANDS

Parathyroid Adenoma

Indications for preoperative localization of parathyroid adenomas remain a topic of debate. In addition, the choice of the appropriate imaging modality is also debated in the literature. When imaging is utilized, the modality options include ultrasonography, CT, MR imaging, and nuclear scintigraphy. Conventional catheter and digital subtraction angiography, as well as selective parathyroid venography with sampling and measurement of PTH levels, are highly accurate in detecting parathyroid adenomas; however, their major drawback is that they are relatively invasive and expensive.

At many institutions with experienced parathyroid surgeons, preoperative localization of the glands with imaging is not performed, as some studies suggest that the morbidity, mortality, and operative time are not greatly affected by preoperative localization.[18–20] In addition, some investigators argue that the cost of imaging outweighs its benefit.[18, 21] However, more recently, many surgeons have reported that imaging has resulted in reduced operative time, reduced morbidity, and lower costs.[14, 22] Specifically, when the cost of preoperative imaging was compared to that of increased operative time, imaging was found to be cheaper.[14]

The surgical technique includes exploration of the perithyroidal region bilaterally, with particular emphasis on the inferior poles of the thyroid glands, as this is where most parathyroid adenomas occur. In the hands of skilled surgeons, this procedure may be performed with a success rate of over 90%.[3, 18, 23–26] When a parathyroid adenoma is not identified in the perithyroidal location, the surgeon may explore the anterior mediastinum, the deep cervical space, and the carotid sheath regions. Successful surgery in these cases is lower (less than 70%), and the surgical complication rate is higher.[23]

Arguments for performing preoperative imaging to localize the parathyroid glands include (1) the need for only unilateral perithyroidal neck exploration when an adenoma is detected[14]; (2) the identification of ectopic adenomas[27]; (3) the detection of other head and neck masses (such as thyroid lesions); and (4) a reduction in operating room time.[13, 25, 28–30] In addition, the operative success rate improves from 90% to close to 100% when preoperative imaging is performed.[14, 31]

Ultrasonography

Ultrasonography of the parathyroid glands is typically performed with a high-resolution linear array transducer (7.5 to 10 MHz) and an experienced sonographer. The patient is imaged in the supine position with the neck mildly hyperextended. Examination includes evaluation of the perithyroidal areas and the region of the carotid sheaths extending from the angle of the mandible superiorly to the sternal notch inferiorly. The typical appearance of a parathyroid adenoma is that of a homogeneous, well demarcated mass with an echogenicity less than that of the thyroid gland (Fig. 40-41).[24, 32] Adenomas are encapsulated and are typically solid; however, they may have cystic and/or hemorrhagic components resulting in regions of decreased and increased echogenicity, respectively. In addition, adenomas may undergo cystic degeneration. Color Doppler may on occasion provide additional information that may help to distinguish thyroid from parathyroid lesions. Specifically, thyroid lesions tend to have some vascularity, whereas small parathyroid lesions more often lack Doppler signal. On occasion, larger parathyroid lesions may be vascular.[33]

For adenomas located in the perithyroidal region, ultrasonography is an excellent modality. Limitations of ultrasonography predominantly center on the fact that it is less accurate than other imaging modalities in identifying ectopic parathyroid adenomas, and evaluation of the anterior mediastinum is limited secondary to acoustic impedance by air and bone. In addition, scanning artifact may obscure adenomas close to air-filled structures such as the trachea or esophagus.

Ultrasonography identifies adenomas in 95% of glands weighing more than 1 g (individual normal parathyroid glands weigh 35 to 55 mg each).[1, 24] Investigators report sensitivity of 50% to 70%, and specificity of 90% to 95% for adenomas in hyperplastic glands.[9, 10, 14, 24, 32, 34, 35]

Cross-Sectional Imaging

Cross-sectional imaging (CT and MR imaging) provides evaluation of the neck from the skull base through the anterior mediastinum, allowing detection of ectopic parathyroid adenomas (Fig. 40-42). CT images should include contiguous thin (3 mm) sections. Intravenous contrast must be used in CT both to distinguish blood vessels from adenomas and because up to 25% of parathyroid adenomas

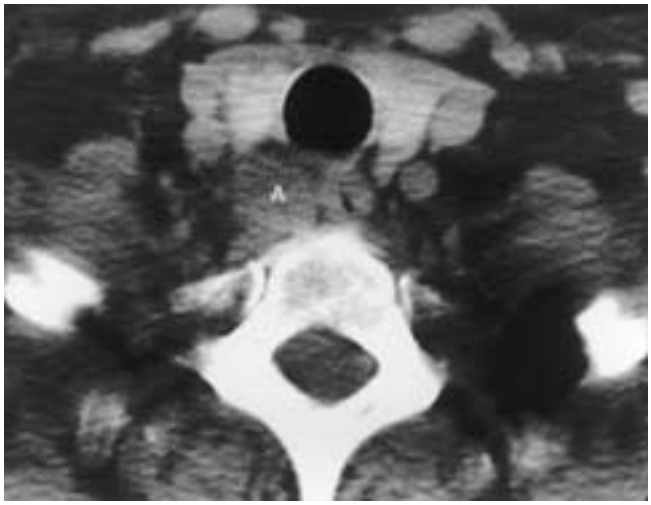
FIGURE 40-41 A pitfall in Tc-99m sestamibi scintigraphy is that thyroid lesions may concentrate sestamibi similarly to parathyroid adenomas. **A**, Sestamibi scan shows increased activity in the right lobe of the thyroid gland. **B**, Transverse ultrasound image reveals a well-demarcated mass in the thyroid (*curved white arrows*) that at surgery was found to be a thyroid adenoma, as well as a rounded mass hypoechoic to and posterior to the thyroid that was a parathyroid adenoma (*straight arrows*). *J*, Jugular vein; *C,* carotid artery.

enhance.[32] Limitations of CT in detecting adenomas include scanning artifacts related to swallowing and breathing. Lymph nodes, tortuous vessels, and the esophagus may also be mistaken for adenomas. As mentioned earlier, a drawback to using CT is the uptake of contrast by the thyroid gland, necessitating a wait of 6 to 8 weeks before nuclear scintigraphy with iodinated agents may be accurately performed.[36] In general, investigators have found that both the sensitivity and specificity of high-resolution CT are improved over those of ultrasound, being approximately 70% and 90%, respectively.[32, 37]

MR imaging, like CT, allows excellent evaluation of the mediastinum. This method offers superior soft-tissue discrimination and is more sensitive than CT for identifying parathyroid adenomas. MR imaging should be performed on a high field strength system. Accuracy may be improved and artifacts related to heart motion reduced by using cardiac gating. The imaging sequences utilized should include axial T1- and T2-weighted 4 to 5 mm thick images extending from the skull base through the mediastinum.[38] The administration of intravenous contrast material (gadolinium) can increase lesion conspicuity.



VIEW IMAGE

FIGURE 40-42 Parathyroid adenoma in the right perithyroidal region. Axial CT image shows the adenoma (*A*) that was detected in the evaluation of this patient with hypercalcemia.

The appearance of adenomas on MR imaging is variable.[39] Usually, adenomas are iso- to hypointense compared to the thyroid gland on T1-weighted images, and they are usually hyperintense on T2-weighted images. They may enhance avidly following intravenous gadolinium administration (Fig. 40-43). Some lesions with dense cellularity may be iso- to hyperintense compared to muscle on T1-weighted images and isointense on T2-weighted images (Fig. 40-44). It is uncommon for an adenoma to be hypointense on T2-weighted images. Pitfalls in detection of parathyroid adenomas on MR imaging include misinterpretation of enlarged cervical lymph nodes for adenomas,[38] large cervical ganglia, and a multiplicity of ectopic sites.[39] Distinction between abnormal gland and vessel is less of a problem with MR imaging due to its ability to readily identify vascular structures (flow voids). MR imaging has a reported accuracy of over 90%.[40]

Nuclear Scintigraphy

Nuclear scintigraphy to identify parathyroid adenomas may be performed with several radionuclides including thallium-201 (Tl-201)/Tc-99m pertechnetate subtraction scanning, Tc-99m sestamibi subtraction imaging with I-123 (Fig. 40-45) or Tc-99m pertechnetate, or Tc-99m sestamibi

FIGURE 40-45 Parathyroid adenomas detected in two different patients by Tl-201/Tc-99m pertechnetate subtraction imaging (**A** to **C**) and by Tc-99m sestamibi subtraction imaging with I-123 (**D**). **A**, Tc-99m pertechnetate concentrated within the thyroid gland. **B**, Tl-201 concentrated within thyroid and parathyroid glands. **C**, Computer techniques allow technetium concentrated in the thyroid gland to be subtracted from thallium that accumulates within both thyroid and parathyroid tissue. After thyroid subtraction, a parathyroid adenoma is noted as a focus of increased thallium uptake (*arrows*). **D**, Tc-99m sestamibi subtraction imaging with I-123 shows an adenoma below the inferior pole of the left lobe of the thyroid gland. (Courtesy of Dr. Joseph Sam, Department of Radiology, Nuclear Medicine Division, University of Pennsylvania Medical Center.)

alone.[41–44] Because no radionuclides are taken up by the parathyroid glands alone, subtraction techniques allow radionuclides that are concentrated in the thyroid gland (technetium and iodine) to be subtracted from those that accumulate within both thyroid and parathyroid tissue (thallium and sestamibi). Tl-201 is a potassium analog that is taken up by the thyroid as well as concentrated in parathyroid adenomas due to changes in potassium turnover. As a sole imaging agent, it cannot distinguish a parathyroid adenoma from the thyroid gland. Thallium emits low-energy photons and washes out of adenomas rapidly. Technetium has higher-energy photons that better penetrate the anterior neck and mediastinum. Tc-99m is trapped in the thyroid gland but not in parathyroid tissue. When Tl-201 and Tc-99m pertechnetate images are coregistered, computer-based subtraction techniques can remove the thyroid component, permitting identification of abnormal parathyroid tissue.

Typically, 2 to 5 mCi of each radiotracer is administered intravenously, and either sequential or dual isotope imaging is performed. The mediastinum should be included in the field of view to assess for the possibility of ectopic adenomas. After thyroid subtraction, a perithyroidal parathyroid adenoma appears as a focus of increased thallium uptake (Fig. 40-45). The major limitation of this examina-

tion is motion artifact that may degrade the images, making superimposition of the images and subtraction unreliable and interpretation difficult.

The reported sensitivity and diagnostic accuracy of Tl-201/Tc-99m subtraction scintigraphy vary, but each is approximately 80% to 85%.[14, 45] False-positive examinations may result secondary to inflammatory conditions, lymphoma, and thyroid nodules. Lesion size is an important factor in determining the sensitivity of subtraction scintigraphy. Specifically, lesions less than 0.5 g are rarely visualized (the combined weight of all parathyroid glands in normal patients is usually less than 200 mg).[1] The histologic content of the adenoma also influences sensitivity, with greater accuracy seen in lesions having a high concentration of mitochondria.[46]

Tc-99m sestamibi scintigraphy was introduced in the late 1980s.[47] Tc-99m sestamibi is a positively charged, lipid-soluble myocardial perfusion tracer. The mechanism for sestamibi uptake is not completely understood, but it could correspond to cellular components (chief and oxyphil cells), mitochondrial density in oxyphil cells, blood flow within adenomas, and/or potassium turnover.[48, 49] However, it has been suggested that the number of oxyphil cells does not clearly affect the results of sestamibi imaging since it is small in most hyperfunctioning glands.[48] Electron microscopy has shown increased mitochondrial density in oxyphilic cells.[49] Uptake is also dependent on gland size as well as on their functional state.[48, 49] The intracellular distribution is determined by the negative transmembrane potential of cellular and mitochondrial membranes. Therefore, cells with high mitochondrial content are believed to retain more of the positively charged tracer.

Tc-99m sestamibi scintigraphy offers several advantages over subtraction imaging including dual-phase acquisition, handling of a single radiotracer, and the capability for single photon emission computed tomography (SPECT). Dual-phase Tc-99m sestamibi used alone takes advantage of the rapid washout of the tracer from the thyroid gland, while there is avid retention in parathyroid lesions. Delayed images are frequently all that are necessary for good localization. Immediately following injection (5 to 30 minutes) of 20 mCi of radiotracer, images are obtained of the neck and chest. Delayed images are obtained in the same sites approximately 1½ to 4 hours following radiotracer injection.[41, 50, 51] The addition of pinhole imaging in the delayed phase may further increase the detection of adenomas.[52] In difficult cases where Tc-99m sestamibi subtraction imaging with I-123 is being utilized, 200 to 300 mCi of I-123 is given orally and a pinhole image of the thyroid is obtained at 60 to 90 minutes. Subsequently, 20 mCi of Tc-99m sestamibi is injected, and immediate as well as 2 hour delayed images of the neck and chest are acquired. Parathyroid adenomas are identified as foci of increased radiotracer uptake. SPECT can be combined with Tc-99m sestamibi scintigraphy for more accurate adenoma localization. When SPECT is combined with sestamibi scintigraphy, early (10 to 30 minutes) and delayed (2 to 4 hours) images after injection are frequently acquired. Some studies suggest that for Tc-99m sestamibi SPECT, early images are more accurate in the detection and localization of adenomas.[53]

The accuracy of Tc-99m sestamibi is higher than that of Tl-201/Tc-99m pertechnetate subtraction scintigraphy, with the accuracy of sestamibi ranging from 80% to 100% and with a consistently high specificity.[14, 15, 35, 51, 54–59] The most recent data on sestamibi suggest that it surpasses all other imaging modalities, including ultrasound and CT, in both sensitivity and accuracy.[14, 15, 35, 51, 54–59] A few studies have been performed to compare the accuracy of sestamibi parathyroid scintigraphy with that of MR imaging. Most, but not all studies, suggest that sestamibi is slightly more accurate.[59–62]

In most studies assessing the accuracy of imaging in detecting parathyroid lesions, one or two imaging modalities were evaluated, and were compared and contrasted with each other. However, a handful of studies assessed the value of combining functional imaging (nuclear scintigraphy) with anatomic imaging (cross-sectional imaging). One study suggested that the greater specificity and anatomic coverage of sestamibi scintigraphy coupled with the greater anatomic detail provided by MR imaging may justify the use of both techniques in high-risk surgical patients or patients undergoing repeat surgery.[62] In a recent study that looked at the utility of scintigraphy combined with cross-sectional imaging (CT, ultrasound, MR imaging), the combination of scintigraphy and ultrasound had grater sensitivity, specificity, and accuracy than any imaging modality alone or than scintigraphy in combination with CT or MR imaging in the preoperative assessment of parathyroid disease.[5] In summary, sestamibi is a highly sensitive and accurate imaging tool for the preoperative localization of parathyroid disease. The addition of cross-sectional imaging in certain cases to provide anatomic detail is helpful, especially in patients with ectopic tissue or in patients who are high surgical risks where operative precision and short surgical times are paramount (Figs. 40-44 and 40-46).

Potential pitfalls in Tc-99m sestamibi scintigraphy include the occasional adenoma with rapid washout attributed to low mitochondrial content,[63] poor conspicuity of lesions near the heart,[15] and the occasional thyroid lesion or Hurthle cell tumor that may retain Tc-99m sestamibi.[38, 64] In addition, small lesions, especially those under 100 to 200 mg, may go undetected.[38, 49, 65] The high incidence of concomitant thyroid lesions (40% to 50%) in patients with parathyroid adenomas may lead to false-positive scintigraphy results because thyroid lesions may concentrate sestamibi to the same degree as parathyroid adenomas (Fig. 40-41).[4, 24, 38, 57, 58, 66] In addition, sestamibi uptake in thyroid cancers, as well as in nodal and distant metastases, can occur,[67, 68] and sestamibi retention in reactive lymph node hyperplasia has been reported.[69]

Reoperation for Hyperparathyroidism

In patients with recurrent hyperparathyroidism following surgery, reoperation reveals abnormal parathyroid glands in the perithyroidal region in 30% to 75% of cases (Fig. 40-40), likely corresponding to parathyroid disease overlooked during the initial surgery.[4, 20, 23] Parathyroid adenomas may also be detected in the anterior mediastinum in 30% of cases (Fig. 40-46), and they may be intrathyroidal in less than 10% of cases. The remainder of adenomas at reoperation are located in the deep cervical region.[4, 20, 70]

A consensus in the literature is that imaging prior to

FIGURE 40-46 Ectopic parathyroid adenoma. **A**, Delayed image from a sestamibi scan shows increased uptake in a surgically proven ectopic parathyroid adenoma in the superior mediastinum (*arrow*). **B**, Enhanced chest CT scan shows the corresponding adenoma in the anterior mediastinum (*arrow*).

reoperation is useful despite the cost.[11, 71] When preoperative imaging is performed, the success rate of surgery is approximately 80% to 90% compared to 65% when imaging is not performed prior to reoperation.[11] In reoperations, the sensitivity of ultrasonography, CT, MR imaging, and scintigraphy is quite variable.[4, 11, 32, 72–74]

One of the major differences in imaging the patient who has failed prior surgery for detection of a parathyroid adenoma is that scar tissue in the operative bed in the perithyroidal region makes image interpretation as well as anatomic detection at surgery more difficult. As with cross-sectional imaging at initial surgery, lymphadenopathy may be mistaken for an adenoma. Because the incidence of false-positive examinations caused by lymphadenopathy is lowest with nuclear imaging,[4] sestamibi scintigraphy as a single study is probably the most accurate and cost-effective means to detect parathyroid adenomas. However, because of the increased surgical risk in cases of reoperation including vocal cord paralysis,[20] as well as the distortion of anatomic landmarks due to prior surgery, many surgeons believe that a functional scintigraphic study combined with an anatomic cross-sectional examination (MR imaging is less likely than CT and ultrasound to mistake a lymph node for an adenoma)[4] is warranted, as it provides the most accurate means of detecting parathyroid tissue despite the fact that it is not the most cost-effective approach. In general, MR imaging in combination with sestamibi scintigraphy allows accurate detection of parathyroid tissue.[62, 74, 75]

I-123 or Tc-99m pertechnetate and Tc-99m sestamibi subtraction images may increase the sensitivity of ectopic parathyroid adenoma detection in cases of failed initial neck explorations.[76] Finally, the sensitivity of sestamibi imaging in patients who require repeat surgery may be increased if the interval between initial surgery and imaging is extended to at least 2 weeks.[77] This is done to avoid trapping of the radiotracer in the thyroid gland that may occur as a result of postoperative inflammation.

Parathyroid Hyperplasia

Chief-cell parathyroid hyperplasia accounts for hyperparathyroidism in up to 15% of patients and may be associated with familial hyperparathyroidism or MEN syndromes.[78, 79] MEN is a spectrum of hereditary (autosomal dominant) conditions characterized by two or more hyperfunctioning endocrine tumors. MEN type I is associated with primary hyperparathyroidism, pancreatic islet cell tumors, and anterior pituitary neoplasms.[80–82] Primary hyperparathyroidism, which is usually multiglandular, is the most common clinical presentation. MEN type IIA is characterized by pheochromocytoma, medullary thyroid cancer, and hyperparathyroidism.[80–83] The hyperparathyroidism of MEN type IIA is also multiglandular but is less severe than that of MEN type I.

Chief-cell hyperplasia accounts for the majority of cases of parathyroid hyperplasia, although uncommonly, clear-cell hyperplasia may occur. Clear cells are chief cells with an abundant amount of cytoplasmic glycogen.[1] Histologically, there are numerous chief cells, occasional oxyphil cells, and sparse adipose tissue. Usually all of the parathyroid glands are enlarged, although usually not to significant degrees.[26, 84] Infrequently, one gland is disproportionately enlarged, and as a result may be mistaken intraoperatively for an adenoma.

Treatment of primary parathyroid hyperplasia is removal of most if not all parathyroid tissue, with or without autotransplantation to the forearm.[30, 78] Parathyroid hyperplasia is difficult to evaluate with any imaging

FIGURE 40-47 Parathyroid carcinoma invading the airway. Unenhanced axial T1-weighted MR image shows a poorly defined soft-tissue mass (*M*) just below the inferior pole of the left lobe of the thyroid gland. The fat plane between this mass and the esophagus (*e*) is obliterated, and there is extension into the left lateral wall of the adjacent airway (*A*).

modality due to the small size of the hyperplastic glands. Because there can be marked heterogeneity in gland size in parathyroid hyperplasia, imaging may detect the dominant gland but fail to identify the other hyperplastic glands.[26] Furthermore, when there is a discrepancy in the size of the glands, the surgeon may conclude that a single parathyroid adenoma is responsible for the hyperparathyroidism. The reported sensitivity for the detection of parathyroid hyperplasia is low, ranging from approximately 30% to 70% with cross-sectional imaging techniques.[9–11, 26, 32] More recently Tc99m sestamibi imaging has detected pararthyroid hyperplasia in 50% to 75% of cases.[10, 11, 15, 26, 38, 57, 65, 85]

Parathyroid Carcinoma

Parathyroid carcinoma is an unusual cause of hyperparathyroidism, accounting for less than 2% of all cases. However, hyperparathyroidism accounts for the clinical presentation of approximately 85% of all parathyroid carcinomas.[1] Patients usually have the typical symptoms associated with hypercalcemia. In addition, because these tumors are frequently large, many patients may have a palpable neck mass at presentation. Grossly, parathyroid carcinomas tend to be large (over 10 g), and histologically are noted to have tumor cells with mitotic figures admixed with fibrous tissue, as well as capsular and vascular invasion.[86]

Parathyroid carcinomas have no characteristic imaging features and may not be distinguishable from adenomas or other soft-tissue masses. Regional cervical and mediastinal lymph node metastases may occur in up to one third of

patients and distant metastases (liver, lung, bone) in approximately 25% of patients. Parathyroid carcinomas may also invade adjacent tissues including surrounding fat, the cervical musculature, the aerodigestive tract, nerves, or the thyroid gland (Fig. 40-47).[87, 88] Only invasion of adjacent tissues, or lymph node or distant metastases, may distinguish a parathyroid carcinoma from an adenoma in the setting of hyperparathyroidism. Some parathyroid carcinomas may take up Tc-99m sestamibi.[89]

Parathyroid Cyst

Parathyroid cysts, like adenomas, most commonly arise in the inferior parathyroid glands (65% of cases), and 95% of these cysts occur below the level of the inferior thyroid border. They are rare in children, more common in women, and typically present in the fourth to fifth decades of life.[1, 90] They are usually large (1 to 4 cm).

Parathyroid cysts represent only 0.6% of all thyroid and parathyroid lesions. Nonfunctioning cysts account for the majority of cases and present at a mean age of 43.3 years. Functioning cysts account for 11.5% to 30% of the cases, are more common in men, and occur at a mean age of 51.9 years.

The origin of parathyroid cysts is unclear. They may arise from pharyngeal pouch remnants or they may be acquired. Proposed acquired etiologies include degeneration of parathyroid adenomas into cysts and enlargement or coalescence of parathyroid microcysts.

Similar to their appearance at gross pathology, on imaging they are usually large and unilocular and have variable MR imaging and CT characteristics, depending on their protein content (Fig. 40-48).[90] They may be difficult to distinguish from cystic or necrotic lymph nodes or from cysts derived from other sources such as solitary thyroid cysts and cervical thymic cysts.

Skin and Soft-Tissue Lesions

Bradley N. Delman, Jane L. Weissman, and Peter M. Som

INTRODUCTION
SKIN AND SUBCUTANEOUS LESIONS
- Scar
- Hypertrophic Scar
- Keloid
- Epidermoid Cyst (Sebaceous Cyst)
- Pilomatrixoma
- Basal Cell Carcinoma
- Squamous Cell Carcinoma of the Skin
- Melanoma
- Merkel Cell Tumor
- Skin Metastasis
- Subcutaneous Fat Necrosis of the Newborn
- Sclerema Neonatorum
- Plexiform Neurofibroma and Skin Neurofibromas
- Silicon Augmentation
- Alloderm Augmentation
- Foreign Bodies

FAT-CONTAINING LESIONS
- Ordinary Lipoma
- Infiltrative (Intramuscular) Lipoma
- Madelung's Disease
- Liposarcoma

INTERSTITIAL LESIONS
- Fibrosarcoma
  - Benign Fibrous Lesions (Fibromatoses)
  - Desmoid Tumor
  - Congenital Fibromatosis (Generalized and Localized)
  - Nodular Fasciitis (Pseudotumor of the Skin)
- Proliferative Fasciitis
- Necrotizing Fasciitis

MUSCLE-RELATED LESIONS
- Levator Claviculae Muscle
- Denervation Atrophy
- Muscle Hypertrophy
- Fibromatosis Colli (Sternomastoid or Sternocleidomastoid Tumor)
- Muscular Torticollis
- Myositis
- Myositis Ossificans
- Muscular Dystrophies
- Myotonic Dystrophy
- Rhabdomyosarcoma
- Metastasis to Muscle

THE STYLOHYOID SYNDROMES
- Eagle's Syndrome
- Styloid Carotodynia
- Hyoid Fasciitis

BLOOD VESSELS AND VASCULAR VARIATIONS
- Veins
  - Asymmetry of the Internal Jugular Veins
  - Multiple Jugular Veins
  - Phlebectasia
  - Thrombosis
  - Pseudocollateral and Collateral Veins
  - Condylar Vein
- Arteries
  - Medial Deviation of the Carotid Artery
  - Aberrant Retroesophageal Right Subclavian Artery
  - Thrombosis and Dissection
  - Aneurysm
- Hemangioma
- Hemangiopericytoma

PERIPHERAL NERVE SHEATH TUMORS
PHARYNGOESOPHAGEAL LESIONS
- Zenker's Diverticulum
- Dilated/Obstructed Cervical Esophagus

VIEW IMAGE

FIGURE 41-1 Axial contrast-enhanced CT scan (**A**) shows mild thickening of the skin in the left neck, marked thickening of the subcutaneous fat with prominence of dilated lymphatic and vascular capillaries and venules, and thickening of the platysma (*arrowheads*), all secondary to an acute left submandibular sialadenitis (*S*). Axial contrast-enhanced CT scan (**B**) on another patient shows the changes of cellulitis in the right submandibular triangle. In addition, there is an abscess with an enhancing rim. The abscess displaces the submandibular gland posteriorly.

INTRODUCTION

There are a variety of skin and soft-tissue lesions in the head and neck with manifestations that can be seen on CT and MR imaging. Although overall there are a large number of such lesions, this chapter will address only some of the more common ones and discuss pertinent differential diagnoses.

SKIN AND SUBCUTANEOUS LESIONS

The skin (integument, cutis) is largely ignored on CT and MR imaging. In this section, the skin (epidermis, dermis, and the skin appendages including the pilosebaceous units [hair, sebaceous and apocrine glands, and associated smooth muscle fascicles]) and the immediate subcutaneous tissues are considered.

Diffuse thickening of the skin is most commonly seen in edematous and inflammatory conditions. However, diffuse skin thickening can also be seen after irradiation or, rarely, with tumor infiltration. Almost always, there is associated thickening of the subcutaneous fat and injection of this fat with a rete-type pattern of soft tissue representing dilated lymphatic and vascular capillaries and venules. In addition, after trauma there can be subcutaneous hemorrhage and hematoma (Figs. 41-1 to 41-3). When clinical and imaging distinction between these entities is difficult, serial imaging may offer increased specificity: hematomas tend to show evolution and resolution; there is relative stability or improvement with radiation changes; and tumors may progress to variable degrees, depending on their histology and aggressiveness. Phlegmon, a collection of watery fluid within the interstitial tissues and spaces of the neck, is usually associated with an acute suppurative inflammation.

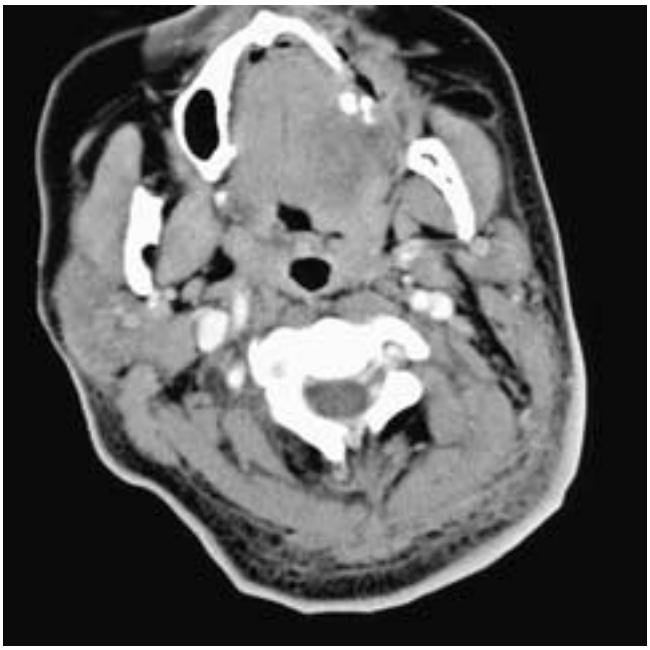

FIGURE 41-2 Axial contrast-enhanced CT scan shows marked thickening of the skin and subcutaneous tissues of the left posterior neck, all secondary to a cellulitis from a skin infection.

VIEW IMAGE

Cellulitis can be seen with simple phlegmon or abscess, with an abscess distinguished from phlegmon by the presence of an enhancing rim (Fig. 41-1B). Further examples of these changes can be seen throughout other sections in this book.

Scar

Scar formation occurs whenever there has been an ulceration or laceration of the skin. The type of scar often reflects the pattern of healing; thus, a scar may be flat, hypertrophic, or atrophic. It may also be firm or, as a result of collagen proliferation, hard. The skin appendages and skin lines are usually lost within the scar bed. On imaging, scars may vary significantly in appearance. The routine flat scar may not be clearly seen, so the only clue to the surgical line may be an infolding of the skin. Conversely, there may be an obvious skin thickening, often in conjunction with subcutaneous scar extending almost as deeply as the muscle line (Fig. 41-4).

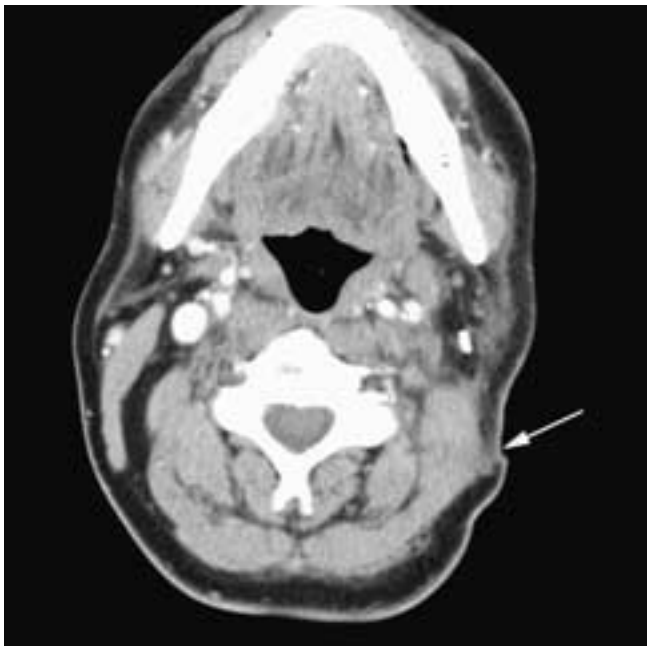

FIGURE 41-4 Axial contrast-enhanced CT scan on a patient who had a left radical neck dissection. A surgical clip is seen in the left neck. Note the thin scar line (*arrow*) and the relatively small amount of fibrosis within the subcutaneous tissues. Minimal edematous change is seen in the adjacent subcutaneous tissues.

VIEW IMAGE

Hypertrophic Scar

A hypertrophic scar usually develops when wound margins are placed under tension. The clinical features distinguishing hypertrophic scars from keloids include the observation that hypertrophic scars remain confined to the original scar line, and with time they tend to flatten out or regress spontaneously. Histologically, they lack hyalinized collagen bundles, and they contain little or no mucinous ground substance. Fibroblasts and foreign body granulomas are also common. Like keloids, these lesions have a higher water content than normal scar and skin, although the water content tends to diminish as the scars age.[1] While distinction from keloids may prove difficult by CT, studies on resected tissue have shown that the T1-weighted signal intensity of hypertrophic scar tends to reach normal levels within 1 to 2 years, unlike keloid, in which the T1-weighted signal intensity may take 10 years to normalize.[1] Treatment of hypertrophic scars is similar to that of keloids, but only about 10% of hypertrophic scars recur.[2]

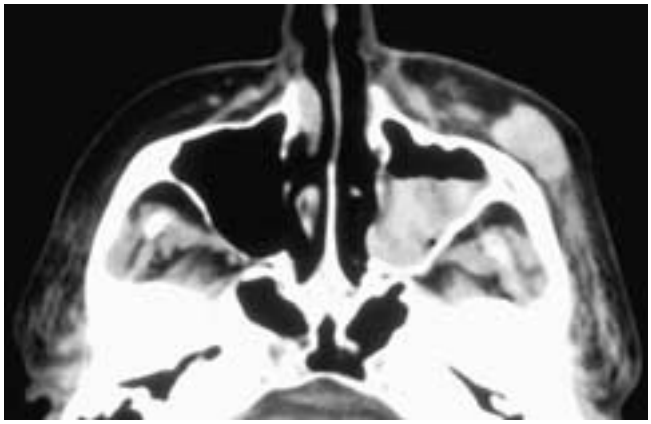

FIGURE 41-3 Axial CT scan shows a soft-tissue density in the subcutaneous tissues of the left facial area representing hematoma. There are also edematous changes in the adjacent soft tissues due to edema. There is dense fluid in the left maxillary sinus. This patient fell and developed a hematoma and edema in the left face with hemorrhage in the left antrum.

VIEW IMAGE

Keloid

Keloids are benign overgrowths of dermal scar tissue that usually develop after local trauma, although sometimes there has been no identifiable insult. They are more common in dark-skinned individuals and in people with blood group A, and a family history may be present. Their growth may be accelerated by pregnancy and puberty. Keloids are slightly more common in women, and most arise in people between 10 and 30 years of age, probably due to the higher incidence of trauma and acne in this age group.[2]

About 70% of postsurgical keloids develop within 6 months of surgery, but up to 17% may appear one year or more after surgery. Most keloids are significant only because of their cosmetic nature, although some may be associated with pruritis, pain, and/or paresthesias. Despite the fact that their borders are usually well demarcated, they tend to be irregular in outline. Keloids usually grow outward from the original scar line and extend into adjacent tissues. On imaging, they are bulky soft-tissue masses that project away from the skin line (Fig. 41-5). There may be subcutaneous infiltration, often related to prior surgery rather than directly to the keloid. Histologically, keloids are composed of thick, glassy, eosinophilic or hyalinized bundles of collagen, often associated with abundant mucinous ground substance. The bulky overgrowth of tissue may reflect an attempt to duplicate the tensile strength of normal skin within this disordered collagen-containing scar tissue. Treatment of

Copyright © 2003, Mosby, Inc. All rights reserved.

keloids includes excision, irradiation, and injection with corticosteroids, although up to 63% may recur after treatment.[2]

Epidermoid Cyst (Sebaceous Cyst)

The epidermoid cyst—the commonly used term *sebaceous cyst* is a misnomer—is the result of the proliferation of surface epidermoid cells within the dermis. The lining of many nontraumatic cysts is believed to be derived from the follicular infundibulum, as these cysts commonly develop from the occlusion of pilosebaceous follicles. Less common causes include the implantation of epidermal cells into the dermis secondary to a penetrating injury and the trapping of epidermal cells along the lines of embryonal fusion planes. These cysts are rare in children but common in adults, and patients with basal cell nevoid syndrome may have numerous lesions. On imaging, these cysts are ovoid in shape, with a noninfiltrating rim. The superficial margin of the cyst usually touches the deep skin line, and the cyst is filled with mucoid attenuation material and scattered dystrophic calcifications (Fig. 41-6).

These cysts are usually slowly growing, painless masses that elevate the skin and often have a central punctum that represents the plugged orifice of the pilosebaceous follicle. The cysts are filled with cheesy, keratinous yellow-white material. They may become infected; uncommonly, they may rupture, causing a foreign body reaction.[3]

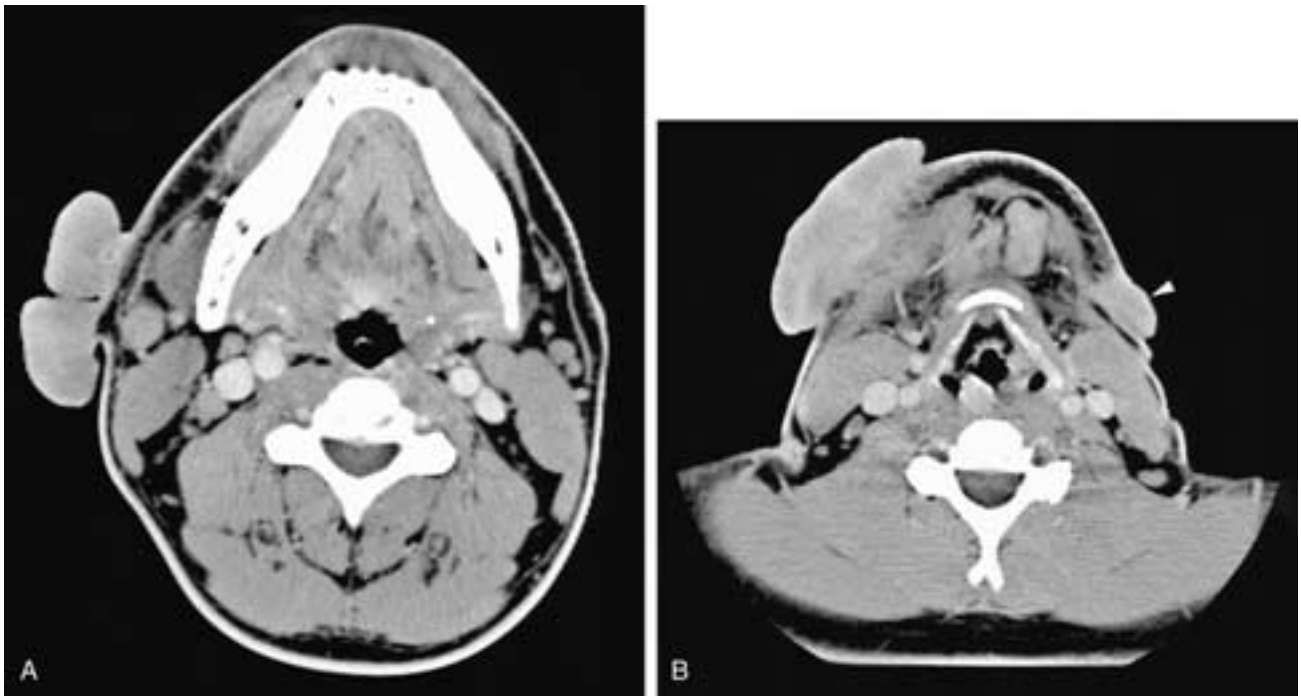
The differential diagnosis includes pilar cyst of the scalp and face and steatocyst simplex.[4] Steatocysts are often confused with epidermoid cysts, although steatocysts can be distinguished by the yellow, oily fluid that they contain.

Pilomatrixoma

Pilomatrixoma, or calcifying epithelioma of Malherbe, is an uncommon benign neoplasm of hair follicle origin. These neoplasms favor the hair-bearing areas, and approximately half of the reported tumors have been in the head and neck region. The majority of cases have been reported in patients in their first two decades of life; however, there is a second peak of occurrence in older patients. Overall, there is a female predominance.

Histopathologically, there are hair matrix–like basaloid cells and shadow or ghost cells, which have a central unstained area that represents a shadow of a lost nucleus. Intracellular and stromal calcification is reported in about 70% of cases, and tumors with large areas or nests of shadow cells proportionally have increased calcium deposition. It has been suggested that osteopontin, a protein marker associated with bone production, may be produced by macrophages and play a role in the deposition of calcium phosphate in the shadow cell nests.

The typical patient presents with an asymptomatic, superficial, solitary, firm mass that is located either within the dermis or in the subcutaneous fat, with tethering to the dermis. The overlying skin often has a reddish-blue discoloration. Even though these tumors usually grow slowly (months to years), excision is usually recommended to avoid a foreign body reaction, associated inflammation, and resulting scar formation. Complete surgical excision is



VIEW IMAGE

FIGURE 41-5 Axial contrast-enhanced cranial (**A**) and caudal (**B**) CT scans show a huge keloid in the right neck. Although there is some subcutaneous extension along the scar line, the vast majority of the mass is superficial to the skin. A second smaller keloid is present in the left neck (*arrowhead* in **B**). Incidentally noted is level I reactive adenopathy.

VIEW IMAGE

FIGURE 41-6 Axial contrast-enhanced CT (**A**) scan shows a typical well-defined cyst in the subcutaneous tissues of the right posterior neck abutting on the deep surface of the skin. Axial contrast-enhanced CT scans (**B** and **C**) on two other patients show cysts in the posterior neck; however, there are scattered calcifications within these cysts. All of these patients had epidermoid cysts. Axial contrast-enhanced CT scan (**D**) on another patient shows an infected cyst in the left neck. Note the enhanced, thickened posterior border of the cyst. Clinically, pus from this sebaceous cyst was evident.

curative. Multiple tumors account for 2% to 3.5% of reported cases, and there have been reported rare associations with myotonic muscular dystrophy, Gardner's syndrome, sarcoidosis, and skull dysostosis. A rare familial occurrence not associated with other syndromes has also been reported.[5]

On CT, the lesion appears as a noninfiltrating mass in the subcutaneous fat with varying degrees of focal calcification. There is no significant enhancement with iodinated contrast. The tumor margin cannot be separated from the epidermis; hence, the mass appears contiguous with the overlying skin. There is no extension into the underlying musculature (Fig. 41-7). Pilomatrixomas have a variable appearance on MR imaging, ranging from intermediate to slightly hyperintense on T1-weighted images and slightly hypointense to slightly hyperintense on T2-weighted images. One report suggests that bands of increased T2-weighted signal intensity seen extending from the periphery of the lesion to its center may represent basaloid sheets identified histologically.[6] No gadolinium enhancement has been described. On ultrasound, this well-defined lesion is typically hyperechoic centrally, with a thin hypoechoic rim; distal shadowing from calcifications is common.[7]

The differential diagnosis includes sebaceous cyst, foreign body reaction, ossifying hematoma, giant cell tumor, chondroma, dermoid cyst, degenerating fibroxanthoma, metastatic bone formation, and osteoma cutis. The very rare malignant counterpart of the pilomatrixoma is the pilomatrix carcinoma, which is characterized by vascular and muscle invasion as well as local recurrence following resection. Distant metastases are uncommon but have been reported. The differential diagnosis of this malignancy includes basal cell carcinoma with matrical differentiation, matricoma, and metastasis.[5] Proliferating trichilemmal tumors, which may appear similar to invasive pilomatrixomas, are instead likely to arise from trichilemmal cysts that have been exposed to trauma or inflammation.[4]

Copyright © 2003, Mosby, Inc. All rights reserved.

Basal Cell Carcinoma

Basal cell carcinoma is the most common type of skin carcinoma. It is more common in males and rarely occurs in dark-skinned people or Asians. The increased incidence in individuals with light hair, light skin, inability to tan, and prolonged sun exposure has long implicated actinic damage in the pathway of basal cell carcinoma development. In addition, patients who have basal cell carcinoma are three times more likely than the normal population to develop another UV–related malignancy, melanoma.[8] Basal cell carcinomas tend to occur in the central midface. Prognostically, these tumors tend to be more aggressive than basal cell tumors at other head and neck sites.[2]

After tumor site, histologic type is the most important factor in determining the prognosis. Overall, basal cell carcinomas rarely metastasize (0.1%), but tumors with squamous differentiation and/or an adenoid pattern occurring about the orbits have the highest incidence of metastasis. Perineural, lymphatic, and vascular-type metastasis can occur, and once metastasis has developed, the average survival is only 1 to 2 years. Histologic analysis shows that basal cell carcinomas grow into the dermis as cords, strands, and sheets of small basaloid cells; centrilobular necrosis is not uncommon.[9] Surgery is the treatment of choice.[2]

On imaging, basal cell carcinomas have a variable appearance, depending on the size of the tumor at the time of imaging. When small, they are soft-tissue masses in the skin line, usually with deep extension into the subcutaneous tissues (Fig. 41-8). When large, they appear as deeply infiltrating soft-tissue masses. Basal cell and squamous cell carcinomas can be difficult to distinguish by imaging, although secondary findings such as adenopathy favor the latter.

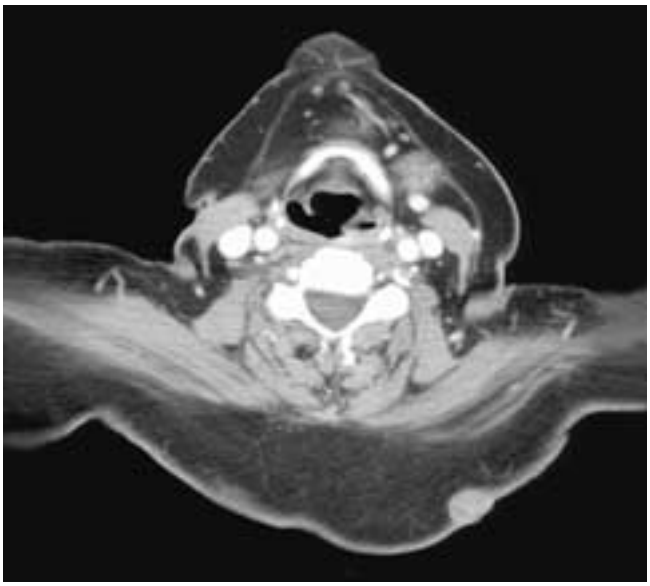

FIGURE 41-8 Axial contrast-enhanced CT scan shows a mass in the skin line of the left posterior neck. The deep margin is unsharp in some areas. This patient had a basal cell carcinoma.

VIEW IMAGE

Basal cell nevoid syndrome (Gorlin syndrome, Gorlin-Goltz syndrome) is an autosomal dominant disorder in which patients develop multiple basal cell carcinomas (especially at a young age), odontogenic keratocysts, palmar and plantar pitting, falx and dural calcifications, and skeletal malformations. Associations with many other benign and malignant tumors have also been reported. Other conditions in which relatively young patients develop basal cell carcinomas include xeroderma pigmentosum and nevus sebaceus.

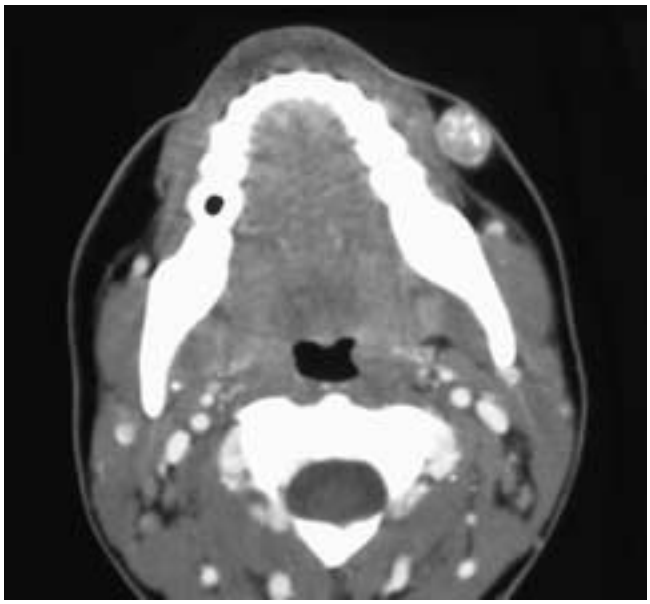

FIGURE 41-7 Axial contrast-enhanced CT scan shows a well-defined cystic-appearing mass with scattered calcifications in the subcutaneous soft tissues of the face. There is a broad margin of the mass abutting the deep aspect of the skin. This patient had a pilomatrixoma. Note the imaging similarity to a epidermoid cyst (Fig. 41-6).

VIEW IMAGE

Squamous Cell Carcinoma of the Skin

Squamous cell carcinoma of the skin commonly occurs in the head and neck. These tumors can arise de novo or in preexisting lesions such as actinic keratosis or squamous cell carcinoma in situ (Bowen's disease). There is a high incidence of squamous cell carcinomas in patients with hereditary skin diseases such as oculocutaneous albinism or xeroderma pigmentosum.[2] Men are more commonly affected than women (2:1), and most tumors arise in the sixth and seventh decades of life. Histologically, these are neoplasms of keratinocytes in the surface epidermis or in the epithelium of adnexal structures. Tumor typically penetrates the reticular dermis. The incidence of metastasis varies from 5% to 30%. Most researchers believe that the prognosis is not related to the histologic grade; however, the depth of invasion and the amount of surface area between the tumor and stroma may be related to the incidence of metastasis. Once squamous cell carcinoma of the skin has metastasized, the prognosis is poor, with 57.3% of patients dead of their disease within 5 years.[2]

Copyright © 2003, Mosby, Inc. All rights reserved.

Melanoma

Melanoma is a highly malignant tumor of melanocytes derived from the neural crest. The primary factor associated with the development of melanoma is excessive exposure to UV radiation, so patients with benign (melanocytic) nevi, freckles, dysplastic nevi, and a history of three or more severe sunburns are all at increased risk. Lymphoscintigraphy has proven useful in defining drainage pathways and suggesting which nodes are most likely to harbor metastatic deposits. Approximately one fourth of supraclavicular cutaneous melanomas arise on the neck; the second most common site is behind the scalp (36%); less frequent sites include the face (22%) and ear (14%).[10]

Numerous studies indicate that females have a better prognosis than males, possibly due to earlier detection and treatment. A possible increase in melanoma progression due to pregnancy and female hormone replacement therapy has recently been disproven.[11] Factors associated with improved survival include age less than 60 years and thinner lesions with less invasion.[12] The 10-year survival rate has been reported as high as 70% in males and almost 90% in females, although most studies report an overall 5-year survival rate of about 70%.[12, 13] Approximately 15% of patients die from their melanoma, and only 5% of patients with metastatic melanoma remain recurrence free for the remainder of their lives.[14] Mucosal melanomas are also associated with significant morbidity; these are discussed in Chapter 6.

Merkel Cell Tumor

Merkel cell tumor (trabecular carcinoma, cutaneous small cell undifferentiated carcinoma, primary neuroendocrine carcinoma) is an undifferentiated tumor of the skin, which in the elderly may clinically mimic a basal cell carcinoma. The typical patient is Caucasian and above 50 years of age.[15] As in melanoma, a neural crest origin is suspected. Approximately 25% of patients also develop squamous cell carcinoma in the same region, either separately or interspersed within the Merkel tumor itself.[9] Overall, the incidence correlates with sun exposure, and the head and neck region may account for two thirds of all cases, although the extremities and buttocks are also frequent sites (Fig. 41-9).[16] Patients with B-cell malignancies who have undergone organ transplantation are also at increased risk.[15] The Merkel cell tumor is usually identified as a slow growing nodule. The vast majority of patients present with localized skin lesions and no nodal disease. However, these are aggressive tumors and should be treated by wide surgical excision. Median survival is 29 months, with evidence that radiotherapy improves absolute 5-year survival (38% vs. 27%).[16, 17] Local recurrence occurs in about a third of patients, while nodal metastases are seen in 50% and visceral metastases in 15%.[2]

Skin Metastasis

Metastasis to the skin has been reported from a number of primary head and neck tumors, as well as from most of the common primary neoplasms arising below the clavicles.[18–27] In all cases, such metastases carry an associated dire prognosis. On imaging, the skin line soft-tissue mass is similar in appearance to a basal cell or squamous cell carcinoma (Fig. 41-10). Tumor implantation has also been reported about the tracts of drains placed during resection of numerous malignancies.

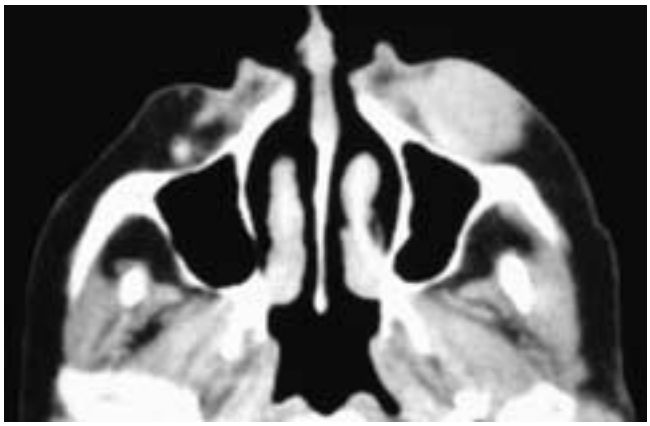

FIGURE 41-9 Axial CT scan shows a soft-tissue mass in the subcutaneous tissues of the left face. Portions of the contour of the lesion are unsharp, suggesting focal infiltration. This patient had a Merkel cell tumor.

VIEW IMAGE

Subcutaneous Fat Necrosis of the Newborn

Subcutaneous fat necrosis of the newborn (SCFN) is a condition affecting full or postterm infants, starting days to weeks after a complicated perinatal period. It is characterized by the appearance of one or more well-defined,

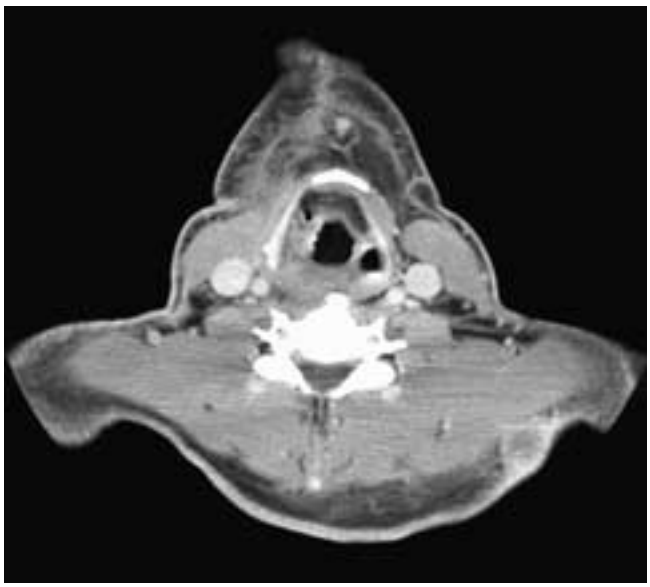

FIGURE 41-10 Axial contrast-enhanced CT scan shows a mass in the skin and subcutaneous tissues of the left posterior neck. The margins of the lesion are unsharp. nonsuppurative, erythematous or violaceous, mobile subcutaneous masses, often with taut overlying skin. There is usually a history of obstetric manipulation, perinatal asphyxia, meconium aspiration, or maternal disease. The typical lesions develop on the shoulders, back, buttocks, thighs, and cheeks. It has been postulated that these lesions result from localized tissue hypoxia and mechanical pressure, which further compromises the local circulation. It has also been suggested that thrombocytosis may play a role in the pathogenesis of adipose tissue necrosis by reducing blood perfusion, leading to relative hypoxia and hypothermia. The nodules of SCFN may enlarge for several weeks to months but then usually involute. Rare local complications include epidermal atrophy, ulceration, scarring, or infection.[28]

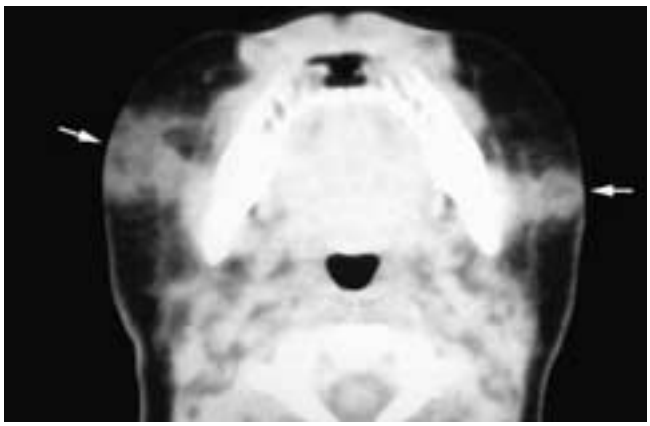
Pathologically, SCFN is characterized by clusters of adipocytes, histiocytes, fibroblasts, scant lymphocytes, and numerous foreign body giant cells. Granulomatous fat necrosis and calcifications are seen. Hypercalcemia is the most serious complication associated with SCFN; it is believed to be caused by an excess production of 1,25-dihydroxyvitamin D by the granulomatous macrophages. Because hypercalcemia may occur anytime from 1 to 6 months after the skin lesions first develop, these neonates should have calcium levels monitored for at least 6 months. The radiologist should monitor for possible renal complications of hypercalcemia, and renal ultrasonography is recommended to exclude nephrocalcinosis and nephrolithiasis. Other clinical associations with hypercalcemia include hypotonia, vomiting, anorexia, irritability, and failure to thrive.[29]

On CT, the lesions of SCFN appear localized to the subcutaneous tissues immediately deep to the skin. The nodules may have minimally infiltrative margins and areas of central low density only slightly higher in attenuation than that of fat. The nodules may partially obliterate the fat planes over the superficial margin of an adjacent deep muscle; however, the muscle itself and the deeper fat planes about the muscle are normal. There also may be a diffuse subcutaneous fullness with increased attenuation in the fat, without a discrete mass (Fig. 41-11).

Linear or sheet-like areas of diminished signal are typically seen on both T1-weighted and T2-weighted images, although increased signal intensity may also be noted on T2-weighted images. Findings are even more conspicuous on fat-suppressed, inversion recovery sequences, where involved areas appear bright.[29]

If the clinical situation warrants, fine needle aspiration of the subcutaneous lesions may be useful to confirm the diagnosis. The finding highly suggestive of SCFN is negatively stained, needle-shaped crystals within histiocytes and multinucleated giant cells. The main reason to establish the diagnosis of this self-limiting entity is to differentiate it from other lesions that may require surgery. The principal clinical differential diagnosis includes other histologically distinct soft-tissue lesions of infancy such as rhabdomyosarcoma, the spectrum of fibrous lesions, hemangioma, neurofibroma, and sclerema neonatorum.[28]



VIEW IMAGE

FIGURE 41-11 Axial CT scan shows a partially infiltrative-appearing subcutaneous soft-tissue mass (*arrows*) in each side of the face. This newborn had subcutaneous fat necrosis.

Sclerema Neonatorum

Sclerema neonatorum is a rare disease of the newborn that is characterized by a diffuse hardening of the subcutaneous adipose tissues. As such, it is distinct from the localized lesions of SCFN. Sclerema appears within the first postnatal week in neonates who are severely ill with pneumonia, peritonitis, or other infectious or congenital diseases. Premature infants are particularly susceptible, and the prognosis is grave. Sclerema may represent a disorder of lipolysis.[30] Histologic analysis has demonstrated subcutaneous fibrosis in all patients, with most having chronic dermal inflammation, epidermal thinning, and hypercollagenization of the dermis.[31]

Plexiform Neurofibroma and Skin Neurofibromas

The presence of a plexiform neurofibroma is sufficient to warrant the diagnosis of von Recklinghausen's disease even in the absence of other associated stigmata. A plexiform lesion can be seen as a fusiform or nodular mass, or as a tortuous enlargement of nerves that has been described as a ''giant nerve'' or ''bag of worms.'' In the head and neck, these lesions are often seen in the subcutaneous tissues (Fig. 41-12). The degree and pattern of calcification vary.

Another manifestation of neurofibromatosis is the presence of multiple neurofibromas on the skin, in addition to neurofibromas within the neck and facial region (Fig. 41-13). A discussion of both neurofibromas and schwannomas also appears in Chapter 6.

Silicon Augmentation

Silicon and silicon products have long been used as tissue expanders and for cosmetic surgery.[32] Historically, silicon had been injected subcutaneously to fill skin contours. Unfortunately, free silicon often invokes a granulomatous and fibrotic reaction that ultimately causes further deformity

FIGURE 41-14 Axial contrast-enhanced cranial (**A**) and caudal (**B**) CT scans show areas of both increased density and intermediate density in the swollen subcutaneous soft tissues of both sides of the face. This patient had had silicon (increased density) injected in his cheeks several years earlier and then formed a foreign body reaction (intermediate density) to the silicon. Axial CT scan (**C**) shows a silicon insert (*arrow*) overlying the right zygoma. This is a fairly typical appearance of recent facial augmentation procedures.

VIEW IMAGE

of the overlying skin. On imaging, one sees thickening of the overlying skin, soft-tissue nodularity within the subcutaneous tissues, and scattered radiodensities (silicon) within this process (Fig. 41-14). If the fibrotic and granulomatous reactions are severe enough, there is considerable deformity of the skin contour. Silicon products are less frequently implanted today, and when used, they are encased in containers that cause little reaction in the adjacent soft tissues.

Alloderm Augmentation

Numerous materials, both autologous and nonautologous, have been used for augmentation of soft-tissue defects in the facial region. There is no ideal material for soft-tissue augmentation, as each material has its limitations. AlloDerm dermal graft (LifeCell Corporation, Branchburg, NJ) combines the benefits of autografts and allografts. There is a very low incidence of complications such as rejection, mobilization, absorption, dislocation, or extrusion. In addition, the use of Alloderm minimizes two surgical problems: donor site morbidity and lack of adequate tissue for reconstruction. Alloderm has been shown to be useful in facial plastic procedures and the repair of burn injuries.[33–42] On CT, Alloderm is of a fairly high attenuation, being greater than that of muscle but less than that of bone (Fig. 41-15). On MR imaging, if seen, it usually has a low-intermediate signal intensity on all sequences.

Foreign Bodies

In addition to surgically placed materials, foreign bodies may be identified following perforation or laceration. Overall, perforations are uncommon, and their major manifestations arise deep to the skin and subcutaneous tissues. Most foreign bodies in the neck are ingested and, after perforating the mucosa, migrate outside the pharynx or cervical esophagus. Oral cavity or oropharynx perforations (especially those involving the tonsillar pillars) are not uncommon in young children, who tend to walk, run, and fall with objects in their mouths; care must also be taken to exclude carotid injury. Finally, penetrating injuries from bullets, wires, knives, and other objects can result in retained foreign bodies. Focal lucency within soft tissues immediately following penetrating trauma often represents gas; however, hypodense foreign bodies made of plastic, glass, or wood can appear similar. While the density of many of these bodies may not change over time, that of rehydrated wood may gradually approach soft-tissue density. Gas may also be generated by certain bacteria in infected wounds. If not removed, foreign objects can cause abscess or pseudoaneurysm formation, or the foreign body can migrate into the chest, spine, or even intracranially.[43–56]

In recent decades, the dietary preferences of many people have changed to favor more fish and fowl and less meat. The bones of chickens, quails, and so on are fairly large and well ossified, making identification on either plain films or CT

FIGURE 41-15 Axial CT scans at narrow (**A**) and wide (**B**) window settings on a patient who has had alloplast sheet (*arrows*) augmentations in her cheeks.

routine. However, special mention of the radiology of fish bones is warranted. Several studies have shown that CT examination identifies almost all types of fish bones, whereas plain films often fail to identify some varieties. Factors that affect the imaging identification of fish bones include the radiodensity of the fish bone, the orientation of the bone in relation to the imaging plane, and the location of the bone (e.g., tonsil, hypopharynx, cricopharyngeus, esophagus). Although there is some variation among reports, in general the bones of herring, salmon, mackerel, trout, blue fish, red fish, and pike are not well seen on plain films.[57–60] Thus, if one suspects that one of these varieties of bones has perforated, CT may provide greater sensitivity than plain film alone.

The bones of striped bass, sea bass, codfish, flounder, fluke, gray sole, haddock, halibut, porgie, red snapper, smelt, monk fish, plaice, gurnard, and white perch are all usually well seen on plain films and CT. Often on CT, the location of the fish bone is also identified by local enhancement due to an inflammatory reaction and small collections of air from the adjacent pharynx (Fig. 41-16).

FAT-CONTAINING LESIONS

Ordinary Lipoma

Fatty or adipose tissue comprises 15% to 25% of the human body, although in obese individuals fat may represent over 40% of body weight.[61] Ordinary lipomas have been described in virtually every tissue of the body. In general, they are more common in females over the age of 40 years; however, in the head and neck, they may occur more frequently in males. The most common supraclavicular location is the posterior neck, with the anterior or lateral neck and the supraclavicular fossa also being frequent sites. Multiple lipomas may be seen in Gardner's syndrome, multiple endocrine neoplasia, neurofibromatosis, or, rarely, in familial lipomatosis, although lipomas are so prevalent that the vast majority are sporadic.[9] Once fat is within a lipoma, it cannot be utilized by the body, even in cases of profound starvation. Thus, when one gains weight a lipoma may enlarge, but when one loses weight the lipoma will not shrink.

Although there are various histologic types of lipoma (myxoid lipoma, angiolipoma, pleomorphic lipoma, spindle cell lipoma, and myelolipoma), on imaging they generally have smooth, noninfiltrative borders and contain almost exclusively fat (Fig. 41-17). Thus, on CT they have a low attenuation, while on MR imaging they have high signal on T1-weighted imaging and intermediate to high signal on fast spin-echo (FSE) T2-weighted imaging. Approximately 8% of ordinary lipomas contain less than 95% fat, in which case distinction from atypical lipomatous tumors may not be possible.[62] Rarely, hemorrhage can occur within an ordinary lipoma. In such cases, imaging shows a well-delineated mass with areas of high attenuation on CT and high signal on both T1-weighted and T2-weighted sequences.

Ultrasound characterizes lipomas as well-defined, compressible, elliptical masses with long axes parallel to the skin. Most are hyperechoic; however, one quarter are isoechoic or hypoechoic relative to muscle. Numerous echogenic lines are seen within the lipomas oriented parallel to the skin surface.[63] Detection of distal shadowing or distal augmentation suggests a different diagnosis.

Infiltrative (Intramuscular) Lipoma

Intramuscular lipomas are uncommon, benign unencapsulated tumors, also referred to as infiltrating lipomas because of their infiltrative growth pattern. Histologically, monovacuolar fat tissue is seen between muscle fibers and, in extreme cases, the muscle may be totally replaced by fatty tissue. Careful pathologic examination is necessary to avoid the mistaken diagnosis of a well-differentiated liposarcoma. Complete resection is often difficult, and the postoperative recurrence rate is 3% to 62%. In fact, incomplete resection is favored because development of muscle dysfunction due to fatty infiltration is gradual, and the patient tends to compensate well through recruitment of other muscles. By comparison, the rapid loss of function secondary to the surgical removal of a muscle is, in general, poorly tolerated.

On CT, the fatty mass is typically centered within the normal areas of adipose tissue within the neck. The MR findings of intramuscular lipoma can vary from those of a homogeneous ordinary lipoma to a large, inhomogeneous lesion with an infiltrative margin. The presence of infiltrative margins and intermingled muscle fibers in an intramuscular lipoma indicates a benign lesion rather than a malignancy, and such ingrowth of fatty tissue among the muscle fibers may be seen in up to one third of cases (Fig. 41-18).[64] In addition, uninodularity of the mass is helpful in differentiating intramuscular lipoma from the usually multinodular well-differentiated liposarcoma.[65–70]

Madelung's Disease

Multiple symmetric lipomatosis, described in Germany by Madelung in 1888 and in France by Launois and Bensaude in 1898, is a rare disease of unknown etiology. It is characterized by the presence of compartmentalized, but unencapsulated, fatty deposits in the neck and upper body. These deposits usually grow slowly, and their initial consequence is purely cosmetic. Rarely, however, they can lead to compression of the larynx, trachea, and cervical esophagus.

This disease usually affects middle-aged males of Mediterranean descent with a history of alcohol abuse. Although most cases have been sporadic, some investigators believe this disorder may be hereditary, and it is thought that this pathology originates from an alteration in lipid metabolism. Surgical removal of the fatty masses is the treatment of choice; however, recurrences are common.[71] The fatty deposits can be present virtually anywhere in the neck, but they are predominantly seen in the posterior neck deep to the trapezius and sternocleidomastoid muscles, in the supraclavicular fossa, and between the paraspinal muscles. Less often, the excess fat is seen in the anterior neck, superior mediastinum, pretracheal and prevertebral spaces, and over the cheeks.[72] On imaging, the compartmentalized appearance of the fat (Fig. 41-19) distinguishes the findings from obesity, in which there is a generalized increase in fat within the subcutaneous tissues (Fig. 41-20). The masses typically show no calcification or ossification, and there is no invasion of adjacent vascular structures.[72]

Liposarcoma

Liposarcomas represent 15% to 18% of all soft-tissue malignant tumors. They typically develop in the fourth through sixth decades and are more common in males. Liposarcomas are found mainly in the deep soft tissues, unlike lipomas, which usually arise superficially. With few exceptions, liposarcomas are believed to develop de novo and not from ordinary lipomas. About 3% occur in the head and neck, with most occurring in the neck and cheek.[61] The treatment of choice is wide surgical resection. Of the 25% to 46% of liposarcomas that recur, most are of the round cell or pleomorphic varieties.

On CT, liposarcomas can appear as ordinary lipomas or they can have variable scattered soft-tissue density (Fig. 41-21). In the more extreme cases, little fat is seen

FIGURE 41-17 **A**, Axial contrast-enhanced CT scan shows a well-delineated fatty mass in the subcutaneous tissues of the back of the neck. **B**, Axial contrast-enhanced CT scan shows a well-delineated fatty mass in the subcutaneous tissues of the left neck. Despite the size of the mass, there are smooth, noninfiltrating borders. Axial T1-weighted image (**C**) shows a well-circumscribed high signal intensity mass situated between the left paraspinal muscles. The lesion is isointense to normal fat. **D**, Axial T1-weighted, fat-suppressed, contrast-enhanced MR image shows that the mass suppresses like normal fat. All of these patients had ordinary lipomas.

(Fig. 41-22). Well-differentiated liposarcomas can have a variety of MR imaging appearances. Typically, they have features suggestive of a benign lipoma (a well-defined mass with high T1-weighted and low-intermediate T2-weighted spin-echo [SE] signal intensities, with little or no contrast enhancement). In less well differentiated liposarcomas (myxoid, pleomorphic, and round cell), the majority of the tumor typically has a low T1-weighted signal intensity, and only scattered fatty islands and septa may be seen. T2-weighted images usually show most of the mass to be of intermediate to high signal intensity, with fatty islands of relatively low to intermediate signal intensity.[73] Much

coarser stromal enhancement is seen in the less differentiated tumors.

INTERSTITIAL LESIONS

Fibrosarcoma

Although fibrosarcoma was once described as being among the most common sarcomas, the improved characterization of previously misdesignated fibromatoses has led to a lower reported incidence of fibrosarcoma. As a result, fibrosarcoma now lags well behind malignant fibrous histiocytoma in frequency.[74] Although it can be seen at any age, fibrosarcoma is most common in the fifth through eighth decades; a smaller peak is seen in the neonatal period and in infancy. There is an increased incidence in males and in sites of previous burn or radiation, but other radiation-induced sarcomas, such as malignant fibrous histiocytoma, are more common.

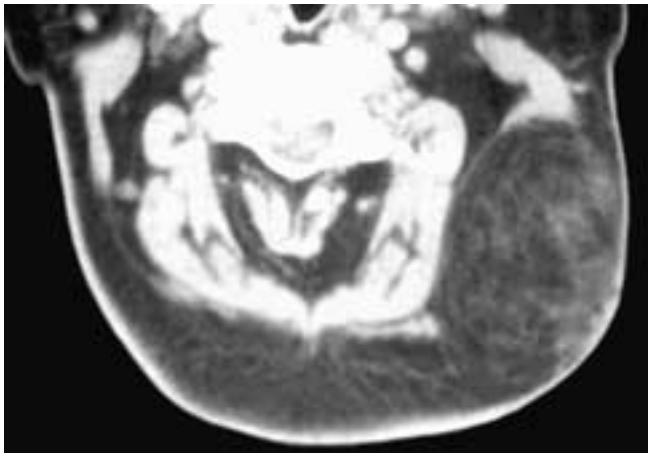

FIGURE 41-21 Axial contrast-enhanced CT scan shows a nonhomogeneous but primarily fatty mass in the posterior left neck. Portions of the lesion contour are well defined; others are poorly seen. This patient had a liposarcoma.

FIGURE 41-22 Axial contrast-enhanced CT scan on a patient who had had prior surgery on the pharynx and left neck for a liposarcoma. There was a sudden enlargement of the left neck, and this CT scan shows a well-defined, slightly enhancing, nonhomogeneous mass. At surgery, this was found to be a recurrent liposarcoma that had hemorrhaged.

Fibrosarcoma typically presents as a painless, slowly growing mass. It can arise superficially, from deep subcutaneous tissue, or deep within the soft tissues of the neck. Superficial tumors tend to be detected at a smaller size than deeper tumors.[74] The histologic appearance varies, with lower-grade tumors seen as solid and higher-grade lesions demonstrating necrosis and hemorrhage. Distinction of lower-grade lesions from aggressive fibromatosis can be difficult, but only fibrosarcoma will metastasize. The apparently worse prognosis of fibrosarcoma in the head and neck compared with extremity lesions may relate to the inability to obtain adequate tumor margins rather than differing biologic activity.

On imaging, the findings of fibrosarcoma are nonspecific. Low-grade lesions are homogeneous on CT and hypointense on T1-weighted and T2-weighted images. Mild to moderate enhancement is seen on MR imaging but not on CT.[75] Distinction from other aggressive fibromatoses can prove difficult, as they can appear quite similar. However, the presence of necrosis strongly favors the diagnosis of a higher-grade fibrosarcoma. Imaging, particularly MR imaging, has played a major role in defining the extent of these tumors. This is important for proper surgical planning or, if indicated, for planning of proper radiation fields.[75]

Benign Fibrous Lesions (Fibromatoses)

The fibromatoses are a heterogeneous group of histologically benign fibroproliferative disorders that share characteristics with both reparative processes and neoplasias. They may be localized or diffuse, symmetric or asymmetric, regress spontaneously or resist treatment and recur. Fibromatoses are often recognized in childhood, but they can occur at any age. Although most follow a benign course, compromise of vital structures may occur.[61] As a group, they do not metastasize.[76]

The etiology of these fibromatoses is unknown, and the classification of these lesions is mainly based on their clinical findings. Although a number of lesions are classified as fibromatoses, this section will only deal with desmoid fibromatosis, congenital fibromatosis, nodular fasciitis and proliferative fasciitis.

Desmoid Tumor

The term *fibromatosis* without any further qualifiers is generally taken to indicate desmoid fibromatosis, which is an infiltrative process not limited to the fascia. Rather, it arises from musculoaponeurotic structures and invades the contiguous tissues. Some pathologists consider them well-differentiated fibrosarcomas, particularly when scattered mitotic figures are identified. Unlike abdominal wall desmoids, which are more common in women, there is no clear gender predilection in head and neck desmoids. They are seen in all age groups, although there is a higher incidence in the first few decades of life.[74] Patients with Gardner's syndrome are at increased risk for developing desmoids.

These lesions are typically firm or hard and usually painless, although occasionally they are tender. Most neck desmoids are found in the upper neck; however, those seen more inferiorly may be more difficult to manage, as they can involve the great vessels, trachea, and brachial plexus. They are locally invasive but do not metastasize (Fig. 41-23).[61, 74] Surgery is the treatment of choice, and while lesions often extend 2 to 3 cm beyond their apparent boundaries, some cases with positive surgical margins may not recur. Irradiation and chemotherapy are reserved for recalcitrant cases.

Congenital Fibromatosis (Generalized and Localized)

Congenital generalized fibromatosis (infantile myofibromatosis) is a rare disease that starts in utero; however, additional lesions may continue to develop after birth. It presents as multiple superficial tumors of the skin and subcutaneous tissues. However, deep lesions involving the heart, lungs, skeletal muscles, viscera, and/or bones also occur, and many patients succumb to the disease. If the infant survives the first few months of life, the tumors often regress spontaneously over the next 6 to 18 months.[61] Somewhat paradoxically, fibrous-rich tissues such as tendons and fascia are rarely affected.

Congenital localized fibromatosis, which may be more common than the generalized form, presents at or just after birth and is localized to just one body area. Typically, the tumors arise in the subcutaneous tissues, skeletal muscle, or bone, and most nonvisceral lesions spontaneously regress. Recurrence following resection of solitary lesions is uncommon.

Histologically, the mesenchymal cells appear more immature than those seen in desmoid tumors, and there is occasional necrosis with calcification that is not seen in other fibromatoses.[74] On CT, the fibromatoses usually are infiltrating lesions that have an attenuation equal to or higher than that of muscle and that enhance significantly after contrast administration. On MR images, these lesions usually are heterogeneous and may be either of intermediate or low signal intensity on T2-weighted images. The signal on T1-weighted images is low to intermediate, and there is strong enhancement after contrast administration.[77, 78]

Nodular Fasciitis (Pseudotumor of the Skin)

Nodular fasciitis is a benign, nonneoplastic, self-limited fibroproliferative disorder. Its importance lies in its occasional pathologic confusion with a sarcoma. The head and neck region is the second most common site, lagging behind the upper extremities, where almost half of the lesions are found. Most often, this entity presents in the superficial fascia as a subcutaneous movable nodule that may be tender or painful. However, it also can arise from the deep fascia and may present as an intramuscular mass. Nearly half of the lesions grow rapidly over a few weeks and then slowly decrease in size over the next weeks to months. About 30% of the lesions show no change in size after presentation. Trauma or infection may increase the risk of developing nodular fasciitis, which is believed to represent a reactive or inflammatory process of the myofibroblasts that are normally concerned with skin repair.[79] Local excision is the treatment of choice, and a local recurrence (7% of cases) need not be resected if the diagnosis is established.

On CT, subcutaneous lesions are well defined by the adjacent fat, but intramuscular lesions may be poorly defined, usually with an attenuation slightly less than that of skeletal muscle. The lesions are well seen by MR imaging; intramuscular lesions are hyperintense to skeletal muscle on T1-weighted and hyperintense to fat on T2-weighted SE images. Subcutaneous lesions may be hypointense to skeletal muscle on all SE pulse sequences or hyperintense on T2-weighted images. Fairly pronounced enhancement occurs after contrast administration (Fig. 41-24). Because there are no unique imaging findings, nodular fasciitis must be included in the preoperative differential diagnosis of small soft-tissue masses.[80, 81] Among other lesions to be considered in this differential diagnosis are neurofibroma, schwannoma, fibrous histiocytoma, fibromatosis, fibrosarcoma, myxoid liposarcoma, and myxofibrosarcoma.

Proliferative Fasciitis

Though used by many researchers as a synonym for nodular fasciitis, the term *proliferative fasciitis* should be reserved for a peculiar subcutaneous and facial lesion that may represent the cutaneous counterpart of proliferative myositis. Proliferative fasciitis clinically is similar to nodular fasciitis except that it occurs in older patients and is less nodular and less defined, growing in the superficial fascia. Lesions may be painful, but the clinical course is benign and recurrences are rare.[61]

FIGURE 41-24 Axial T2-weighted MR image (**A**) shows a hyperintense nodule in the right paraspinal muscles. Axial T1-weighted, fat-suppressed, contrast-enhanced MR image (**B**) shows an intensely enhancing nodule. The appearance is not specific, as a primary muscle tumor or metastasis could have a similar appearance. This patient had nodular fasciitis.

Necrotizing Fasciitis

Necrotizing fasciitis is a potentially fatal bacterial infection that spreads within fascial planes. Although it is rare in the neck, possibly due to its relatively rich vascularity, this entity is included because of the potentially devastating sequelae of a delayed diagnosis.[82] Although it was once attributed primarily to extension of dental or pharyngotonsillar infections, numerous case reports have recently implicated sinus infections, epiglottitis, insect bites, radiotherapy, and trauma.[83–86] Inadequately treated infections can lead to mediastinal extension, considerable necrosis of the surrounding soft tissues and skin, and systemic toxicity.

Relatively constant CT findings in surgically proven necrotizing fasciitis include diffuse thickening and infiltration of the skin and subcutaneous tissue (cellulitis), enhancement and/or thickening of cervical fascia (fasciitis) and dominant muscles (myositis), and compartmental fluid collections.[87] Variable findings include soft-tissue gas, mediastinitis, and effusions. Subsequent CT imaging can demonstrate clinically unsuspected progression of disease, allowing for debridement sooner than would otherwise be considered.[87] MR imaging is sensitive for both cellulitis and fasciitis. In cellulitis without fasciitis, there may be enhancement of subcutaneous tissues or superficial fascia, as well as subcutaneous thickening and fluid collections. When fasciitis is present, however, there is thickening, enhancement, or increased T2-weighted signal intensity within the deep fascia, and deep fluid collections are not uncommonly seen. This fluid represents necrosis or abscess formation, the distinction of which can be difficult, as both are seen as areas lacking enhancement.[88]

MUSCLE-RELATED LESIONS

Levator Claviculae Muscle

The levator claviculae is a normal muscle found in 2% to 3% of the population. The muscle arises from the anterior tubercles of the transverse processes of the upper cervical vertebrae, runs down the neck medial to the sternocleidomastoid muscle, and inserts onto the middle third or lateral half of the clavicle (Fig. 41-25). It may be unilateral or bilateral. The imaging importance of this muscle lies in its recognition as a normal structure rather than as an enlarged lymph node, an unenhanced blood vessel, or some other mass.[89, 90]

Denervation Atrophy

Denervation of a muscle leads to predictable changes that end in a small, atrophic muscle, much of which is replaced by fat. Acute and subacute denervation results in a neurogenic edema that actually causes some muscle enlargement and high T2-weighted signal intensity on MR imaging.[91, 92] Chronic denervation is best seen on T1-weighted images, manifest as a loss of muscle bulk with diffuse areas of increased signal intensity within the muscle corresponding to fatty replacement. On CT, a similar pattern of fatty changes is seen, but it is slightly less well defined than on MR images. The rate of progression varies widely, with some investigators showing acute/subacute edematous findings persisting for up to 48 months after denervation in some patients and chronic fatty changes developing as early as 2 months in others.[92] On both CT and MR imaging,

Copyright © 2003, Mosby, Inc. All rights reserved.

end-stage fat replacement often results in fatty tissue without any identifiable muscle fibers (Fig. 41-26).

Muscle Hypertrophy

Muscle hypertrophy can develop as a result of exercise, in association with myotonic disorders (increased spontaneous activity), or idiopathically (some cases of masticator muscle hypertrophy). In true muscle hypertrophy, the muscle is enlarged but otherwise normal on all imaging. There also can be a pseudohypertrophy of muscle due to infiltration of the muscle by muscular dystrophies, amyloidosis, sarcoidosis, thyroid disease, and parasitic infestations. Lastly, a myositis can enlarge a muscle. On CT, the enlarged hypertrophic muscle may appear normal in density, but abnormal MR signal intensity is seen in most muscles that are enlarged due to pseudohypertrophy or a myositis.

A fairly common example of exercise muscle hypertrophy in the head and neck occurs with masticator muscle hypertrophy and in patients after a radical neck dissection (Fig. 41-27). After surgery, there is shoulder drop following denervation of the trapezius muscle; most patients, therefore, recruit the ipsilateral levator scapulae muscle to elevate the scapula. The resulting hypertrophy of the levator can been seen as a ''pseudomass'' on imaging, often misinterpreted as a tumor recurrence. Similarly, patients who lift weights often develop hypertrophy of the lower neck, upper back, and shoulder muscles, although these changes tend to be symmetric bilaterally.

Fibromatosis Colli (Sternomastoid or Sternocleidomastoid Tumor)

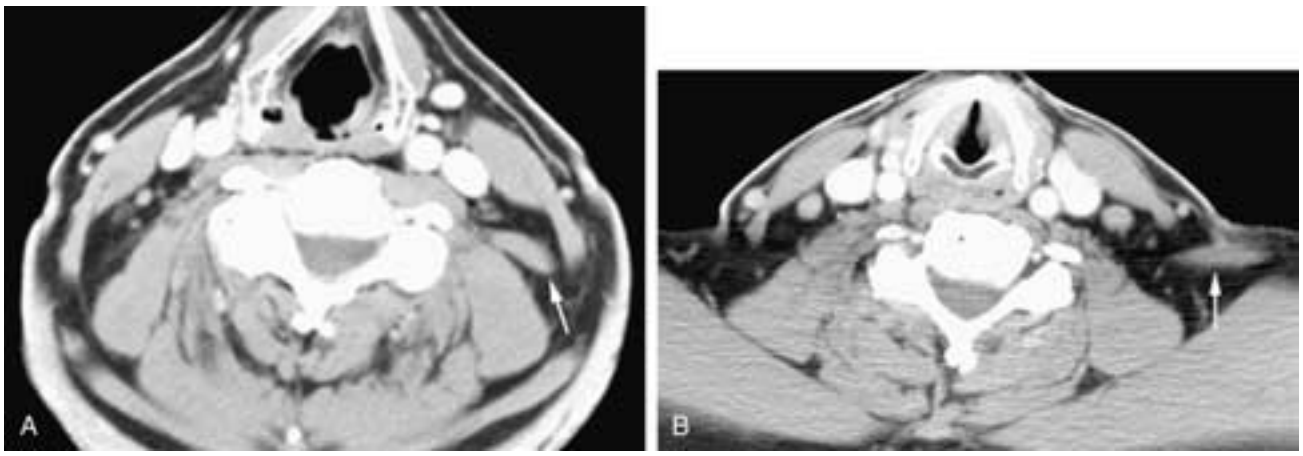
Torticollis may be either congenital or acquired. The cause may be muscular, neurogenic, infectious, neoplastic, posttraumatic, or even psychogenic. When torticollis is caused by a fibrocollagenous infiltration of the sternocleidomastoid muscle with a palpable mass in the newborn, the disease is called fibromatosis colli or sternocleidomastoid tumor. This must be distinguished from muscular torticollis, which is a tightening of the muscle without a palpable mass. However, between 15% and 20% of patients with fibromatosis colli progress to muscular torticollis despite therapy.[61] The right neck is affected in 75% of cases, and rarely, fibromatosis colli may be bilateral. About 70% of the cases present between birth and 2 months of age. Most cases spontaneously regress without resulting deformity, and conservative therapy is the treatment of choice. Although multiple explanations of the exact etiology have been offered, the cause remains unknown.[93, 94]

Sternocleidomastoid tumor presents as a benign, firm, fibrous swelling predominantly involving the middle or inferior third of the sternocleidomastoid muscle (Fig. 41-28). This pseudotumor affects 0.4% of infants in their first few weeks of life, with the vast majority showing complete regression over the ensuing few months. On ultrasound, fibromatosis usually appears as a hyperechoic mass or as diffuse enlargement of the sternocleidomastoid muscle of mixed echogenicity; other patterns are identified but are less common. The adjacent soft tissues should remain normal.[95] Although the signal characteristics relative to normal muscle may vary, signal intensity in fibromatosis is slightly increased on T2-weighted images and more significantly increased on gradient-recalled T1-weighted images; the SE T1-weighted signal intensity is essentially normal.[96]

Muscular Torticollis

Pathologically, muscular torticollis shows a limited collagenous and/or fibroblastic proliferation that does not cause a mass. It thus might be considered within the spectrum of fibromatosis colli, although 73% of cases of muscular torticollis present after 1 year of age. If it presents prior to 6 months of age, passive stretching may prove beneficial. After that age, a tenotomy may have to be performed.[61]

Congenital muscular torticollis, or idiopathic spasmodic torticollis, may be of unknown etiology, or may be related to



VIEW IMAGE

FIGURE 41-26 Serial axial contrast-enhanced CT scans from cranial (**A**) to caudal (**D**) on a patient who has had skull base surgery with damage to his right cranial nerves V, VII, and IX to XII. In **A**, there is marked atrophy of the right sternocleidomastoid muscle (*arrowhead*) and fatty replacement of the right-sided tongue muscles. As a result, the right base of the tongue prolapses back farther than the left side, possibly suggesting the presence of a mass on the right. The right internal pterygoid and masseter muscles are also smaller than their left-sided counterparts. In **B**, there is atrophy of the right sternocleidomastoid (*arrowhead*) and trapezius muscles. There also is atrophy of the muscles in the right side of the floor of the mouth. In **C**, the marked atrophy of the right sternocleidomastoid (*arrowhead*) and trapezius (*arrow*) muscles is clearly evident. In **D**, an axial contrast-enhanced CT scan through the lower neck of a different patient who has had a left radical neck dissection shows denervation atrophy of the left trapezius muscle (*arrowhead*). The right trapezius is normal, but its bulk could be mistaken for a mass (*arrow*).

trauma or found in conjunction with a variety of intracranial, atlantoaxial, and spinal pathology.[94, 97–125] Because of the association of congenital muscular torticollis with other intrauterine positioning disorders, it has been postulated that head positioning in utero may selectively injure the sternocleidomastoid muscle, leading to development of a compartment-type syndrome.[117] Singer et al. studied torticollis patients with CT and MR imaging and found signs suggestive of fibrosis within the sternocleidomastoid, which was confirmed at surgery.[113] Although congenital muscular torticollis is usually discovered in infancy or childhood, it may also present in adolescence or young adulthood. It should be considered in the differential diagnosis of nondystonic causes of abnormal head posture.

In a series of pediatric patients who presented with acute torticollis, including some without a history of trauma, almost two thirds (13/21) had atlantoaxial rotatory subluxation (AARS) on CT.[126] It has been suggested that torticollis related to AARS may not adequately resolve until this subluxation is addressed, either with fluoroscopically guided reduction or by fusion.[127] These reports underscore the importance of the cervical spine CT examinations in

FIGURE 41-27 Axial T1-weighted MR image (**A**) shows bilateral enlargement of the masseter muscles (*M*) in this patient with masseteric hypertrophy. In **B**, an axial contrast-enhanced CT scan on a patient who has had a left radical neck dissection shows atrophy of the left trapezius muscle (*arrowhead*). There is early hypertrophic enlargement of the left levator scapulae muscle (*arrow*).

evaluating the cause of acute torticollis that does not resolve spontaneously.

In 1969, Snyder described paroxysmal torticollis, which developed in patients between ages 2 and 8 months. The spells of head tilting lasted for a few hours to three days and were occasionally accompanied by pallor, vomiting, and agitation at the beginning of the spells. In most children, the spells stopped spontaneously by age 5 years.[128] This disease may have a familial occurrence, and 12% of patients with benign paroxysmal vertigo of childhood previously had paroxysmal torticollis of infancy.[129]

The evaluation of torticollis is often performed by ultrasound, which shows a diffuse enlargement of the sternocleidomastoid muscle. The abnormality may be either isoechoic or hypoechoic, depending on the age of the lesion. Although the enlarged muscle may be mistaken for a mass, it always moves with the muscle on real-time sonography.[130] Because ultrasound is always abnormal in patients with

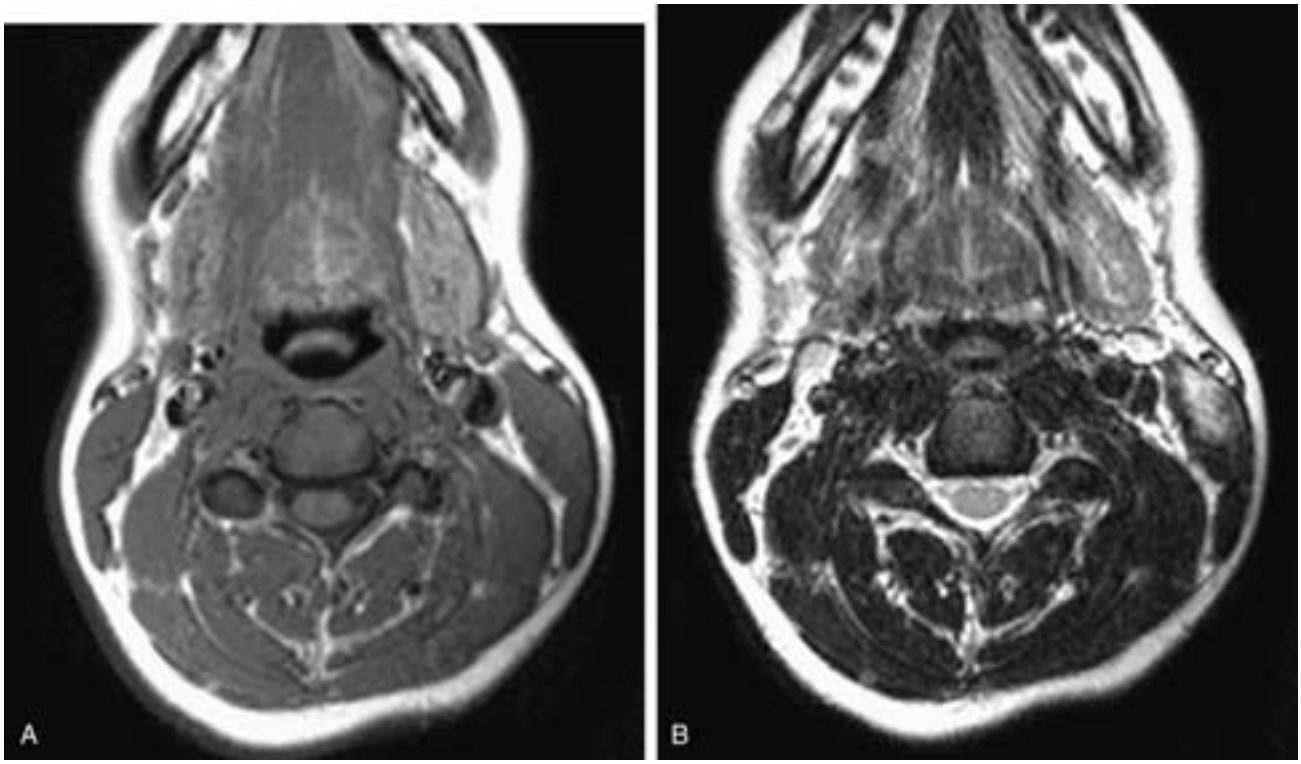
fibromatosis colli, this study should be included in the evaluation of infants with this suspected condition.[131]

On CT, the enlarged sternocleidomastoid muscle is isodense to normal muscle and either homogeneous or slightly inhomogeneous. On MR images, the muscle can be either isointense or of a lower signal intensity than normal muscle, either homogeneous or slightly nonhomogeneous, and the caudal portion of the muscle is usually more affected than the cranial margin. It is important to exclude other neck masses such as branchial cleft cysts, cystic lymphangiomas, and malignancies such as rhabdomyosarcoma and neuroblastoma.[130]

Myositis

Skeletal muscle may be inflamed secondary to an adjacent cellulitis and/or abscess. In such instances, technically the term *myositis* can be applied. The muscle typically is swollen and enhances on both CT and MR images (Figs. 41-29 and 41-30). On MR imaging, the muscle has higher than normal T2-weighted signal intensity, and there is evidence of inflammation in adjacent structures.

The term *proliferative myositis* describes a rapidly growing pseudosarcomatous lesion of skeletal muscle. In the head and neck, it usually affects the sternocleidomastoid muscle. It tends to occur in older patients, and it is not seen



VIEW IMAGE

FIGURE 41-30 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show minimal thickening of the anterior left sternocleidomastoid muscle and an area of high T2-weighted signal intensity. This patient had a left submandibular gland acute sialadenitis with a cellulitis. He was treated with antibiotics, and although the other signs of infection subsided, he had persistent muscle pain in his sternocleidomastoid muscle. This was an inflammatory myositis.

in children. Rarely, foci of osteoid or bone may be present, and simple excision is curative.[61]

Focal myositis is a benign, inflammatory pseudotumor of skeletal muscle. It grows rapidly and involves a single muscle. Both children and adults are affected. It is rare in the head and neck but has been reported in the sternocleidomastoid muscle, the submental region, and the buccal region. Surgery is curative.

Myositis Ossificans

Myositis ossificans occurs in two forms. The more common variant is myositis ossificans circumscripta (MOC), which usually is a localized process that occurs outside the head and neck region. The rarer and more diffuse form of the disease is myositis ossificans progressiva. MOC is an uncommon disease that has been reported to occur in patients after trauma, burns, and infections and in patients with no known underlying pathology. Although the etiology remains unknown, most investigators believe that MOC represents a localized nonneoplastic, reactive process that results in the proliferation of undifferentiated mesenchymal tissue that then infiltrates into the surrounding soft tissues. Suggested etiologies include ossification of a hematoma, tearing of periosteum allowing subperiosteal cells to invade the muscle, and metaplasia of muscle and connective tissue. Although MOC can involve any skeletal muscle, it is uncommon within the head and neck; it has been reported in the masseter, medial pterygoid, temporalis, buccinator, geniohyoid, genioglossus, sternocleidomastoid, and paraspinal muscles. Although MOC occurs in both males and females, the most commonly affected group is young, athletic males. In cases where there is a definite history of trauma, the time period between injury and clinical detection of MOC ranges from 3 weeks to 20 years. From the time of documented trauma, radiographic evidence of calcification in MOC can be seen as early as 2 to 4 weeks and mature bone as soon as 4 to 5 months.[132]

On CT, mature MOC shows a peripheral shell of calcification and/or ossification in a focal mass. However, very early calcification may be misinterpreted as enhancement, especially if the protocol for CT imaging of the neck does not include both pre- and postcontrast studies. Early imaging may also suggest a neoplastic mass and adjacent inflammation. The appearance is consistent with the early histologic description of central fibroblast proliferation and myofibroblasts with associated edema (Fig. 41-31),[133, 134] which may hinder histopathologic distinction of MOC from malignancy. Therefore, the possibility of MOC should be communicated to the pathologist if a biopsy is performed.

Three phases of evolution of MOC have been described: a pseudoinflammatory phase, a pseudotumoral phase, and a chronic phase. Imaging findings depend on the phase of the disease. On T2-weighted SE images, early lesions typically show a nonhomogeneous soft-tissue mass with extensive surrounding edema. Postgadolinium images often show marked enhancement of the mass. Mature lesions are typically better defined, without associated edema. MR imaging, however, is not definitive in its ability to exclude malignancy.

MR imaging of mature lesions has shown well-defined, inhomogeneous masses with signal intensity close to that of fat on both T1-weighted and T2-weighted images, hypointense rims, and no surrounding edema (Fig. 41-32). On MR imaging, the differential diagnosis includes an early abscess, necrotic adenopathy, and neoplasm. The imaging appearance of pyomyositis and polymyositis can also mimic that of early MOC lesions on both CT and MR imaging. If fine needle aspiration is utilized to arrive at a diagnosis of MOC, a sample of the periphery of the lesion must be obtained.[132]

Muscular Dystrophies

The muscular dystrophies are a group of primary muscle disorders that are hereditary in nature. The underlying biochemical defects are not well described. Of the dystrophies, the primary one that affects the neck muscles is fascioscapulohumeral (FSH) dystrophy. Outliers dystrophy, which lies on a spectrum somewhere between Duchenne's and Becker's muscular dystrophies, affects the flexor muscles of the neck so that the supine patient cannot lift the head against gravity. Walking is also affected after the age of 12 years. Other dystrophies, such as Emery-Dreifuss muscular dystrophy and scapuloperoneal dystrophy, affect the shoulder muscles and may uncommonly involve muscle changes seen on neck imaging studies. There also are isolated dystrophies that seem to affect a single group of muscles, such as the extensor back muscles.

FSH dystrophy is inherited as an autosomal dominant trait. Its prevalence is about 1 per 100,000 population. The cause remains unknown. Variable facial weakness is usually first noted in the second decade of life. Shoulder weakness especially affects the scapular fixators. Leg weakness also may occur. A more severe form of the disease occurs in infancy. Treatment is supportive.[135]

On CT, there is almost total fatty replacement of the affected muscles (Figs. 41-33 and 41-34). On MR imaging, the muscle has signal intensities close to those of fat, and the normal low muscle signal intensity is absent.

Myotonic Dystrophy

Myotonic dystrophy is one of the most common dystrophies, with an incidence of 2.5 to 5 per 100,000 population. It is estimated that between 1/20,000 and 1/7500 people carry the gene mutation for the disease. The syndrome is inherited as an autosomal dominant trait with variable transmission. The abnormality has been mapped as a CTG trinucleotide repeat sequence on the q13.3 band of chromosome 19, and when the disease is inherited from the mother, it tends to be more severe. Paternal transmission is rare.[136, 137]

Typically, the disease presents in the second to fourth decades of life; however, children can also be affected. Commonly, the small muscles of the hands and the extensor muscles of the forearms are the first to atrophy. However, in some patients, ptosis and facial muscle atrophy are the initial findings. Usually affected are the masseter and sternocleidomastoid muscles, leading to a deformed mandible and a ''swan neck.'' The association of frontal baldness and a

wrinkled forehead give the patient a distinctive appearance. Virtually all muscles can be affected, and most patients are confined to either a wheelchair or bed by the age of 15 to 20 years. Myotonia may precede muscle weakness (Fig. 41-35). Opacity of the lenses is common.

Also associated is a generalized hyperostosis affecting the skull and skull base. CT findings include thickened bone within the calvarium, mastoid portion of the temporal bone, petrous pyramid, anterior clinoid process, dorsum sellae, and clivus. Involvement of the glenoid fossa may lead to dislocation of the temporomandibular joint. Lytic and nonexpansile, sclerotic changes have also been seen in the temporal bone.[138, 139] Patients may also have huge frontal sinuses and a small sella turcica. Less common findings include craniokyphosis, a small nasal angle, narrowing of the internal auditory canals, hypotelorism, and enlargement of the mandible. Changes may be unilateral or bilateral. For the most part, the areas of expanded bone have a grossly normal cortical and trabecular pattern. The cause of these bony findings is still unknown.[140, 141]

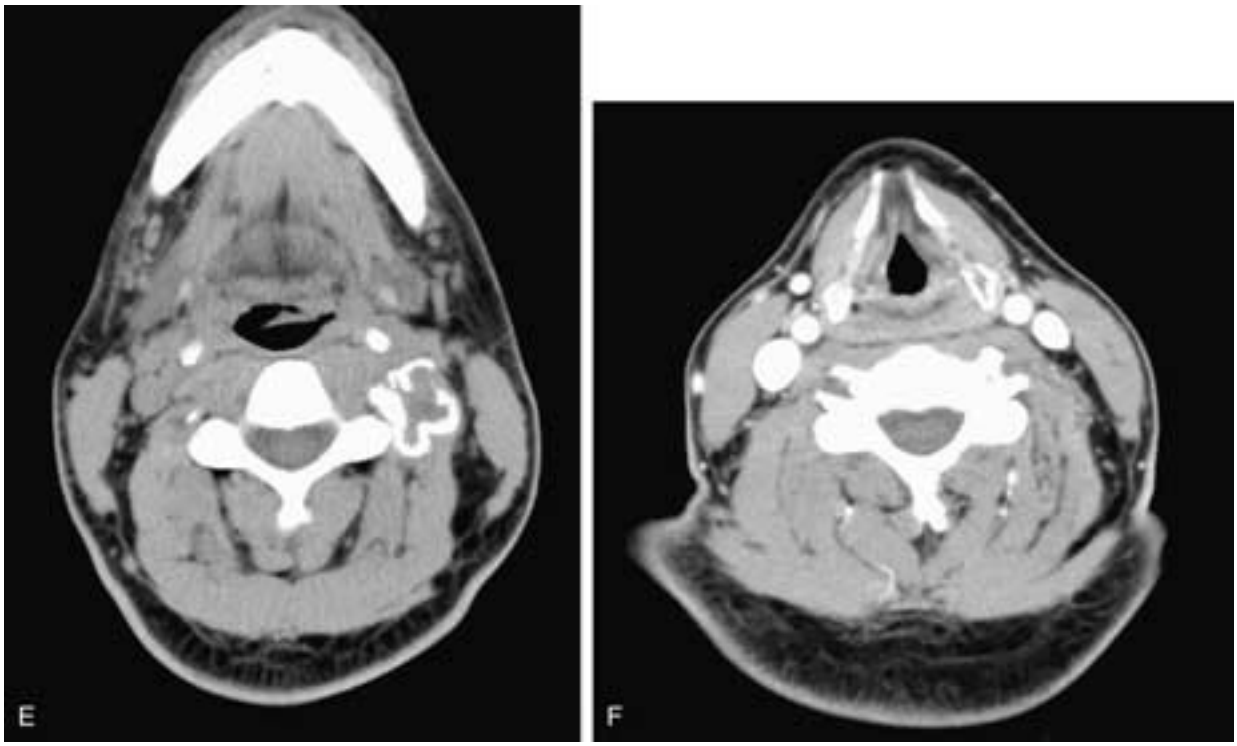
Rhabdomyosarcoma

Rhabdomyosarcoma (RMS), the malignant tumor of striated muscle, accounts for 8% to 19% of all soft-tissue sarcomas, and 35% to 45% of such sarcomas occur in the head and neck. Almost all tumors (98% to 99%) containing skeletal muscle are RMS, with the small remainder representing rhabdomyomas.[74] RMS is primarily a tumor of children and young adults, with most cases arising in patients under 12 years and 43% seen in patients less than 5 years of age. It is the most common sarcoma in children and the seventh most common malignancy in children overall after leukemia, central nervous system tumors, lymphoma, neuroblastoma, Wilms' tumor, and bone cancer.[61] Varieties include embryonal, alveolar, pleomorphic, botryoid, and mixed types. Most pathologists consider mixed RMS to be composed of two or more of these histologic types.[75]

More than half of RMS are of the embryonal variety, and of those, 70% to 90% arise in the head and neck or genitourinary tract. Most are seen in patients less than 10 years of age; however, nearly one quarter of cases are seen after the second decade. Regional nodal metastasis occurs in 10% to 38% of cases.[61]

Alveolar RMS is the second most common variety, representing approximately one fifth of all cases of RMS. It occurs mainly in patients 15 to 25 years of age and primarily affects the extremities and trunk. Only 18% of cases occur in the head and neck. Nodal metastases are most common in this variety, with regional lymph node involvement seen in 33% of cases and regional or distant nodal disease in 75% to 85%.[61, 75]

Botryoid RMS differs from embryonal RMS only in its gross appearance. About 75% of these tumors arise in the vagina, prostate, or bladder. The remaining tumors arise in the head and neck or bile ducts. Most patients are between 2 and 5 years of age.



VIEW IMAGE

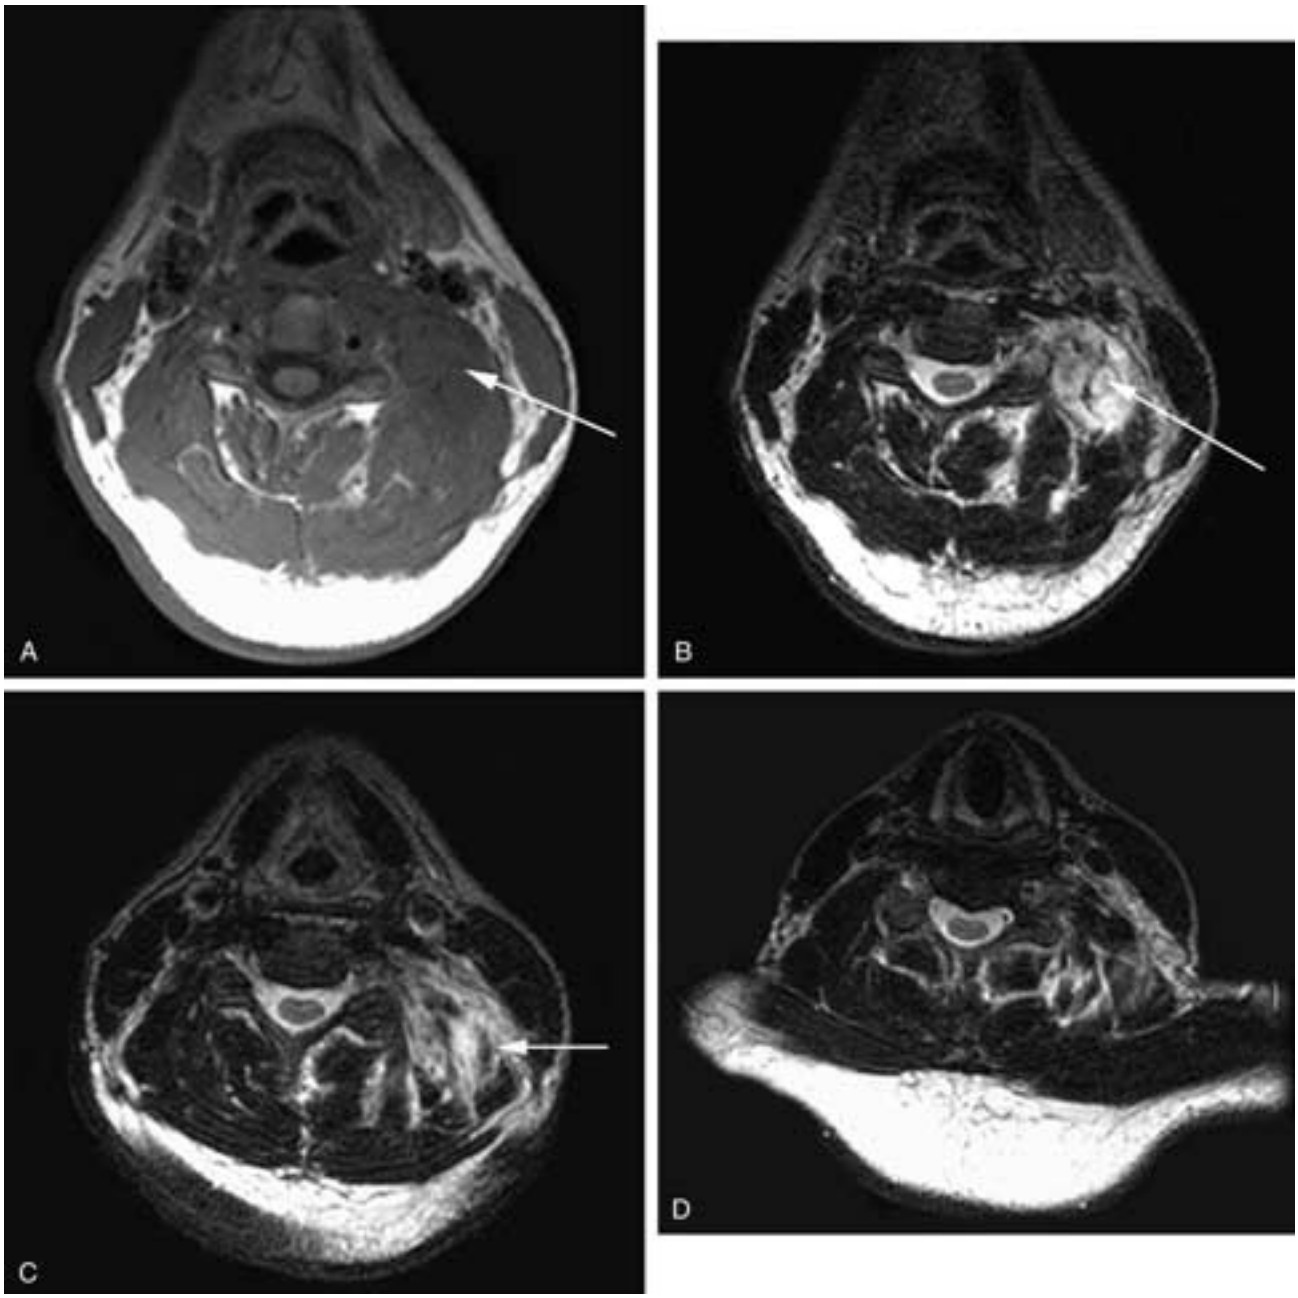
FIGURE 41-31 *Continued.* CT scans (**E** and **F**) obtained 4 months after onset show that in **E** the calcified/ossified density remains on this unenhanced image; however, the low attenuation and swelling of the left paraspinal muscles are no longer seen. Following contrast administration (**F**), there is now a symmetric and normal appearance of the paraspinal muscles. These findings illustrate the progression of myositis ossificans.

Copyright © 2003, Mosby, Inc. All rights reserved.

Pleomorphic RMS is seen primarily in patients 40 to 60 years of age, with only 6% discovered in patients less than 15 years of age. Most cases arise in the extremities, and only 7% affect the head and neck. Metastasis is primarily vascular, and only 9% of patients have regional nodal metastasis.[61] Survival is poorest with this variety of RMS.[75]

Clinically, RMS is usually a solitary, rapidly enlarging, firm mass that involves a striated muscle. Since the introduction of radiation and chemotherapy in RMS treatment, there has been significant improvement in long-term survival (now 85% or better).[74] The prognosis correlates more closely with extent of tumor involvement than with tumor type. By location, tumor in the orbit tends to be more localized and has a lower incidence of lymph node metastasis than other supraclavicular tumors; accordingly, orbital RMS has a significantly higher 5-year survival than RMS at other head and neck sites (89% vs. 55%).[74]

On imaging, RMS is seen as a densely cellular infiltrating



VIEW IMAGE

FIGURE 41-32 Same patient as in Figure 41-30. MR images obtained 1 week after onset of neck pain. In **A**, a T1-weighted MR image, there is a poorly defined soft-tissue mass (*arrow*), while in **B**, a T2-weighted MR image, the mass (*arrow*) has signal voids that could be interpreted as either vascular or fibrous in origin. There is also edematous-type high signal intensity in the immediate region. In **C**, a T2-weighted MR image more caudal in the neck, there is fullness and high signal intensity in the muscles and adjacent soft tissues (*arrow*). In **D**, a T2-weighted MR image obtained 1 month after onset, the mass and edema in the paraspinal muscles have decreased. This patient had myositis ossificans.

neoplasm (Fig. 41-36). Skeletal muscle is always seen as the site of origin. On both CT and MR imaging, masses are typically homogeneous, with destruction of adjacent bone. Necrosis can be seen, but intratumoral hemorrhage is uncommon and calcification is typically absent. Tumor is isointense to muscle on T1-weighted images and hyperintense on T2-weighted images.[142] Just over half of the cases enhance homogeneously, and the degree of enhancement is similar to that of normal skeletal muscle. In most cases, tumor margins are poorly defined.

Metastasis to Muscle

Hematogenous metastasis to muscle is rare. The relatively low incidence may be related to muscle enzyme inhibitors, the acidic environment of muscle, or the vessel-squeezing effect of muscular contractions.[143] Most frequently, the metastases come from primary tumors in the lung, colon, pancreas, breast, or kidney. Although pain, tenderness, and a mass are usually present, some such metastases may be clinically silent (Fig. 41-37).

THE STYLOHYOID SYNDROMES

Three dominant syndromes are related to the stylohyoid structures: Eagle's syndrome, styloid carotodynia, and hyoid fasciitis.

Eagle's Syndrome

In 1937, Eagle described the elongated styloid process syndrome, which consists of pharyngeal pain, referred otalgia, and a foreign body sensation in the throat occurring after tonsillectomy. It is believed that this syndrome develops because of fibrosis between the tonsillar fossa and an elongated styloid process; hence, the symptoms are greatest during deglutition, phonation, and deep inspiration, when maximal pharyngeal movement occurs. Since the time of its discovery, the term *Eagle's syndrome* has come to be applied to any patient who has these symptoms and an abnormally elongated styloid process. The normal styloid process may be as long as 2.5 cm. Thus, Eagle's syndrome may be present whenever a longer styloid process is seen on imaging in a patient, whether or not there has been prior tonsillectomy (Fig. 41-38). Complicating the picture even more is that some patients also have ossified stylohyoid ligament(s), which can themselves fracture and become symptomatic.[144] The treatment, if any, is surgical removal of the elongated styloid process(es).[145–152] Because there are many asymptomatic patients who have elongated styloid processes and/or ossified stylohyoid ligaments, some clinicians question the validity of Eagle's syndrome. Nonetheless, in the symptomatic patient, shortening of the styloid process usually relieves the complaint. The presence of an elongated styloid process also makes this structure more prone to injury during flexion-type trauma. The symptoms related to Eagle's syndrome can also be confused with those

Copyright © 2003, Mosby, Inc. All rights reserved.

attributed to a wide variety of facial neuralgias as well as oral, dental, and temporomandibular diseases.

Styloid Carotodynia

A related syndrome is styloid carotodynia, caused by a normal or elongated styloid process whose tip is deviated so that it causes pressure on either the internal or external carotid arteries. This pressure causes stimulation of the pain-sensitive receptors found in the adventitia of these vessels and results in pain along the vascular distribution of the affected vessel. When the internal carotid artery is affected, pain occurs in the parietal and ophthalmic regions and there is little or no pain below the level of the orbits. When the external carotid artery is involved, the pain is in the ipsilateral face below the level of the orbit. Again, surgery is curative.

Hyoid Fasciitis

The least common of these syndromes is hyoid fasciitis, which is usually found in patients who have not had previous neck surgery. Pain and discomfort in the throat are exacerbated when the patient's head is turned to the affected side. The head turning stretches the muscles between the hyoid bone and the styloid process. Palpation of the neck elicits tenderness over the region of the hyoid bone. It is believed that this hyoid syndrome may be due to tendinitis/fasciitis of the muscular attachments (and of the attachment of the stylohyoid ligament) to the hyoid bone. Some researchers have proposed that certain patients with similar

symptoms may instead have a tenosynovitis of the intermediate tendon of the digastric muscle.[153] Treatment of hyoid fasciitis consists of local heat applied to the area and/or injection of an anesthetic combined with corticosteroids along the affected greater horn(s). If these measures fail, relief may be difficult to achieve, as surgery is not considered a good option.[154, 155]

BLOOD VESSELS AND VASCULAR VARIATIONS

Veins

There are usually at least three jugular veins on each side of the neck. They are named by their position relative to the sternocleidomastoid muscle. Thus, there are the anterior jugular, external jugular, and internal jugular veins. Of these, the internal jugular veins usually have the greatest venous flow and thus are the largest vessels.

Asymmetry of the Internal Jugular Veins

The internal jugular veins are almost always asymmetric, with the right one being larger in nearly 80% of people. In the upper neck, the crowding of structures often prevents passive venous distention, and the asymmetry in the internal jugular veins appears minimal. However, more inferiorly the asymmetry is most notable, as the larger spaces of the neck allow more passive distention of the veins. The asymmetry is usually more evident on CT or MR imaging than it is clinically. The disparity in the size of the veins can be so great as to cause the larger vein to be mistaken for a vascular mass. Tracing the course of the vein clarifies such a case. After a radical neck dissection, the shunting of venous blood to the contralateral internal jugular vein can also cause massive enlargement of the vein (Fig. 41-39); this is a normal postoperative finding.

Multiple Jugular Veins

Occasionally, one or both of the internal jugular veins may be multiple. In such cases, the more dorsal of the veins is usually the smaller and may not enhance as well as the larger ipsilateral vein on contrast-enhanced images. In these instances, on axial images the poorly enhanced vein may be mistaken for adenopathy. However, tracing the course of the vein will again clarify the situation.

The external jugular veins are even more variable than the internal jugular veins, and they may also be single or multiple. Rarely, they can be larger than the ipsilateral internal jugular vein. Similarly, the anterior jugular veins are usually asymmetric from side to side. These veins most often are seen along the anterior and medial margins of the sternocleidomastoid muscle. There is usually a small vein just above the level of the manubrium that provides communication between the two anterior jugular veins. Occasionally, this small vein may be severed during a tracheotomy, causing a bloodied operative field. This small vessel is rarely seen on CT or MR imaging.

Phlebectasia

Phlebectasia is an uncommon condition of the venous system, possibly of a congenital etiology. Clinically, phlebectasia usually presents as a neck mass that enlarges when the patient performs a Valsalva maneuver, talks, or lies down. This normally asymptomatic mass decreases in size at rest or when the patient sits upright. When the internal jugular vein is affected, it presents as a cervical swelling that can mimic the signs of either a pharyngocele or a laryngocele. Because of its rarity, phlebectasia is frequently misdiagnosed.

In the neck, phlebectasia most often affects the internal jugular vein in both children and adults. However, almost any of the cervicofacial veins, such as the anterior jugular vein or the anterior facial vein, may also be affected. Usually no treatment is necessary for this benign condition, although some authors have recommended surgical excision in selected asymptomatic patients for cosmetic and psychological purposes. Venography, anteriography, color Doppler sonography, and CT have previously been used to diagnose this unusual condition.[156–164]

Thrombosis

Thrombosis of the jugular veins can occur secondary to placement of a central line, placement of a porta-cath, infection, surgery, neoplasm, and intravenous drug abuse.[165, 166] On CT, a thrombosed jugular vein is usually enlarged, and on contrast-enhanced images, an older clot is of lower attenuation than the normal vessel; enhancement of the vasa vasorum causes the vessel wall to be well seen. On dynamic contrast-enhanced CT, a thrombus is usually less dense than opacified blood. An acute clot may appear as dense as contrast-enhanced blood. In such a case, the clot is

Copyright © 2003, Mosby, Inc. All rights reserved.

better seen on either noncontrast images or delayed, contrast-enhanced scans as the vascular density decreases (Fig. 41-40). If inflammation is present, there will be a fasciitis around the vein, with edema of the surrounding fat planes. On MR imaging, jugular venous thrombosis may be more difficult to detect because slow or turbulent flow may mimic a clot.

Lemierre's syndrome is the association of an acute pharyngotonsillitis (which is an anaerobic oropharyngitis), septic thrombophlebitis of the ipsilateral internal jugular vein, and septicemia with septic emboli, most often to the lungs and large joints.[167] There usually is an associated regional reactive lymphadenitis (see Chapter 38).

Pseudocollateral and Collateral Veins

Due to the current rapid CT scan times and the rapid injection of contrast with power injectors, contrast enhancement of collateral veins in the muscles of the neck and back may become quite conspicuous (Fig. 41-41). Such opacification occurs even when the internal jugular vein is patent and well opacified. In such cases, visualization of these veins does not necessarily imply thrombosis of the great veins in the lower neck or superior mediastinum. However, when asymmetric posterior muscular collaterals are seen, it is usually prudent to check the lower neck and superior mediastinal veins on that side for the possibility of thrombosis.

Condylar Vein

The vein of the condylar canal is a normal emissary vein that exits the skull base through the posterior condylar canal.[168] The condylar vein may be present on one side or both sides, or it may be absent bilaterally. When bilateral, the two veins may be quite asymmetric in size. The importance of familiarity with the condylar vein lies in not mistaking it for lymphadenopathy or a mass (Fig. 41-42).

Arteries

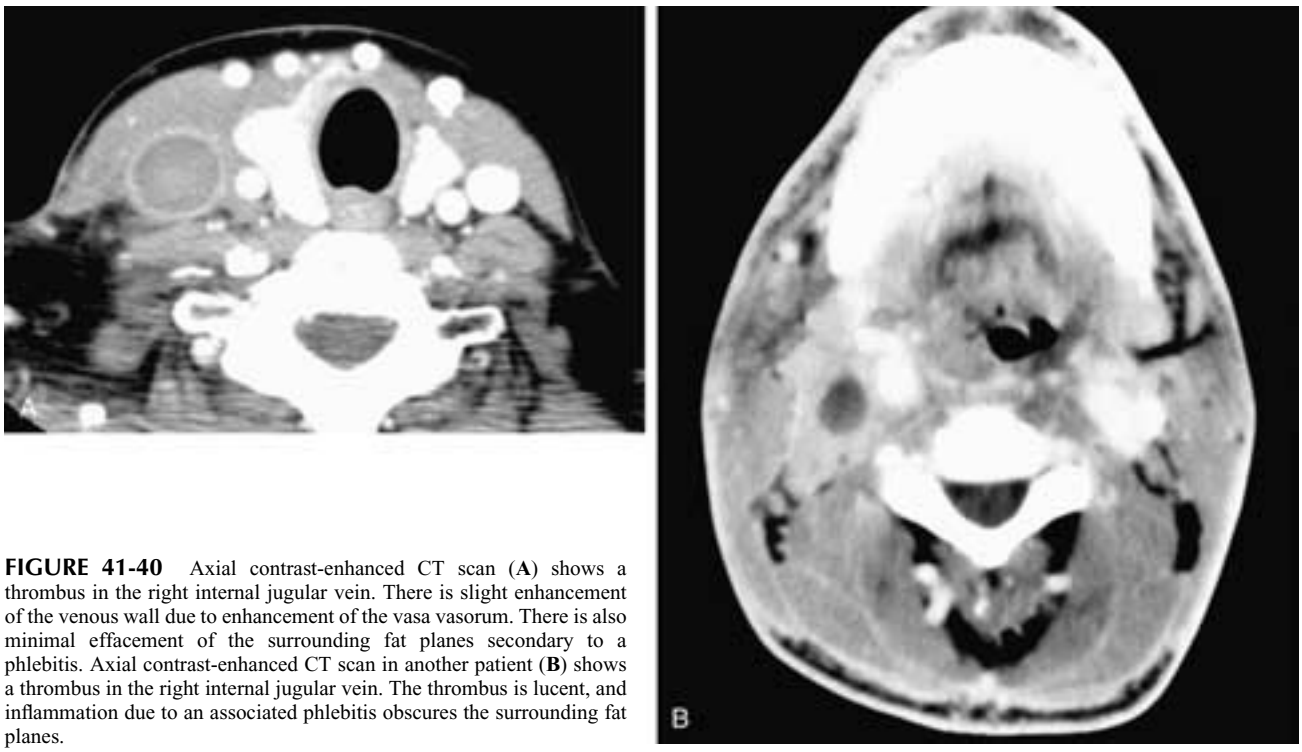
Medial Deviation of the Internal Carotid Artery

The internal carotid arteries are more consistently symmetric than the jugular veins. Thrombosis and dissection of the internal carotid artery are discussed further in Chapter 40 and postoperative thrombosis of the internal carotid artery is shown in Chapter 45. The medial positioning of the internal carotid artery(s) and, less frequently, of the carotid bulb may cause a bulge in the posterior pharyngeal wall; this is shown in Chapter 40 and in Figure 41-43. Recognition of this normal variant, and its inclusion in the written interpretation, will help to prevent potentially catastrophic biopsy of the associated pharyngeal wall fullness.

An aneurysmal dilatation of an artery may also cause an altered course of the vessel that may mimic a mass in the neck. This is especially so in the lower neck (Fig. 41-44).

Aberrant Retroesophageal Right Subclavian Artery

Although an aberrant retroesophageal right subclavian artery may be an incidental observation on CT or MR studies, it occasionally may cause symptoms of dysphagia (dysphagia lusoria). A barium swallow shows the artery's impression on the right posterolateral wall of the esophagus, and the vessel can be seen on CT and MR studies (Fig. 41-45). An



VIEW IMAGE

FIGURE 41-40 Axial contrast-enhanced CT scan (**A**) shows a thrombus in the right internal jugular vein. There is slight enhancement of the venous wall due to enhancement of the vasa vasorum. There is also minimal effacement of the surrounding fat planes secondary to a phlebitis. Axial contrast-enhanced CT scan in another patient (**B**) shows a thrombus in the right internal jugular vein. The thrombus is lucent, and inflammation due to an associated phlebitis obscures the surrounding fat planes.

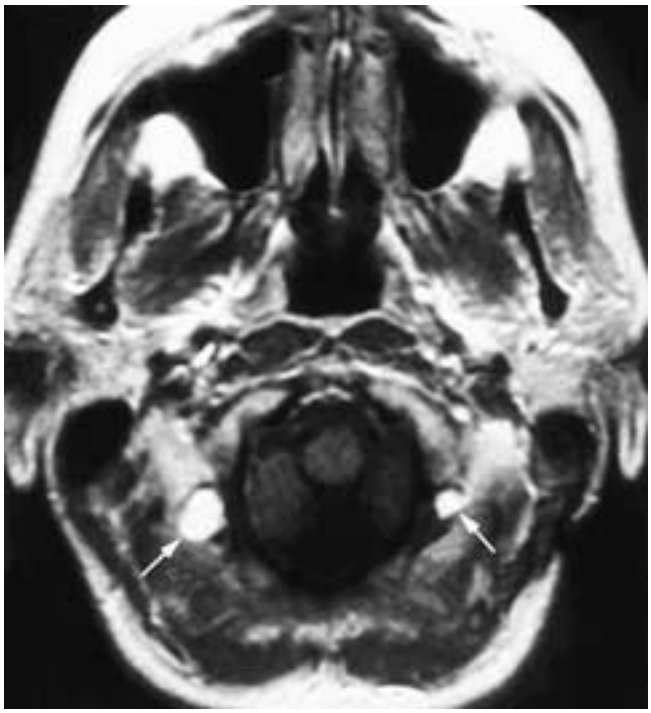
VIEW IMAGE

FIGURE 41-41 Axial contrast-enhanced CT scan (**A**) on a normal patient shows intense enhancement of the muscular vessels of the posterior neck (*arrows*). Although this could be seen in a patient with venous obstruction, there was no such obstruction and these were not collateral vessels. The contrast was administered by rapid injection, and the patient was scanned during contrast administration (1 second per scan). The vessels are probably veins opacified by reflux from the internal jugular vein (note the asymmetry of jugular opacity). Axial contrast-enhanced CT scan (**B**) shows a lucent thrombus in the left internal jugular vein and enhancement of the vein wall due to contrast in the vasa vasorum. There are also numerous large collateral venous channels (*arrows*) in the lateral and posterior left neck.



VIEW IMAGE

FIGURE 41-42 Axial T1-weighted image through the level of the foramen magnum shows a condylar vein with high signal intensity on each side of the neck (*arrows*). Asymmetry of the condylar veins is normal, and the high signal intensity reflects slow or turbulent venous flow. The importance of the condylar veins lies in their not being mistaken for abnormal lymph nodes.

aberrant right subclavian artery is associated with nonrecurrence of the recurrent laryngeal nerve.

Thrombosis and Dissection

Dissections of the great arteries in the neck can be spontaneous or related to blunt or penetrating trauma, strangulation, manipulation, angioplasty, infection, or intrinsic disorders of the vessels such as collagen-vascular disease.[169–171] Approximately one fourth of patients with internal carotid artery dissection will develop an associated pseudoaneurysm.[172] In a series of dissections related to manipulation, vertebral artery involvement was four times as frequent as carotid artery involvement; all vertebral lesions were seen around the atlantoaxial region, and 38% were bilateral.[170]

Imaging findings depend on the patient's age at the time of dissection and degree of resolution. On CT, fusiform narrowing of the arterial contrast column is more reliably demonstrated than actual subintimal hemorrhage. The classic MR appearance is that of a variably sized central flow void with a hyperintense rim or crescent on axial T1-weighted images, although this hyperintensity may not be seen in chronic cases (Fig. 41-46); conspicuity is augmented by fat saturation. MR angiography may falsely represent the degree of vascular compromise due to changes in flow rate through the dissection; the addition of contrast may help to better define the residual lumen.

Aneurysm

Aneurysms of the cervical internal carotid artery are rare lesions that typically present as pulsatile cervical masses. A series of 38 cases demonstrated relatively common associa-

FIGURE 41-43 Axial contrast-enhanced CT scan (**A**) shows a normal variant, a medially displaced right carotid bulb indenting the posterior wall of the hypopharynx. The left carotid bulb, which has calcific atherosclerotic changes, is seen more laterally relative to the pharynx on the opposite side. Axial T1-weighted MR image of another patient (**B**) shows an almost midline-deviated right internal carotid artery (*arrow*). (Courtesy of Dr. David W. Johnson.)

tions with atherosclerosis, fibromuscular disease, dissection, and trauma.[173] These aneurysms tend to arise in the distal third of the cervical internal carotid artery, and pseudoaneurysms are more common than true aneurysms.[174] On imaging, there is intense enhancement. Since there may be significant flow-related signal loss within the aneurysm itself on MR imaging, the lumen may be better appreciated on contrast-enhanced CT (Fig. 41-44).

Hemangioma

Cutaneous hemangiomas are the most common tumors of infancy and childhood; pathologically, they are classified as infantile, capillary, or cellular. These tumors have a characteristic clinical course that consists of rapid postnatal growth (proliferating phase), slow, spontaneous regression (involuting phase), and finally, restoration of either normal or altered skin (involuted phase).[175] Pathologically similar lesions occur in adults, although these lesions do not spontaneously involute. Despite the difference in clinical behavior, most pathologists still tend to refer to all of these lesions as hemangiomas. However, there is an alternative clinical/pathologic classification that restricts the term *hemangioma* to the typical lesion described above, with onset in the infant or child. The pathologically similar lesion that has its onset in adults is referred to as a vascular malformation.[175] In addition, a variety of other vascular malformations occur in adults, which are classified by the dominant vessel (i.e., venous, arteriovenous, or arterial). The imaging of hemangiomas is described in various chapters in this book.

Hemangiopericytoma

Hemangiopericytomas are unusual tumors of vascular origin that usually present as painless masses. Approximately one in six tumors arise in the head and neck region, less frequently than those seen in the trunk, pelvis/retroperitoneum, and extremities. Males and females are affected equally, and the peak incidence is near the mid-fourth decade, although there is a wide age range at presentation (first through seventh decades).[176] The small percentage of these tumors seen in the neonatal period tend to be more benign, with some maturing to hemangiomas.[177]

Benign hemangiopericytomas are characterized histologically by branched vessels lined with normal epithelial cells and surrounded by a connective tissue matrix. Features of malignant transformation include increased mitoses, irregular or unusual vascular spaces, and proliferation of connective tissue; necrosis and hemorrhage do not appear to be common. Up to half of even benign-appearing tumors may recur, and wide local excision is recommended. Patients should be monitored carefully for delayed recurrences, which may be seen a decade or more after initial tumor excision.[176]

The majority of tumors arise in extramucosal sites.[178] The location of the tumor adds prognostic value, since soft-tissue tumors are more likely than mucosal tumors to recur locally and metastasize.[176] The utility of radiation therapy has been questioned, and its use may be limited to tumors with positive margins, high-grade tumors, and recurrences.[178] The tumor may be embolized preoperatively to minimize blood loss, although many surgeons first use

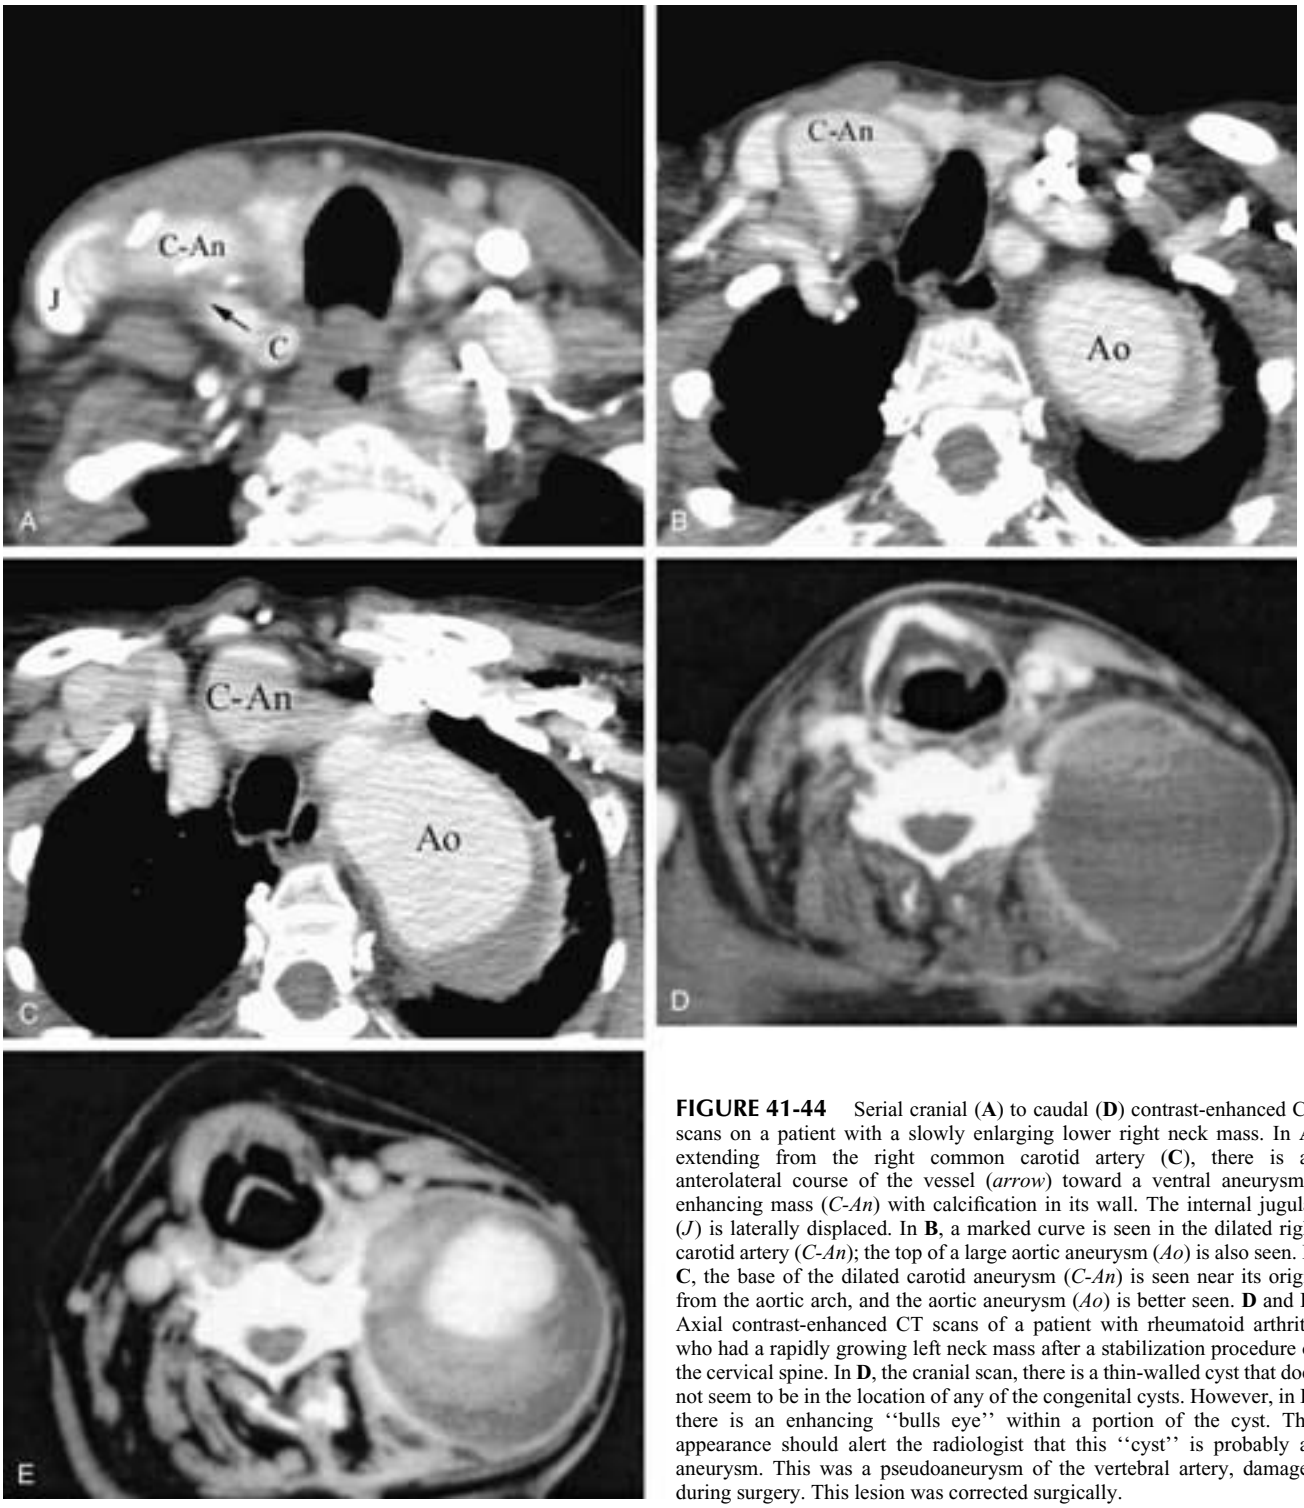

FIGURE 41-44 Serial cranial (**A**) to caudal (**D**) contrast-enhanced CT scans on a patient with a slowly enlarging lower right neck mass. In **A**, extending from the right common carotid artery (**C**), there is an anterolateral course of the vessel (*arrow*) toward a ventral aneurysmal enhancing mass (*C-An*) with calcification in its wall. The internal jugular (*J*) is laterally displaced. In **B**, a marked curve is seen in the dilated right carotid artery (*C-An*); the top of a large aortic aneurysm (*Ao*) is also seen. In **C**, the base of the dilated carotid aneurysm (*C-An*) is seen near its origin from the aortic arch, and the aortic aneurysm (*Ao*) is better seen. **D** and **E**, Axial contrast-enhanced CT scans of a patient with rheumatoid arthritis who had a rapidly growing left neck mass after a stabilization procedure of the cervical spine. In **D**, the cranial scan, there is a thin-walled cyst that does not seem to be in the location of any of the congenital cysts. However, in **E**, there is an enhancing ''bulls eye'' within a portion of the cyst. This appearance should alert the radiologist that this ''cyst'' is probably an aneurysm. This was a pseudoaneurysm of the vertebral artery, damaged during surgery. This lesion was corrected surgically.

embolization with recurrences, when adequate surgical margins may be difficult to obtain.

On imaging, hemangiopericytomas are usually well circumscribed. They have intermediate T1-weighted and increased T2-weighted signal intensities. The tumors enhance well on both CT and MR imaging, and flow voids are commonly seen on MR (Fig. 41-47). Calcification is an unusual feature. Prominent vascularity and tumor blush are seen on angiography. Sonographically, these tumors are well circumscribed and hypoechoic, with half showing sound through-transmission. To date, there are no reliable criteria to exclude malignancy; thus, all hemangiopericytomas should be considered potentially malignant.

PERIPHERAL NERVE SHEATH TUMORS

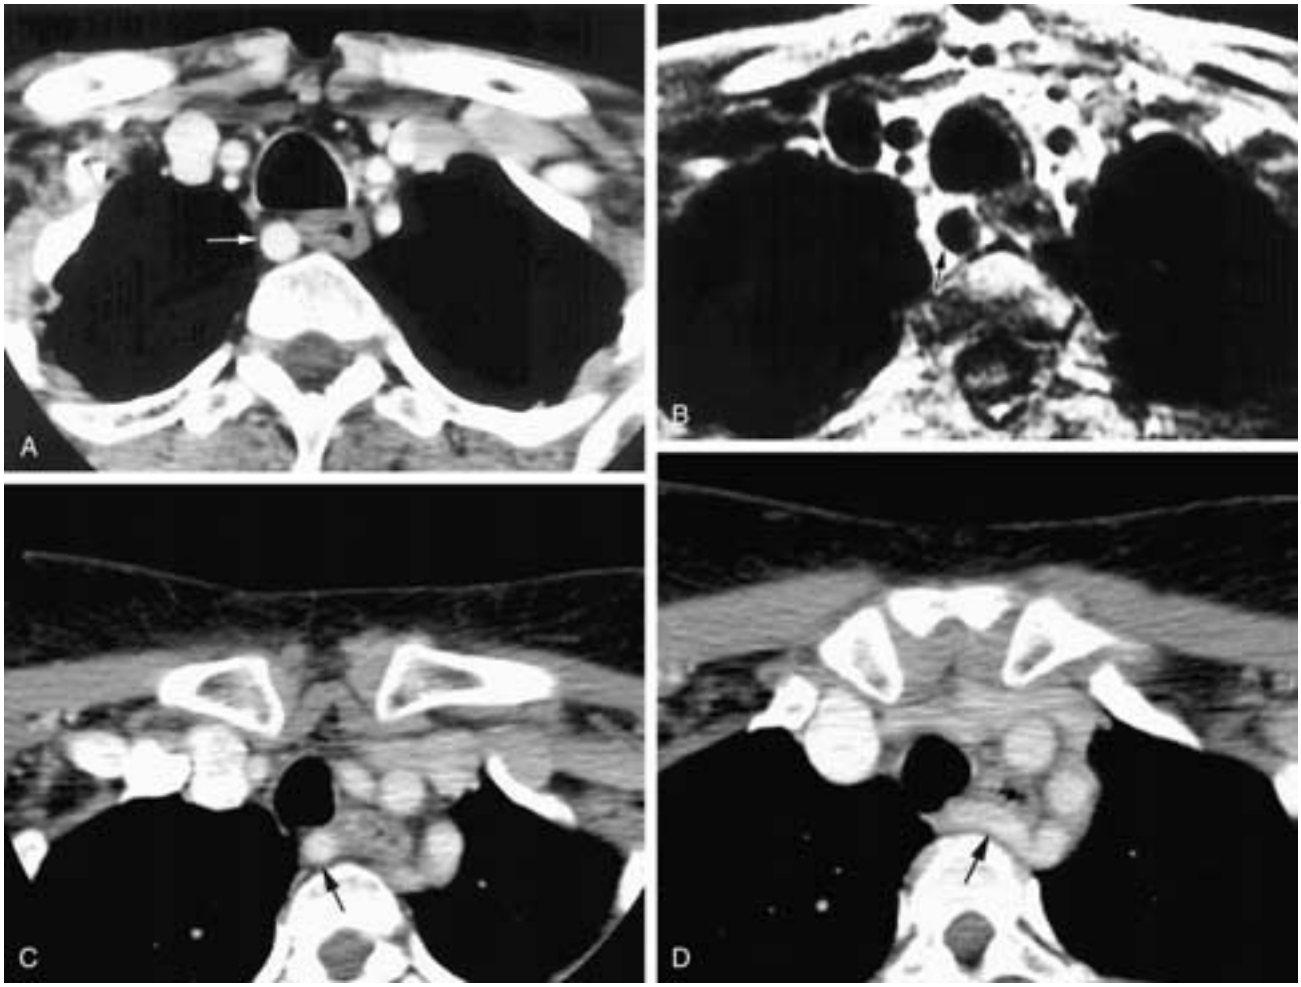
Peripheral nerve sheath tumors may be either benign or malignant. The benign lesions are either schwannomas or neurofibromas, and the neurofibromas may be solitary, multiple, or plexiform. The latter two varieties are usually associated with von Recklinghausen's disease. Malignant schwannoma, or malignant peripheral nerve sheath tumors, may occur spontaneously or arise from a neurofibroma or plexiform neurofibroma. Malignant transformation of a schwannoma is very rare.[179]

Schwannomas may arise from any nerve that contains Schwann cells and, with the exception of cranial nerves I and II, can occur in any cranial nerve, autonomic nerve, or peripheral nerve. The imaging of these lesions is discussed in various chapters throughout the book.

PHARYNGOESOPHAGEAL LESIONS

Zenker's Diverticulum

A Zenker's diverticulum is an outpouching lined by mucosa that extends through Killian's dehiscence, which



VIEW IMAGE

FIGURE 41-45 Axial contrast-enhanced CT scan (**A**) through the lower neck shows an aberrant right subclavian artery (*arrow*) adjacent to the cervical esophagus. A corresponding axial T1-weighted MR image (**B**) shows the aberrant artery (*arrow*). Cranial (**C**) and caudal (**D**) contrast-enhanced CT scans on another patient show an aberrant right subclavian artery (*arrows*) extending behind the cervical esophagus.

is above the cricopharyngeus muscle and below the caudal oblique fibers of the inferior pharyngeal constrictor. The diverticulum typically projects posterolaterally from the lumen, and dyssynergy of the cricopharyngeus muscle may play a role in its formation. The diagnosis is readily made on a barium swallow and, rarely, a large Zenker's diverticulum may be apparent on a CT scan (Fig. 41-48).

Dilated/Obstructed Cervical Esophagus

On rare occasions, a dilated cervical esophagus can present as a low neck mass, often clinically mimicking a thyroid mass (Fig. 41-49). Patients may not offer a history relating to esophageal dysfunction, or they may complain of weight loss, heartburn, or a sensation of fullness. Causes of a dilated cervical esophagus include achalasia, esophageal tumor, strictures, and, in the older patient, presbyesophagus.[180–185]

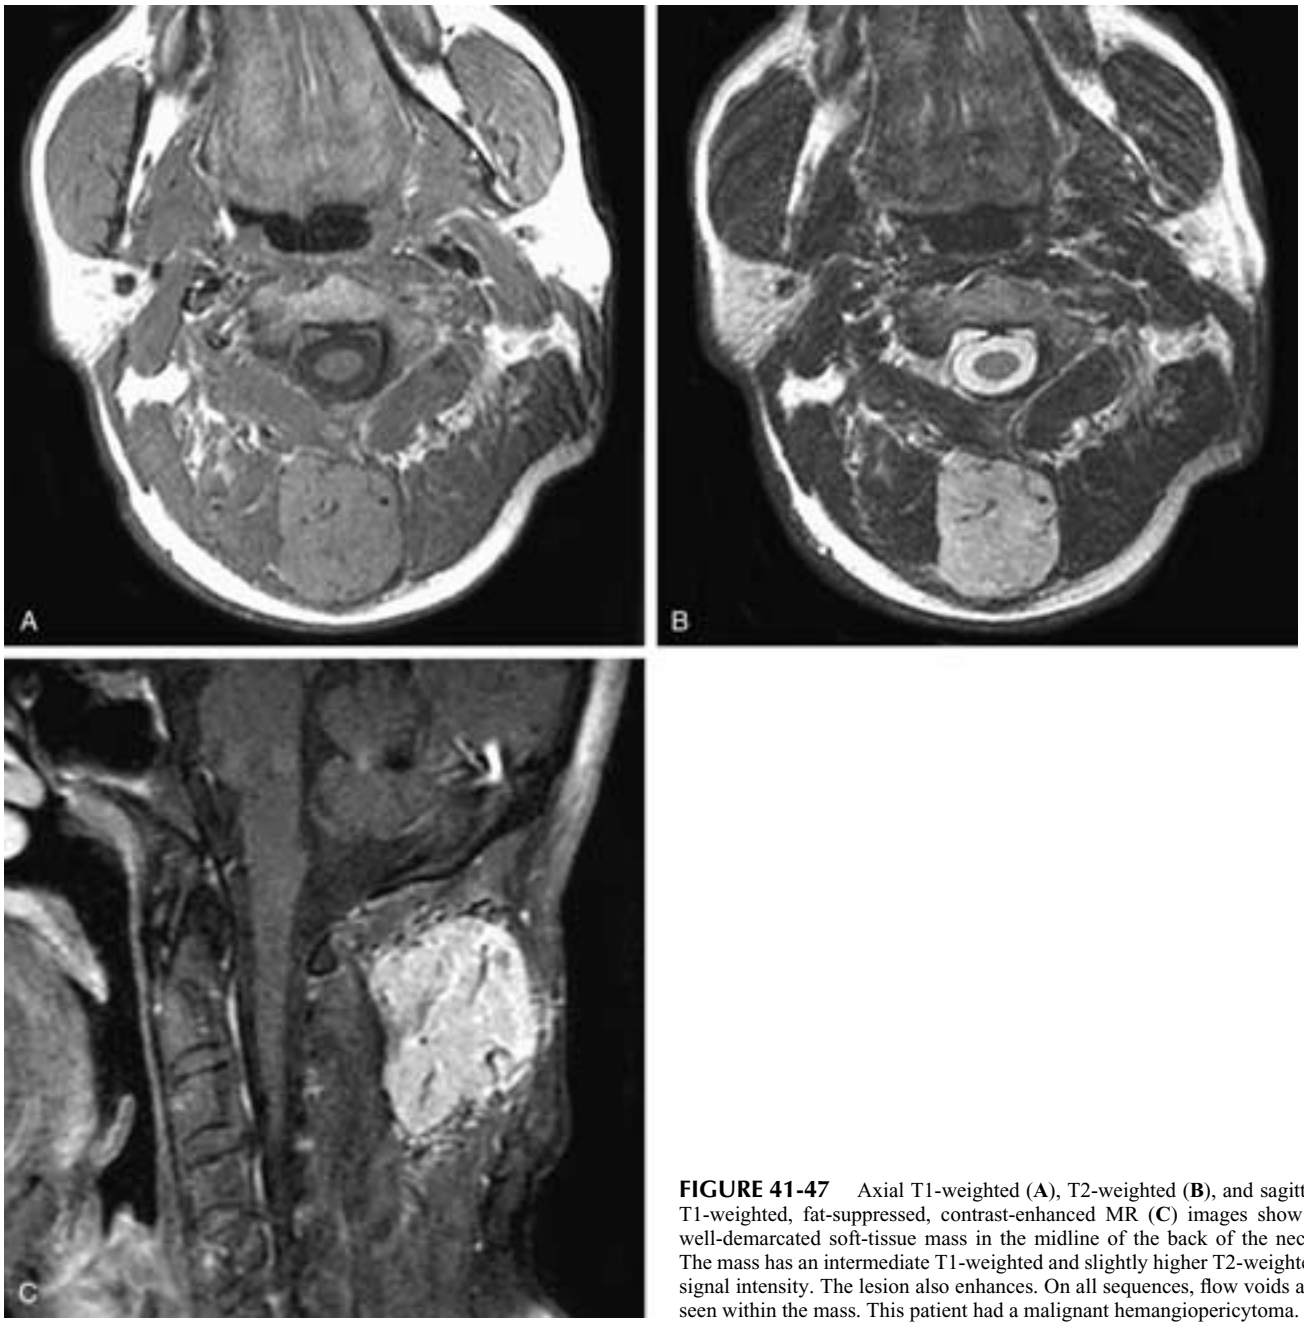

FIGURE 41-47 Axial T1-weighted (**A**), T2-weighted (**B**), and sagittal T1-weighted, fat-suppressed, contrast-enhanced MR (**C**) images show a well-demarcated soft-tissue mass in the midline of the back of the neck. The mass has an intermediate T1-weighted and slightly higher T2-weighted signal intensity. The lesion also enhances. On all sequences, flow voids are seen within the mass. This patient had a malignant hemangiopericytoma.

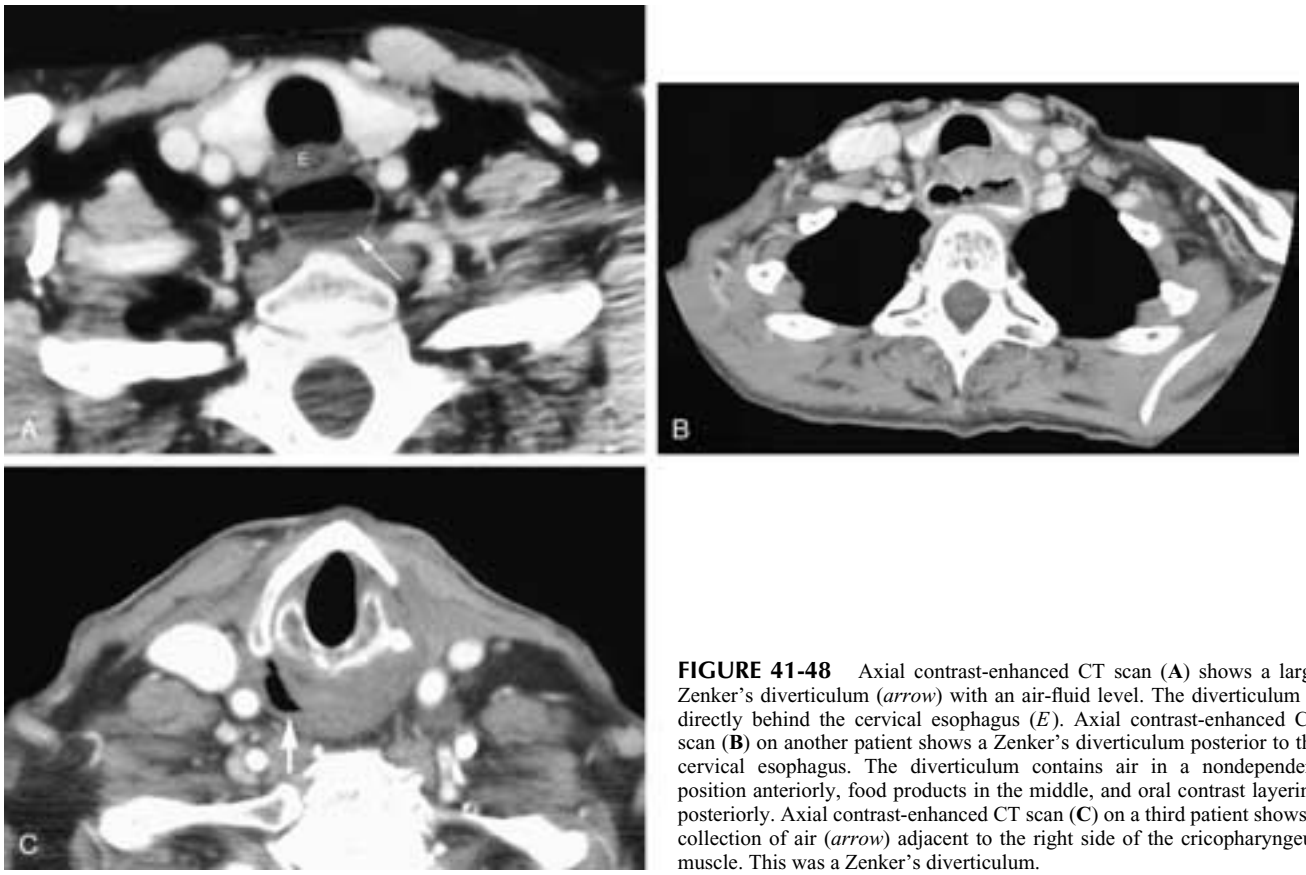

FIGURE 41-48 Axial contrast-enhanced CT scan (**A**) shows a large Zenker's diverticulum (*arrow*) with an air-fluid level. The diverticulum is directly behind the cervical esophagus (*E*). Axial contrast-enhanced CT scan (**B**) on another patient shows a Zenker's diverticulum posterior to the cervical esophagus. The diverticulum contains air in a nondependent position anteriorly, food products in the middle, and oral contrast layering posteriorly. Axial contrast-enhanced CT scan (**C**) on a third patient shows a collection of air (*arrow*) adjacent to the right side of the cricopharyngeus muscle. This was a Zenker's diverticulum.

INTRODUCTION
BRACHIAL PLEXUS
Normal Anatomy
Imaging Strategies
Clinical Findings
BRACHIAL PLEXOPATHIES
VAGUS NERVE
PHRENIC NERVE

INTRODUCTION

The thoracic inlet or root of the neck is a narrow space that serves as the junction between the neck and the thorax.[10, 18, 26, 29, 36] This space is widest in the transverse plane. Its boundaries are the manubrium anteriorly, the first thoracic vertebra posteriorly, and on either side, the first rib laterally. This area is delineated further by Sibson's fascia, which extends on either side of the neck from the transverse process of the seventh cervical vertebra posteriorly to the medial border of the first rib. Since the first rib slants caudally as it extends anteriorly, this fascia's posterior attachment to the rib is more cranial than its anterior aspect. Thus, the plane of the thoracic inlet is tilted downward anteriorly and laterally on either side, being highest medially and posteriorly. Because of this orientation, when viewed in the sagittal plane, the lung apices are seen posteriorly and the structures at the base of the neck are located anteriorly. On axial images the apices of the lungs are located in the posterior lateral aspect of the thoracic inlet, and the major visceral structures, which pass between the neck and the thoracic inlet, are located anteriorly between the lungs. The major structures found in the thoracic inlet are listed in Table 42-1.

The anterior scalene muscle is the key reference point used to locate the major neural and vascular structures in the region. This muscle originates from the anterior tubercles of the fourth through sixth cervical vertebrae and extends downward and laterally to insert on the superior aspect of the first rib on the scalene tubercle and ridge.

The subclavian vein is located anterior to the anterior scalene muscle. The anterior scalene muscle divides the subclavian artery into three anatomic portions. The first portion is found medial to the anterior scalene muscle as the artery crosses the apex of the lung superficial to the subpleural membrane. The second portion of the artery is directly posterior to the anterior scalene muscle, and the third portion is lateral to this muscle. The ansa subclavia (a connection between the middle and inferior (or stellate) sympathetic ganglia looping around the subclavian artery), phrenic nerve, and vagus nerve cross the thoracic inlet anterior to the first portion of the subclavian artery (Fig. 42-1). As they cross the inlet, the phrenic nerve is located laterally and the vagus nerve medially; between these nerves is the ansa subclavia. Components of the brachial plexus are found directly posterior or superior to all three portions of the subclavian artery. Also located posterior to the subclavian artery are some of the components of the cervical sympathetic chain.[5, 24, 30, 32, 47]

An understanding of this region is imperative for those who interpret cross-sectional images of the neck and chest, and knowledge of the location of the neural structures that traverse this region is important when looking for lesions that produce palsies of these nerves and when predicting what nerves will be affected by a mass in this region of the neck.

BRACHIAL PLEXUS

Normal Anatomy

The brachial plexus provides sensory and motor innervation to the upper extremity. It is formed by the ventral rami of C5-T1 with occasional contributions from C4 and T2. These roots join to form trunks, divisions, cords, and subsequently peripheral nerves (Fig. 42-2). Although the anatomic communication among these structures is complex, the components of the brachial plexus have a constant relationship to structures that are readily identified on both CT and MR imaging. The direct visualization of these nerves is accomplished more often with MR imaging than

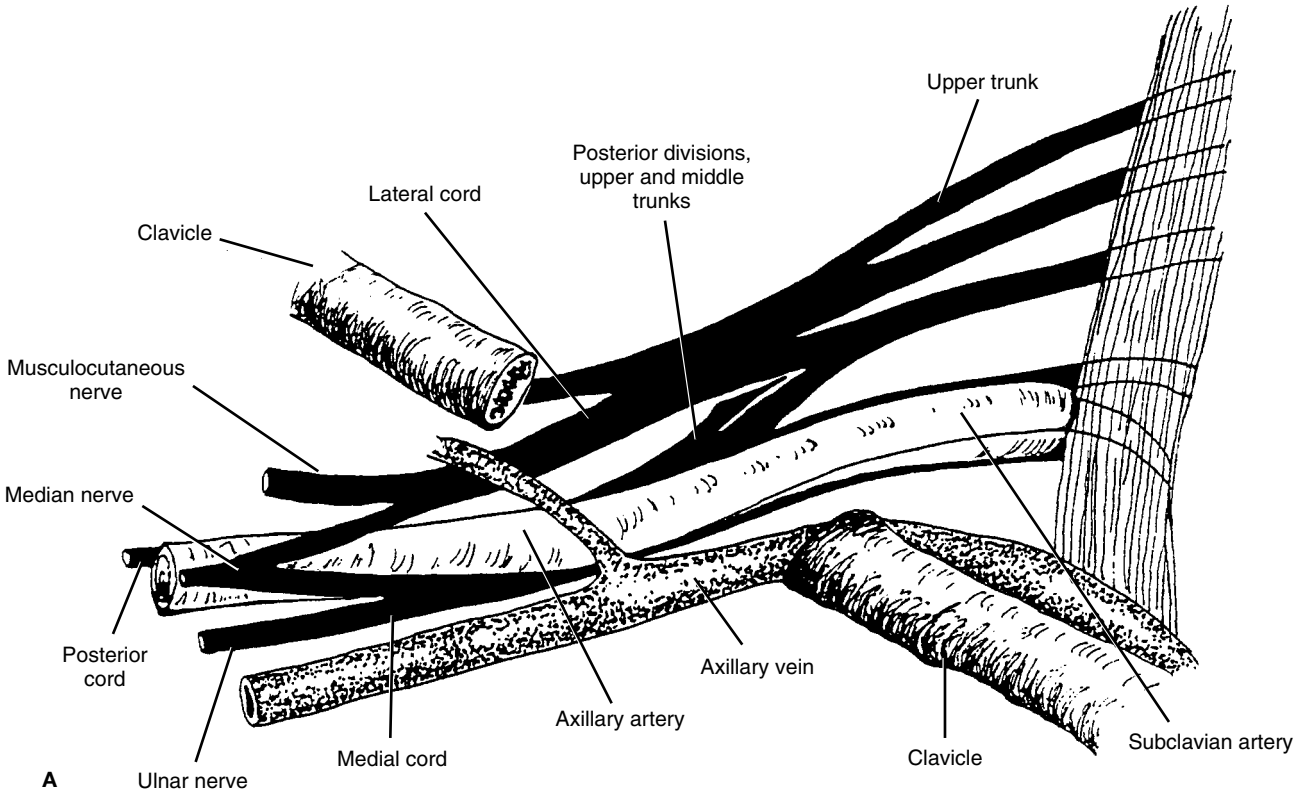
VIEW IMAGE

with CT. Since these nerves are not routinely identified on conventional studies with either of these imaging modalities, one needs to be familiar with the location of the components of the brachial plexus and knowledgeable about specific imaging studies if cross-sectional imaging is to be used to evaluate patients with brachial plexopathies.

Due to the lordotic curvature of the spine, the more superior nerve roots are located anterior to the inferior nerve roots, and the cervical nerve roots in the upper neck are located posteromedially, adjacent to the neural foramina. The superior nerve roots run inferiorly, laterally, and anteriorly to pass between the anterior and middle scalene muscles (Fig. 42-3). Nerve roots C5 and C6 unite adjacent to the lateral border of the anterior scalene muscle to form the upper trunk of the brachial plexus, whereas the C7 nerve root travels by itself as the middle trunk. In the lower neck, the C8 and T1 nerves join behind the anterior scalene muscle to form the lower trunk (Fig. 42-4). Each trunk has an anterior and a posterior division. The divisions of the



VIEW IMAGE

FIGURE 42-4 Lower trunk of the brachial plexus. Axial CT scan (**A**) and axial MR image (**B**) obtained at the level of the thoracic inlet show the T1 nerve root (*arrow*) on either side traveling medial to the lung apex to join nerve root C8 behind the subclavian artery (*A*). Note that the anterior scalene muscle (*S*) is anterior to the artery at this level.

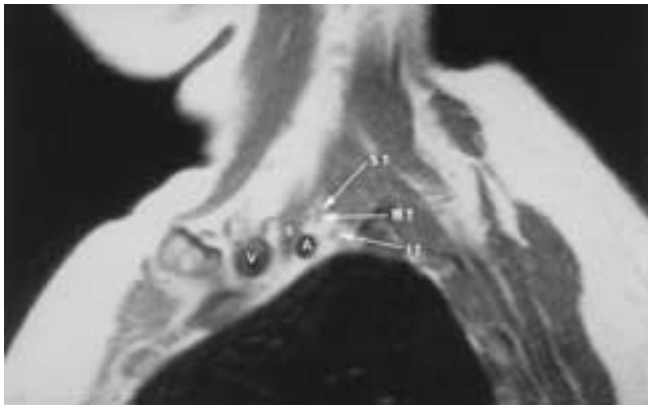
superior and middle trunks form at or after the nerves pass lateral to the anterior scalene muscle. The divisions of the lower trunk are formed at or after the nerves cross the first rib (behind the clavicle or in the axilla). These components of the brachial plexus are found slightly above (superior and middle trunks) and directly posterior (inferior trunk) to the subclavian artery (Fig. 42-5).

Three cords are formed from the divisions:

1. The lateral cord is formed by the anterior divisions of the upper and middle trunks, which unite in the lower neck (i.e., the anterior divisions of nerves C5, C6, and C7).
2. The median cord is derived from the anterior division of the lower trunk in the lower neck (i.e., nerves C8 and T1).
3. The posterior cord is formed by the posterior divisions of all three trunks in the axilla (it has components of all of the nerves that form the brachial plexus).

These three cords enter the axilla by traveling between the clavicle and the first rib. Here they are found in the axillary sheath (a continuation of Sibson's fascia, a part of the deep layer of the deep cervical fascia) adjacent to the axillary artery and vein. After traveling a short distance in the axilla, the cords form peripheral nerves, lateral to the lateral margin of the pectoralis minor muscle. These nerves surround the axillary artery (Fig. 42-6). The peripheral nerves that originate from the cords of the brachial plexus are listed in Table 42-2.

Like the subclavian artery, the axillary artery is divided into three parts by a muscle. In this instance, it is the pectoralis muscle that crosses the axillary artery and divides it into three parts: the first part is medial, the second part is behind, and the third part is lateral to this muscle. The anatomic relationships of the nerves to the various parts of the axillary artery are listed in Table 42-3.[5, 24, 30, 32, 47]



VIEW IMAGE

FIGURE 42-5 Sagittal MR T1-weighted image shows the trunks of the brachial plexus. The superior trunk (*ST*) and middle trunk (*MT*) are posterior superior and the inferior trunk (*IT*) is directly posterior to the subclavian artery (*A*). The subclavian vein (*V*) is anterior to the anterior scalene muscle (*S*).

Imaging Strategies

Although a number of imaging modalities, including plain films of the cervical spine and shoulder girdle, CT, MR imaging, and myelograms, can be used to evaluate patients with brachial plexopathies,[3, 9, 18, 38, 46] MR imaging has become the initial imaging modality of choice because its multiplanar capability allows for easier mapping of the course of the brachial plexus and reliable differentiation of vascular from nonvascular structures without the use of iodinated contrast. However, the initial imaging modality used should be determined by the clinical setting.

Optimal MR imaging of the brachial plexus is best accomplished by the use of phased array-surface coils.[23] Diagnostic-quality images, however, may also be obtained with a body-coil on 1.0 or 1.5 Tesla magnets (Fig. 42-7). One imaging protocol is a coronal localizer scout; sagittal T1-weighted images from the spinal canal to the lateral aspect of the clavicle on the affected side; axial T1-weighted images from the C4 vertebra to the carina, perpendicular to the long axis of the trachea (the field of view [FOV] should include the neck and thorax); oblique coronal T1-weighted images along the course of the distal subclavian and proximal axillary arteries (Fig. 42-8); and a T2-weighted

FIGURE 42-6 Brachial plexus, supraclavicular and axillary regions. Coronal MR image (**A**) shows the components of the brachial plexus in the supraclavicular region and axilla. The nerves surround the axillary artery (*A*). Sagittal MR image (**B**) obtained through the axilla demonstrates the peripheral nerves formed by the brachial plexus surrounding the axillary artery (*A*).

sequence usually in the axial plane. Factors such as slice thickness, slice gap, FOV, and number of acquisitions will vary with the equipment used. Ideally, slice thickness should be no greater than 5 mm, and higher-resolution matrices are recommended.

Rapid spin-echo (SE) or half-Fourier acquisition single shot turbo spin-echo (HASTE) images may be used to decrease scanning time. The effectiveness of routine contrast-enhanced MR imaging of the brachial plexus has yet to be proven. The administration of intravenous contrast may accentuate vascular artifacts and usually requires fat-saturation techniques to best identify subtle nerve enhancement.

An alternate protocol uses a torso coil. This protocol is designed to image in all three planes, and to utilize the ability to compare the involved side with the contralateral side to help define the normal anatomy in each patient and to aid in detection of subtle changes. Imaging starts with a T1-weighted SE coronal localizing sequence (5 mm thickness × 2.5 mm interslice gap, 48 cm FOV). From this localizer are planned the axial T1-weighted, SE and axial T2-weighted fast spin-echo (FSE) sequences with an adequate field to cover both plexi simultaneously (5 × 2.0 mm, 38 cm FOV). Detailed pre- and postgadolinium T1-weighted SE sequences of each plexus are then performed using a smaller FOV (24 cm) in the coronal oblique (4 × 1 mm) and sagittal oblique (5 × 3.0 mm) planes, oriented parallel and perpendicular to the nerves, respectively. Saturation bands are used to minimize artifacts from cardiac pulsation, and fat saturation is used on the postgadolinium sequences to increase lesion conspicuity.

The use of CT for the evaluation of the brachial plexus is largely reserved for patients who cannot undergo diagnostic MR imaging or in whom a biopsy of a mass using CT imaging guidance is contemplated.[11] Contrast should be administered via the asymptomatic arm to avoid obscuring subtle disease adjacent to the axillary or subclavicular veins.

The development of nonincremental (helical, spiral) CT scanners and the newer multidetector CT scanners have greatly improved the CT evaluation of the brachial plexus. A screening examination should be performed with images obtained from the superior aspect of the C4 vertebra to the level of the carina. Placing the arms away from the lateral chest wall facilitates the identification of structures in the axilla and the proximal arm.

A survey examination consisting of images with 5 mm collimation and 4 mm spacing may be obtained using a pitch from 1.2 to 1.4 to 1, depending upon the patient's size. Image data may be targeted retrospectively or manipulated at a workstation for analysis in the sagittal, coronal, and oblique-coronal projections. If such CT scanners are not available, the examination should be performed in two distinct acquisitions, cervical and thoracic, by using appropriate FOVs for each segment.

The sonographic features of the normal brachial plexus have been described. A linear transducer of at least 7.5 MHz is recommended to perform these examinations. The nerve roots are identified by imaging the lower neck in an oblique coronal plane. The trunks can be identified in the supraclavicular fossa when the transducer is positioned at a right angle to the subclavian artery. The cords are identified by scanning in a plane parallel to the axillary artery inferior to the clavicle.[41]

Sonography can be used as a guide in catheter placement for brachial plexus anesthesia.[50] However, the role of sonography in the evaluation of patients with brachial plexopathy has yet to be determined.

Clinical Findings

Brachial plexopathies develop when lesions occur anywhere along the course of the brachial plexus or, in some cases, adjacent to the brachial plexus. Patients with brachial plexopathies may present with pain and with sensory and motor deficits in the upper extremities. Pain, if present, may increase with neck traction, shoulder movement, or deep inspiration. Palpation or percussion in the supraclavicular fossa often elicits tenderness. Occasionally, a mass is palpated in the lower neck or axilla.

Long-term complications of brachial plexopathies include muscle wasting, arm edema, joint contractures, osteoporosis, and degenerative joint disease.[34] Localization of the precise site of involvement based on physical examination may be difficult since several sites of involvement may produce similar signs and symptoms.

Since the nerves that form the brachial plexus cover a wide territory from their point of origin in the spine to the muscles they innervate, an attempt should be made to localize the site of the abnormality (central or peripheral) prior to performing an imaging study. Such information can direct the imaging to a cervical spine examination instead of a brachial plexus study. Electromyography (EMG) may aid in distinguishing a lesion involving the nerve roots (central lesion) from one affecting the brachial plexus. EMG abnormalities in the paraspinal muscles indicate that a lesion is proximal to the plexus trunks, suggesting that there is a central lesion in the epidural space or neural foramen. EMG abnormalities in the peripheral muscles will define which peripheral nerve territories are involved.[37]

Neurologic evaluation of a patient with brachial plexopathy should include a search for other nerve dysfunction, as this may help localize the site of the abnormality. For example, the presence of Horner's syndrome points to involvement of the lower trunk. This is usually secondary to a mass in the lung apex, and chest radiography should be performed in these patients prior to cross-sectional imaging of the brachial plexus. Similarly, the combination of brachial plexopathy and phrenic nerve dysfunction should prompt careful analysis of the upper trunk of the plexus.

A patient questionnaire is useful in obtaining the basic

Copyright © 2003, Mosby, Inc. All rights reserved.

information needed to tailor the cross-sectional examination and to analyze the sectional images. Questions to be asked include:

1. Are symptoms unilateral or bilateral? The presence of bilateral brachial plexopathies is usually associated with a lesion in the epidural space or neural foramina, and these patients should be evaluated initially with a dedicated imaging study of the cervical spine.
2. Is there a history of trauma? These patients often require dedicated sectional imaging studies of the cervical spine to supplement the evaluation of the peripheral components of the plexus.
3. Is there an associated mass in the neck, supraclavicular fossa, or axilla? Characterization of a palpable mass may require the use of double-echo—T2-weighted rather than SE—T2-weighted sequences and the administration of intravenous contrast.
4. Are the symptoms produced by a particular arm position? Hand pain with arm elevation is a common finding with thoracic outlet syndrome secondary to a cervical rib, and identification of a cervical rib on a frontal radiograph should prompt further evaluation of the subclavian and axillary arteries rather than the soft-tissue components of the brachial plexus.
5. Does the patient have a prior history of carcinoma? Studies of patients with a history of malignancy require a careful search for abnormal signal within the trabecular bone of the cervical spine, clavicle, scapula, and shoulder as well as the soft tissues adjacent to the nerves. This is especially important if pain is the only presenting symptom.
6. Is there a history of surgery or radiation therapy to the affected axilla, neck, or supraclavicular fossa? Images of the affected side in these patients are often confusing, and oblique coronal and sagittal imaging of the opposite brachial plexus is often useful for comparison and identification of subtle changes.

BRACHIAL PLEXOPATHIES

Brachial plexopathies have a number of causes, which can be categorized as being either traumatic or nontraumatic. Trauma accounts for approximately 50% of the cases. The traumatic and nontraumatic causes of brachial plexopathy are listed in Tables 42-4 and 42-5, respectively. Posttraumatic injuries, with or without fractures, can cause compression, stretching, or tearing of the nerve roots. In these cases, the upper trunk is most frequently involved and the middle trunk is traumatized infrequently.

The primary concern in patients who have suffered a traumatic injury and who have a brachial plexopathy is whether there is a fracture (cervical spine or clavicle) or an avulsed nerve root, but it should be noted that soft-tissue swelling and/or hematomas in the region of the brachial plexus can produce the same symptoms (Fig. 42-9). If a fracture is suspected, a plain film examination of the area in question should be the initial radiographic study.

Primary neural tumors such as meningiomas and schwannomas
Metastatic disease
Pancoast tumor
Postirradiation injury
Radiculopathy secondary to disk disease
Bony abnormalities such as cervical ribs

Cross-sectional imaging is usually not performed until at least 4 to 6 weeks after a suspected traumatic brachial plexus injury, and the primary goal of the study is to differentiate intraforaminal from extraforaminal causes. Intraforaminal (also know as preganglionic) injuries of the brachial plexus are characterized by a range of abnormalities including traumatic pseudomeningoceles, nerve root avulsions, and, less commonly, spinal cord contusion. The most common of these abnormalities are the traumatic pseudomeningoceles, which are bulges of the arachnoid membrane through a dural tear.[17] Although pseudomeningoceles are commonly associated with a nerve root avulsion, approximately 20% of nerve root avulsions are not associated with pseudomeningoceles.[22]

Extraforaminal (also known as postganglionic) injuries account for as much as one quarter of all cases of traumatic brachial plexopathies. Extraforaminal injuries, which carry a better prognosis than intraforaminal injuries, can be divided into two groups: lesions immediately deep or inferior to the clavicle and lesions distal to the plexus, commonly

involving the terminal branches such as the suprascapular, axillary, or musculocutaneous nerves.[1]

High-resolution CT myelography has been traditionally advocated as the standard of reference for the detection of nerve root avulsion.[46] However, three-dimensional MR imaging has been suggested as a screening examination of the cervical spine.[17] On MR imaging, the absence of the low signal intensity nerve root in the fat of the neural foramen on the T1-weighted images is consistent with a nerve root avulsion, and this is best appreciated on parasagittal images. Increased T2-weighted signal intensity has also been observed in traumatized nerves,[27, 42, 48] and although the cause of the high signal intensity is uncertain, it is believed to be the result of neural edema.[37] Small pseudomeningoceles appear as an extra-arachnoid CSF intensity mass extending outside the spinal canal, and axial and coronal scans offer the best visualization of such lesions (Fig. 42-10). Increased signal intensity in the posterior cervical paraspinal muscles on T2-weighted or T2*-weighted images has also been reported as a reliable indicator of nerve root avulsion; however, the absence of such increased signal on MR studies does not imply nerve root integrity.[44] Because neither CT myelography nor MR imaging has 100% sensitivity or specificity for depicting nerve root avulsion, intraoperative neurophysiologic testing is an essential component of surgical attempts to repair the plexus.[13]

MR imaging is useful for the detection of extraforaminal lesions that are amenable to neurolysis or nerve grafting. Posttraumatic neuromas are identified on T1-weighted images as irregular areas of plexus thickening, largely isointense to skeletal muscle (Figs. 42-11 and 42-12). Neuromas have a marked increase in signal intensity on T2-weighted or short time inversion recovery (STIR) images. STIR images are also useful in identifying injury in cases in which a neuroma cannot be identified. Edema or other inflammatory responses in the tissues adjacent to the plexus appear as areas of abnormally increased signal intensity.[35]

Obstetric brachial plexus palsy occurs as the result of extreme lateral traction on the head during the last phase of delivery, with resulting stretching of the brachial plexus. The traction is exerted via the shoulder in delivering the head in a breech delivery and via the head in delivering the shoulder in a cephalic delivery. The upper roots are most vulnerable, although total paralysis can occur. *Erb's palsy*, a term erroneously thought synonymous with *obstetric brachial plexus palsy*, is but one type of brachial plexus injury characteristically involving the fifth and sixth cervical roots. In this palsy, there is weakness of shoulder abduction, external rotation, flexion and supination of the elbow, and extension of the wrist and fingers. This results in the characteristic ''waiter's tip'' posture. As with adult traumatic plexopathy, there is no role for sectional imaging in the acute phase of the injury, and many infants recover with no or minor residual functional impairment.[7]

At a number of institutions MR imaging has replaced CT myelography, which requires a lumbar puncture, iodinated contrast material, ionizing radiation, and general anesthesia for the evaluation of persistent obstetric brachial plexopathy. A combination of high-resolution MR imaging and intraoperative neurophysiologic testing is adequate for the evaluation and surgical planning of obstetric plexopathy.

A suggested imaging protocol usually requires sedation of the infant. The examination is performed on a 1.5 Tesla MR scanner with the infant in the head coil. For evaluation of potential intraforaminal abnormalities, thin-slice (2 to 3 mm) rapid SE T2-weighted imaging is used, rather than the axial T2*-weighted imaging used in adult cervical spine imaging. The evaluation for potential extraforaminal lesions consists of axial STIR and oblique coronal high-resolution T2-weighted images. T1-weighted images are obtained only when the high-resolution T2-weighted images provide insufficient anatomic detail. Since posterior glenohumeral

dislocations are common in obstetric trauma, axial and oblique coronal images are obtained by using an FOV large enough to include the shoulder.

The MR evaluation of patients with posttraumatic brachial plexopathy should focus on certain specific findings. Analysis of the central spinal axis should focus more on the integrity of the nerve roots than on the identification of pseudomeningoceles. Matted or lobulated nerve roots should prompt an analysis of the spinal cord for evidence of posttraumatic changes. Extraforaminal abnormalities, particularly suspected posttraumatic neuromas, should be localized with respect to both the clavicle and the acromion process of the scapula to facilitate identification at surgery. This will aid in making decisions regarding the surgical approach. Lesions located above the clavicle (involving the roots and trunks) can usually be treated via a supraclavicular approach. The divisions of the brachial plexus are retroclavicular in location, and the cords are infraclavicular.

The analysis of sectional imaging studies in cases of nontraumatic brachial plexopathy should be a two-step process. First, one should identify any mass lesion(s) involving the plexus. The most common masses compromising the plexus are metastatic tumors, neural tumors, and extrathoracic extension of primary lung neoplasms (Pancoast tumors). Second, an analysis of the contour and signal characteristics of plexus components should be performed. Inflammatory processes such as radiation-induced brachial plexopathy, infectious brachial neuritis, or postsurgery-related brachial neuritis commonly present as abnormalities of plexus contour and signal intensity (Fig. 42-13).

Common conditions such as cervical disk disease should

be ruled out before undertaking expensive and extensive radiologic evaluations. From 80% to 90% of cervical radiculopathy secondary to disk disease occurs at the C5-C6 (C6 root) and C6-C7 (C7 root) levels, and the clinical symptoms produced by disk and degenerative disease at these levels may mimic those seen in other causes of brachial plexopathy. These patients often present with pain, numbness, and sensory deficit in the upper extremity, and the upper extremity reflexes may be absent or decreased (biceps, triceps, and radioperiosteal [brachioradial] jerks). Coughing, sneezing, or lateral head movement often exacerbates the pain and causes it to radiate into the ipsilateral upper extremity, and the ipsilateral paraspinal muscles are often tender when palpated.[20, 43]

With nontraumatic cases, an attempt should be made to determine if the plexopathy is idiopathic, since this is a benign, self-limiting condition that usually resolves within 3 years. However, the most common cause of nontraumatic brachial plexopathy is metastatic disease, and a mass should be suspected as the cause of a brachial plexopathy if Horner's syndrome, lower plexus symptoms, and/or a history of a neoplasm are present.

Metastatic disease involving the plexus is usually secondary to extracapsular tumor extension of nodal metastases in the axilla, supraclavicular fossa, or scalene nodes (Figs. 42-14 and 42-15). A wide variety of carcinomas, including breast, lung, gastrointestinal, thyroid, and head and neck carcinomas may metastasize to these nodes.[34] The signal characteristics of metastatic nodes are typically nonspecific, appearing isointense or mildly hyperintense to skeletal muscle on T1-weighted images and moderately hyperintense to skeletal muscle on T2-weighted images (see Chapter 36).[25] Extracapsular extension of nodal metastases is often manifested as nodes with spiculated or indistinct margins, and this extracapsular disease is visible more often on CT than on MR studies.

Primary neural tumors involving the brachial plexus are rare and consist of neurofibromas, schwannomas, and malignant peripheral nerve sheath tumors (malignant schwannomas).[12, 31, 40] Benign lesions are more common, and neurofibromas are more common than schwannomas. In two studies, only 14% of the neural tumors in this region were malignant.[13, 31] The majority of neurofibromas affecting the brachial plexus are sporadic; only one third occur in association with neurofibromatosis type I.

The imaging characteristic of neural tumors on CT and MR imaging have been well described in the literature, and it has been shown that it is impossible to distinguish a neurofibroma from a schwannoma based on imaging characteristics.[34] The internal architecture and degree of contrast enhancement are subject to a wide range of variation on both CT and MR imaging. Regardless of their internal appearance, all benign tumors appear smoothly marginated and well encapsulated on sectional imaging studies.

Patients with known neoplasms who have had previous radiation therapy may develop brachial plexopathies, which are secondary to either recurrent disease or radiation fibrosis. A study of 100 such cases showed that the clinical findings in these two entities were different. Radiation fibrosis is unlikely to occur with doses of less than 60 Gy. If neurologic symptoms occur in less than a year after a dose of 60 Gy or more, radiation damage is the most likely diagnosis. If the symptoms occur after a year, the plexopathy may be secondary to tumor recurrence or radiation damage.

FIGURE 42-16 Radiation fibrosis. Status postradiation therapy for breast cancer. T1-weighted (**A**) and T2-weighted fat-suppressed (**B**) coronal MR images demonstrate a sharply marginated area of thickening adjacent to the brachial plexus (*arrows*). This area is isointense to muscle on both sequences.

Pain and weakness in the distribution of the lower plexus and Horner's syndrome suggest metastatic disease. Patients with postradiation plexopathy usually have painless weakness of the shoulder abductors and arm flexors as well as lymphedema.[28]

MR imaging can be used to distinguish between radiation fibrosis and recurrent disease. Radiation fibrosis has a signal intensity similar to that of muscle on T1-weighted and T2-weighted sequences;[19] that is, fibrous tissue has a long T1-weighted and a short T2-weighted relaxation time.[15] Although tumor and fibrosis may have a similar appearance on T1-weighted sequences, their signal intensities are different on T2-weighted sequences, with tumor being hyperintense to muscle and radiation fibrosis being isointense to muscle (Fig. 42-16). It should be noted that hemorrhage and infection may produce high signal intensity T2-weighted images and thus may simulate tumor recurrence. Immature radiation fibrosis may mimic recurrent disease. In some cases, correlation of sectional imaging with function imaging studies or tumor antibody titers may be required to obviate biopsy.

Brachial neuritis, whether infectious, postradiation, or idiopathic, is often a self-limited condition. Sectional imaging in these patients is usually deferred until 2 to 3 months after the onset of symptoms. In cases of brachial neuritis, the plexus components appear diffusely thickened on T1-weighted images, often without the indistinct contour seen in cases of radiation fibrosis. The components also may have abnormally increased signal intensity on T2-weighted or contrast-enhanced T1-weighted images.[33]

In 1932 Henry Pancoast described a clinical syndrome associated with tumors in the lung apex. This syndrome (Pancoast's syndrome) consists of a constellation of signs and symptoms that include shoulder and arm pain in the distribution of the C8, T1, and T2 nerve roots, Horner's syndrome, and atrophy of the hand muscles. Horner's syndrome is the clinical triad of ipsilateral ptosis, miosis, and anhydrosis. This syndrome, when seen in conjunction with a tumor in the lung apex, is caused by invasion of the prevertebral sympathetic chain or the inferior or stellate ganglion.[2, 4, 13, 14, 16] The inferior cervical and first thoracic sympathetic ganglia are fused in 80% of patients, and when this occurs, the resultant ganglion is called the stellate ganglion.

Most cases of Pancoast's syndrome are caused by a non-small cell bronchogenic carcinoma; squamous cell carcinoma is the most common, followed by adenocarcinoma and large cell carcinoma. Other etiologies of this syndrome include lymphoma, plasmacytoma, and infection.[2]

Pancoast tumors at the time of presentation are usually T3 lesions because of their involvement of the chest wall. These tumors are classified as T4 lesions when there is involvement of the brachial plexus, mediastinal structures or vertebrae. Staging for lymph node involvement and distant metastasis is the same as that used for non-small cell carcinoma in other locations in the lung. The presence of lymph node involvement or distant metastases usually eliminates surgery as a treatment option.

A Pancoast tumor should be ruled out whenever unilateral apical pleura thickening or asymmetric thickening greater than 5 mm is noted on a chest radiograph.[16] CT or MR imaging can be used to evaluate patients with these findings, as both imaging modalities can detect the presence and extent of tumor. However, MR imaging is presently superior for the detection of brachial plexus and chest wall involvement (Figs. 42-17 and 42-18), although with the use of spiral and multidetector machines, CT with multiplanar reformatted images may become comparable to MR imaging.

Although either CT or MR imaging can be used to evaluate patients in the nontraumatic category of brachial plexopathy,[1, 5, 7, 14, 23] MR imaging is the imaging modality of choice because of its ability to visualize nerves and blood vessels directly, its relative lack of artifact, and its multiplanar imaging capabilities. One of the major disadvantages of CT in the evaluation of the lower neck is that only direct axial images can be obtained routinely. Additionally, beam-hardening artifacts are encountered at the level of the thoracic inlet, and contrast administration is required to visualize blood vessels. But, regardless of which of these imaging modalities is used, knowledge of the location of the components of the brachial plexus is

necessary to diagnose a mass or an anatomic alteration that is likely to be the cause of a brachial plexopathy. To achieve this goal, the following discussion covers examples of lesions along the course of the brachial plexus as seen on both CT and MR imaging.

The most common causes of disease in the region of the nerve roots are neural tumors (whose point of origin in the neural foramen or spinal canal can often be identified), posttraumatic injuries, and metastatic disease. Since the nerve roots pass between the anterior and middle scalene muscles, they may also be affected by lesions in this region (Figs. 42-19 and 42-20). Although axial CT and MR imaging are ideal for the evaluation of this region, coronal and sagittal images may also be advantageous, with sagittal images being particularly useful when assessing an absent nerve root (avulsion) in the neural foramen.

Lesions involving the trunks and divisions of the brachial plexus occur in the posterior triangle of the neck lateral to the anterior scalene muscle, and in the supraclavicular and retroclavicular regions. Metastatic disease and Pancoast tumors are primarily encountered in this region. Occasionally, neural tumors are seen in the supraclavicular region and near the apex of the lung. These tumors tend to be well circumscribed and have a sharp interface with adjacent structures (Fig. 42-21). By comparison, metastatic disease and primary neoplasms tend to have irregular infiltrating borders (Figs. 42-22 to 42-24). Lesions in the supraclavicular region and thoracic inlet may produce Horner's syndrome, either by direct invasion of the sympathetic chain, which is located anterior to the prevertebral muscles (Fig. 42-25), or by involving the ansa subclavia as it loops around the first portion of the subclavian artery.

The cords and proximal portions of the peripheral nerves formed by the brachial plexus are located in the axilla, where they are found adjacent to the axillary artery. Thus, a lesion that abuts the axillary artery anywhere in the axilla may produce brachial plexus symptoms (Fig. 42-26). Metastatic disease is commonly encountered in this region (Fig. 42-27). Primary neural tumors (Fig. 42-28) and soft-tissue tumors, as well as trauma, may affect the brachial plexus in this area.

VIEW IMAGE

The bones of the cervical spine, shoulder, and thoracic inlet should be evaluated in patients with brachial plexopathy. Alterations in the bony anatomy in the lower neck and thoracic inlet, such as cervical ribs or lesions of the first rib and clavicle, may impinge on the nerves, and this may lead to the development of brachial plexus symptoms. Alternatively, primary bone lesions of the shoulder may produce symptoms that mimic those seen in brachial plexopathies (Figs. 42-29 and 42-30).

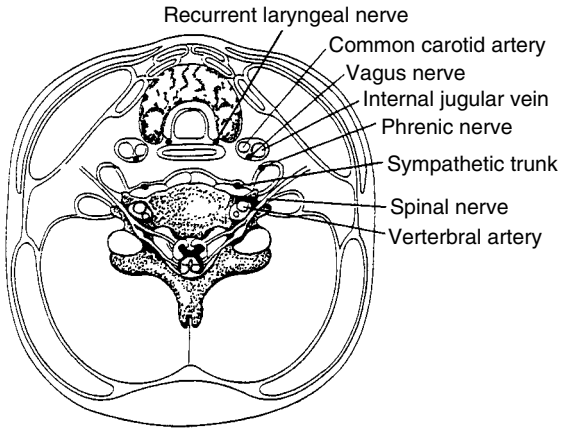

FIGURE 42-25 Cross-sectional diagram showing the location of the major nerves in the neck.

VIEW IMAGE

Cervical ribs are seen in approximately 1% of the population, are symptomatic in only 10%, are unilateral in 50% to 80%, and are twice as common in females as in males.[24] These ribs vary in length and may be connected to the first rib by a fibrous band.

Cervical ribs may affect the nerves of the brachial plexus in one of two ways. First, the cervical rib may narrow the space between the posterior aspect of the first rib and the anterior scalene muscle through which the nerves and subclavian artery must pass en route to the axilla. Second, the cervical rib may be situated such that a portion of the brachial plexus must pass over it in order to enter the axilla. In the latter situation, the lower plexus trunk rests against the top of the cervical rib.[24] If the lower trunk is stretched as it crosses the cervical rib, or if the fibrous band that attaches the cervical rib to the first rib abuts the trunk, symptoms may develop. This is called the cervical rib syndrome, and it is seen primarily in females. Sensory symptoms, either pain or paresthesias, usually antedate motor involvement and occur along the ulnar border of the forearm and hand. Muscle weakness and wasting are seen primarily in the thenar eminence. In long-standing cases, there is generalized wasting of the small hand muscles.[37]

VAGUS NERVE

The vagus nerve has the longest course of all the cranial nerves, and portions of this nerve can be found extending from the brainstem to the abdomen. This nerve originates from four nuclei in the medulla. Nerve fibers from three of these nuclei—the dorsal vagal nucleus, the nucleus solitarius, and the spinal nucleus of the trigeminal nerve—emerge as rootlets from the medulla, below the glossopharyngeal nerve in the retro-olivary sulcus between the olive and the inferior cerebellar peduncle. These rootlets converge in the basal cistern to form a single nerve that exits from the skull through the jugular foramen. There are two sensory ganglia of the vagus nerve. The superior (jugular) ganglion is situated within the jugular fossa, and the inferior (nodose) ganglion is situated just caudal to the jugular foramen. Fibers from the nucleus ambiguus that travel with the spinal accessory nerve for a short distance join the vagus nerve after the nerve passes below the inferior ganglion.

In the neck, the vagus nerve is located in the posterior aspect of the carotid sheath between the carotid artery (medially) and the internal jugular vein (laterally) (Fig. 42-25). There are three major branches of the vagus nerve in the neck; the pharyngeal branch, the superior laryngeal nerve, and the recurrent laryngeal nerve.

The pharyngeal branch is formed on the superior aspect of the inferior ganglion of the vagus nerve and consists primarily of fibers from the spinal accessory nerve. It travels

FIGURE 42-27 Metastatic breast carcinoma. Axial (**A**) and coronal (**B**) T1-weighted MR images show a mass in the right axilla that surrounds the axillary artery. Note the increased signal in the muscles of the right shoulder girdle. This is consistent with denervation atrophy.

between the internal and external carotid arteries to the superior border of the middle constrictor muscle. There it divides into numerous branches that join branches of the sympathetic trunk, glossopharyngeal nerves, and external laryngeal nerves to form the pharyngeal plexus. This plexus is the principal motor supply to the muscles of the pharynx and the levator veli palatini muscles.

The superior laryngeal nerve originates from the inferior ganglion of the vagus nerve, caudal to the pharyngeal branch. It also receives branches from the superior cervical ganglion of the sympathetic trunk. It descends adjacent to the pharynx, and at the level of the hyoid bone divides into the external (motor) and internal (sensory) laryngeal nerves. The external laryngeal nerve (branch) of the superior laryngeal nerve sends motor fibers to the inferior constrictor and cricothyroid muscles. It also has branches that join the pharyngeal plexus and the superior cardiac nerves. The internal laryngeal nerve (branch) of the superior laryngeal nerve enters the larynx via the thyrohyoid membrane and gives the sensory supply to the mucous membranes of the hypopharynx and larynx.

The points of origin of the left and right recurrent laryngeal nerves differ. On the right side, the recurrent laryngeal nerve arises from the vagus nerve below the level

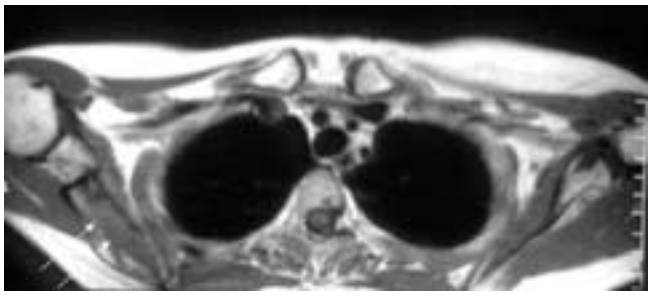
of the subclavian artery at the level of the thoracic inlet. The right recurrent laryngeal nerve loops under the artery to lie on its posterior surface, and then travels superiorly in the tracheoesophageal sulcus (Fig. 42-31) en route to the larynx, where it enters the larynx above the cricothyroid articulation. On the left side, the recurrent laryngeal nerve arises from the vagus nerve in the mediastinum after the nerve crosses the aortic arch anterolaterally. The left recurrent laryngeal nerve then loops under the aortic arch, traveling between the aorta and the left pulmonary artery in the aortic pulmonic window, extends posteriorly to reach the tracheoesophageal sulcus, and then ascends in this sulcus to enter the larynx above the cricothyroid joint. Because the left recurrent laryngeal nerve has an intrathoracic course, it is susceptible to damage from mediastinal pathology as well as from disease in the neck.[8, 24, 30, 32, 47]



VIEW IMAGE

The list of causes of recurrent laryngeal palsy is lengthy and includes broad categories of disease such as inflammatory neuropathies, neoplasms of the neck and chest, trauma, cardiovascular disease (aortic aneurysm and left atrial enlargement), Parkinson's disease, and idiopathic disorders. The nerve paralysis may be acute or chronic; in either case, the patient will have hoarseness and vocal cord paralysis.

An acute unilateral recurrent laryngeal nerve paralysis is often idiopathic, secondary to a toxic or infectious condition or the result of trauma. Most of these patients recover complete vocal cord function, especially when the cause is inflammatory or idiopathic, in which over 80% of the patients recover spontaneously within 6 months of the onset of paralysis. However, recovery is unlikely if function has not returned within 9 months.

A chronic unilateral nerve palsy is usually secondary to a neoplasm most commonly in the thyroid gland or the adjacent extralaryngeal tissues.

The radiologist is often asked to evaluate patients with vocal cord paralysis. Since lesions anywhere along the course of the vagus nerve can produce vocal cord paralysis, it is important to try to identify the level of the abnormality prior to proceeding with an imaging evaluation. A paralyzed cord may be in an intermediate (almost completely abducted) or a paramedian (off midline) position. Lesions above the jugular foramen may result in paralysis of the vocal cord in either the intermediate or paramedian position. Supratentorial and brainstem lesions may produce bilateral cord paralysis, and hemiparesis may be seen in association with supratentorial lesions. Infarcts in the posterior inferior cerebellar artery territory are often the cause of Wallen-

berg's syndrome (lateral medullary plate syndrome). Patients with this syndrome present with ipsilateral loss of facial sensation, contralateral loss of pain and temperature sensation over the body, ipsilateral Horner's syndrome, vertigo, hiccups, dysphagia, and ipsilateral ataxia of limbs. Involvement of the nerve in the jugular foramen above the recurrent laryngeal nerve tends to produce a paralyzed cord in the intermediate position, whereas lesions of the recurrent laryngeal nerve tend to result in cord paralysis in the paramedian position. If a lesion is situated between the pharyngeal branch and the superior laryngeal nerve, the cord usually is in the paramedian position and there is loss of sensation in the hypopharynx and pharynx.[5, 20, 21, 49]

If the lesion causing the vocal cord paralysis is cranial to the origin of the recurrent laryngeal nerve, there usually is paralysis of the ipsilateral pharyngeal constictor muscles, and the ipsilateral pharyngeal wall may be seen to be thinned and dilated compared to the normal contralateral side.

Thus, the position of the vocal cord, as well as the presence of other cranial nerve palsies and neurologic findings, may assist in identifying the level of the lesion. By dividing the vagal neuropathies into proximal and distal categories based on clinical findings, it is possible to determine the region to be scanned and the preferred imaging modality to use. The neurologic manifestations commonly encountered with lesions at various levels along the course of the vagus nerve are summarized in Table 42-6 and Figure 42-32.

Lesions involving the proximal portion of the vagus nerve usually are accompanied by neuropathies of one or more associated cranial nerves (IX, XI, XII), since these nerves travel in close proximity to the vagus nerve both at their point of origin in the brainstem and below the skull base.[39] MR imaging is the imaging modality of choice in these patients. The scans should be obtained through the levels of the brainstem and oropharynx. T1-weighted

Table 42-6
VOCAL CORD PARALYSIS CAUSED BY LESIONS AT VARIOUS LEVELS

	Level of Pathology	Vocal Cord Position	Cranial Nerve Deficit	Associated Findings
I.	Supratentorial	Variable Typically bilateral	None	Hemiparesis, etc.
II.	Brainstem	Variable Sometimes bilateral	Multiple	Wallenberg, etc.
III.	Cisternal	Variable	IX, X, XI, XII	Sometimes paralysis of soft palate
IV.	Skull base/jugular bulb	Usually Intermediate	IX, X, XI	Paralysis of soft palate
	Proximal to pharyngeal branch	Usually Intermediate	X, sometimes IX, and/or XI	Paralysis of soft palate
V.	Proximal to superior laryngeal nerve	Usually Intermediate	X	No paralysis of soft palate
VI.	Distal to superior laryngeal nerve	Usually Paramedian	X	No paralysis of soft palate
VII.	Recurrent laryngeal nerve	Usually Paramedian	Other vagal functions intact	No paralysis of soft palate

images are most helpful in the extracranial region, whereas T2-weighted images are more diagnostic in the brainstem.[21, 42]

If a patient presents with an isolated recurrent laryngeal nerve palsy (distal vagal neuropathy), CT is the preferred imaging modality and the scans should be obtained with intravenous contrast. With today's rapid acquisition CT studies, the scan plane should be aligned with the true vocal cords as seen on a lateral scout film, and the entire neck down to the carina should be scanned. Such a protocol includes the entire distal course of both recurrent laryngeal nerves. In the neck, a lesion in the tracheoesophageal sulcus (Figs. 42-33 and 42-34) or carotid sheath (Fig. 42-22) may produce a recurrent laryngeal palsy, and both recurrent laryngeal nerves can be involved by lesions at the level of the thoracic inlet. As mentioned, because the left recurrent laryngeal nerve has a longer intrathoracic course, it is

commonly involved by mediastinal pathology (Figs. 42-35 to 42-37).

PHRENIC NERVE

The phrenic nerve is formed primarily from the C4 nerve root, with minor contributions from C3 and C5. It is formed adjacent to the superior lateral border of the anterior scalene muscle and travels across this muscle beneath the deep layer of the deep cervical fascia that envelopes the muscle. This nerve has a vertical course that crosses the muscle from superolaterally to inferomedially. Inferiorly, the nerve passes medial to the muscle (Fig. 42-38) and thus comes to lie on the anterior surface of the first portion of the subclavian artery.

Both phrenic nerves in the mediastinum are in contact with the mediastinal pleura laterally. However, the length, vertical orientation, and medial relationships of these two nerves differ.

The right phrenic nerve is shorter and more vertically oriented that the left. Medially throughout its course, this nerve borders venous structures (right brachiocephalic vein, superior vena cava, right atrium, and inferior vena cava). This nerve crosses the diaphragm either through the inferior vena cava orifice or lateral to it.

The left phrenic nerve is found between the left common carotid and subclavian arteries in the superior mediastinum. It then passes medially and anteriorly, superficial to the left vagus nerve above the level of the aortic arch. It crosses the

aortic arch superficial to the superior intercostal vein and then passes laterally over the pericardium and left ventricle. This nerve passes through the muscular portion of the diaphragm anterior to the central tendon adjacent to the left side of the heart.

The phrenic nerve is usually the sole motor supply to the diaphragm. Occasionally, there may be an accessory phrenic nerve that is derived from C4, C6, or the ansa subclavia. Paralysis and atrophy of the diaphragm are manifestations of phrenic nerve palsy. This diagnosis can be made when diaphragmatic motion is absent on inspiratory and expiratory plain films or when paradoxical motion of the diaphragms is observed on fluoroscopy. However, it should be remembered that if the patient has an accessory phrenic nerve, the diaphragm may not be completely paralyzed.

Phrenic nerve palsy has a number of causes including viral neuritis, a mass pressing on the nerve, trauma, and iatrogenic causes (surgery). Radiographically, the goal is to identify a mass along the course of the nerve. Thus, a mass

that abuts the anterior border of the anterior scalene muscle in the neck (Fig. 42-39) or the anterior border of the subclavian artery at the thoracic inlet, or that lies in the mediastinum lateral to the vascular structures, can produce a phrenic nerve palsy (Fig. 42-40).

INTRODUCTION

Any discussion of the posttreatment neck, especially the postoperative neck, should be based on an understanding of the current treatment philosophies regarding neck metastases, as the management of cervical nodal disease is a critical part of the overall treatment of patients with head and neck squamous cell carcinoma. Since the early 1900s, surgery has been the primary treatment modality, and the operation of choice has been the radical neck dissection (RND).[1] However, in the past two decades, a number of surgical options other than the RND have been devised. In addition, radiation therapy with or without chemotherapy has become a major component of treatment.

The development of any rational approach to the treatment of cervical nodal metastases requires an understanding of the frequency, pattern of distribution, and prognostic implications of such nodal disease for the various head and neck primary tumors. Further discussion on this topic is presented in Chapter 36.

The early work on the incidence of cervical nodal metastasis was based almost exclusively on physical examination.[2] More recently, data from those studies have been modified by statistics that include palpation, clinical assessment, and histologic evaluation of surgical specimens.[3, 4] The results of these studies have shown a wide range of nodal involvement, depending on the primary site of the tumor. Carcinomas arising in the nasopharynx, palatine tonsil, hypopharynx, and base of the tongue have nodal metastases in 70% to 90% of cases, whereas

Copyright © 2003, Mosby, Inc. All rights reserved.

carcinomas of the oral cavity have nodal metastases in only 2% to 25% of the cases.[1]

With regard to the pattern of nodal metastases in the neck from specific primary tumor sites, it has been well documented that carcinomas of the oral cavity tend to spread to nodes in levels IA, IB, II, and III, while carcinomas of the oropharynx, hypopharynx, and supraglottic larynx tend to metastasize to nodes in levels II, III, and IV (see Chapter 36). The clinically silent but imaging-identified retropharyngeal nodes tend to harbor metastases from primaries in the hypopharynx, lateral and posterior oropharynx, tonsillar fossa, and soft palate. The visceral nodes (levels VI and VII) tend to be involved in primary carcinomas of the subglottic larynx, cervical esophagus, cervical trachea, and thyroid.[1] These patterns of spread have been utilized to develop rational surgical alternatives to the standard RND, with the selection of a modified or selective neck dissection strongly influenced by the location of the primary tumor.

The treatment of one particular group of patients with head and neck carcinomas remains controversial and illustrates the problems that persist in creating treatment decision algorithms. This specific group includes patients who present with a primary carcinoma and no clinical or imaging evidence of nodal disease (N0). Specifically, the problem of the N0 neck focuses on how to select those patients who require surgery, since when one considers all head and neck primary sites, only about 15% of N0 necks will eventually develop clinical nodal metastasis.[5, 6]

The recent literature contains guidelines, based on the above-cited studies, to approach the treatment of the N0 neck patient. That is, an elective or prophylactic neck dissection is not generally considered necessary for a patient with an N0 neck who has a T1 tumor with a risk of occult metastasis of less than 20% (i.e, true vocal cord, suprahyoid epiglottis).[7] However, the treatment of the patient with an N0 neck and a T1 carcinoma at a site that has a high probability of metastatic neck disease (i.e., pharynx, tonsil, tongue, and supraglottic larynx) is a clinically relevant issue because the possibility that metastatic nodal disease will develop in one or both sides of the neck is greater than 20%.[5, 8]

Once a decision has been made to treat a neck, the surgeon must select the type of neck dissection most appropriate for that patient. Except in cases of advanced nodal disease, most surgeons no longer believe that a standard RND is necessary, especially in patients with N0 and N1 staged necks.[6] However, most surgeons believe that some form of initial neck treatment is necessary, as there is evidence that failure to primarily treat such a neck results in a lower survival rate.[9]

Radiotherapy (RT) is another treatment option in these patients. Supporters of elective regional neck RT believe that irradiation is at least as effective as neck dissection, with a similar or lesser morbidity. They contend that elective neck irradiation can sterilize an N0 neck with subclinical disease.[9, 10] However, others suggest that substantive scientific evidence is limited, being for the most part indirect, inferential, and not well supported by direct comparison with surgery in formal clinical trials.[10] Nevertheless, RT is a recognized treatment option in these patients, and it can be utilized primarily or postoperatively, especially if extracapsular nodal spread has been found. Alternatively, it may be held in reserve for treatment of a late recurrence.

Chemotherapy also has a role in the treatment of head and neck cancer, either as part of an organ-sparing protocol, along with definitive or preoperative RT, or as part of a palliative or salvage treatment. A clinical observation now well established in the literature is that a rapid tumor response to chemoradiation is not predictive of improved survival, and ongoing treatment strategies should not be altered on the basis of initial tumor regression.[11, 12] Similarly, the inability to identify tumor on imaging studies, or the lack of interval change on serial imaging obtained during chemotherapy, should not be interpreted as indicating the absence of tumor. In most cases of head and neck cancer, the carcinoma will recur after the cessation of chemotherapy.

TYPES OF NECK DISSECTION

When considering the surgical treatment of neck disease, in addition to the traditional or full RND, there are five other recognized, more limited types of neck dissection: (1) the modified neck dissection, (2) the supraomohyoid type of selective neck dissection, (3) the lateral type of selective neck dissection, (4) the posterolateral type of selective neck dissection, and (5) the anterior compartment type of selective neck dissection.[6] There is also the option to perform a more extensive operation than the standard RND, the extended radical neck dissection. The nodal levels referred to are defined by the standard nomenclature used either in the 1997 version of the American Joint Committee on Cancer or the imaging-based nodal classification of 1999 (Fig. 43-1).[13, 14]

However, there are some procedures that do not precisely fit into such a classification system because a specific nodal level was or was not resected. It has been suggested that the procedure be described by a listing of the specific nodal levels resected. In this system, the nonnodal structures resected in modified neck dissection should also be identified. It is hoped that this strategy will eliminate any confusion, and it will be used in the discussion following.

Although a number of other surgical classifications are suggested in the literature, the nomenclature most widely used to describe the various types of neck dissections is the one developed by the Committee for Head and Neck Surgery and Oncology of the American Academy of Otolaryngology/Head and Neck Surgery.[6, 15–17] It is based on the concept that the RND is the standard or basic procedure for treating cervical lymphadenopathy in the cancer patient.[6] The RND removes en bloc all of the ipsilateral nodes extending from the mandible to the clavicle, the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. Compared to the RND, if the surgery preserves one or more nonlymphatic structures, the procedure is called a modified neck dissection (MND). When the procedure involves preservation of one or more lymph node levels (primarily relating to levels I to V), the

FIGURE 43-1 **A**, Drawing of the left side of the neck with the skin and superficial faciae removed. The clinical level staging system is used. The bold lines outline the limits of a radical lymph node dissection, and the roman numerals refer to the nodal levels. Note the locations of the spinal accessory nerve and the inferior belly of the omohyoid muscle in the posterior triangle of the neck. (Modified from Robbins KT, Medina JE, Wolfe GT. Standardizing neck dissection terminology. Official report of the Academy's Committee for Head and Neck Surgery and Oncology [see comments]. Arch Otolaryngol Head Neck Surg 1991;117:601–605.) **B**, Drawing of the left side of the neck viewed from anteriorly and obliquely. The pertinent anatomy used to define the imaging-based nodal classification is illustrated. The bold lines outline the nodal level boundaries, and the roman numerals refer to the nodal levels.

surgery is referred to as a selective neck dissection (SND). Finally, when the procedure involves the removal of lymph node groups or nonlymphatic structures in addition to those encompassed by an RND, the procedure is referred to as an extended radical neck dissection (ERND).

Although there is some variation among surgeons as to when each type of operation is performed, there is a generally accepted approach to which most surgeons adhere. If there is extensive neck disease, with or without extracapsular nodal extension, the RND is the operation of choice. When there is extracapsular nodal tumor, most surgeons will give postoperative RT to the neck. The MND is considered when there is limited neck disease in an N1 or N2 neck, without extracapsular tumor spread. That is, the nodal disease is anatomically localized to areas that allow some nonnodal structures to be spared. If a MND is considered preoperatively and extracapsular nodal spread is found at surgery, most surgeons will perform a RND. The SND is performed on N0 necks. If nodal metastasis is found at surgery, most surgeons will perform a more comprehensive procedure such as a MND or, if extracapsular tumor is present, a RND.

RADICAL NECK DISSECTION (I, II, III, IV, V)

Using the level classifications described in Chapter 36, and in particular the imaging-based classification (Fig. 43-2), the classic RND removes en bloc all of the ipsilateral nodes extending from the mandible to the clavicle[14] (Fig. 43-1B). The resection extends anteriorly from the lateral border of the sternohyoid muscle, hyoid bone, and contralateral medial border of the anterior belly of the digastric muscle to the anterior border of the trapezius muscle posteriorly. The specimen thus includes all of the level I to V nodes, the ipsilateral submandibular gland, spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle. Occasionally included in the resection are the ipsilateral sternohyoid and sternothyroid muscles, one or both of the muscle bellies of the ispsilateral digastric muscle, and the ipsilateral thyroid lobe. This procedure does not include removal of the postauricular and suboccipital nodes, the periparotid nodes (except for a few nodes in the tail of the parotid gland), the perifacial and buccinator nodes, the retropharyngeal nodes, and the level VI and VII nodes. As a result of the surgery, the denervated trapezius atrophies, and

FIGURE 43-2 Diagram of radical neck dissection. The skin and superficial fasciae have been removed, and the bold lines define the surgical boundaries that contain the nodal levels removed. Removed are the sternocleidomastoid muscle, the internal jugular vein, and the spinal accessory nerve. The lymph nodes removed include those in levels I, II, III, IV, and V.

the patient develops the shoulder syndrome, which is characterized by progressive shoulder drop, shoulder pain, scapula prominence and deformity of the shoulder girdle, and limitation of shoulder abduction. Usually there is compensatory hypertrophy of the ipsilateral levator scapulae muscle. The RND is utilized in patients with extensive nodal metastases, with or without extranodal tumor extension that involves the spinal accessory nerve and/or the internal jugular vein.[6, 17]

MODIFIED NECK DISSECTION (I, II, III, IV, V) WITH PRESERVATION OF ONE OR MORE STRUCTURES—THE IPSILATERAL INTERNAL JUGULAR VEIN, SPINAL ACCESSORY NERVE, STERNOCLEIDOMASTOID MUSCLE, AND SUBMANDIBULAR GLAND

The MND removes all of the lymph nodes routinely removed in a RND but preserves one or more of the following structures: the ipsilateral internal jugular vein (IJV), the spinal accessory nerve (SAN), the sternocleidomastoid muscle (SCM), and the submandibular gland (SMG) (Fig. 43-3). When describing the operation, the particular structures preserved should be specifically mentioned. For example, a MND that preserves the SAN should be described as a ''MND with preservation of SAN.''

The greatest decrease in morbidity when compared to the RND comes from the preservation of the SAN. The decrease in morbidity from preserving the IJV and the SCM muscle is small unless bilateral neck dissections are required. Occasionally, resection of a dominant right IJV may result in massive head and neck edema equal to that found with bilateral vein ligation. If bilateral neck dissections are deemed necessary, by utilizing a modified neck operation with preservation of the IJV, there is less severe facial and neck swelling and little if any increase in intracranial pressure compared to what is seen with bilateral radical neck dissections.[6, 17]

The terms *functional neck dissection* and *conservation neck dissection* also previously appeared in the literature to describe the physiologic benefits of this procedure. However, at present, the term *modified neck dissection* is the one used by most clinicians.[6, 17, 18] The MND is an en bloc removal of level I to V nodes. The dissection extends from the inferior border of the mandible to the clavicle. It extends medially from the lateral border of the strap muscles to the anterior border of the trapezius muscle laterally. However, as already described, there is preservation of the ipsilateral IJV, SAN, SMG, and SCM, either singly or in some combination.

The major indication for performing a MND is to remove probable or grossly visible nodal disease that is not directly infiltrating the nonlymphatic structures mentioned.[6, 17]

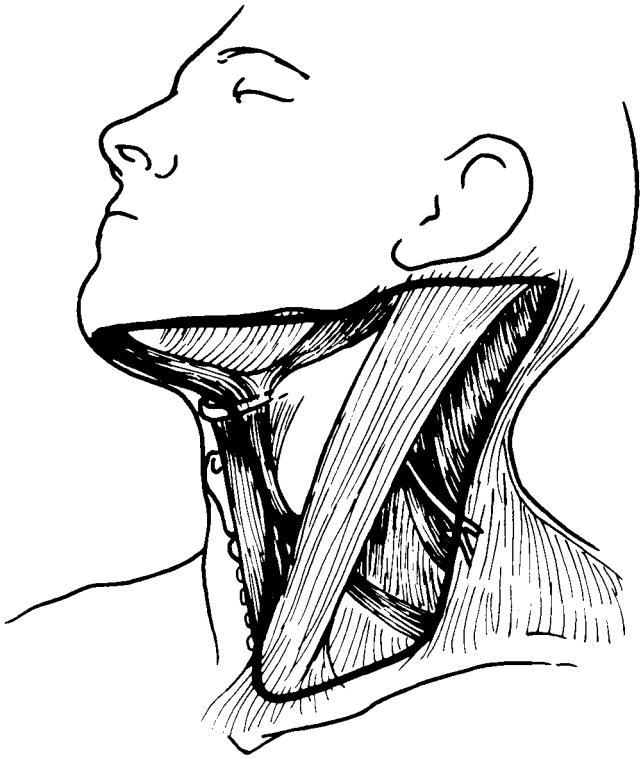

FIGURE 43-3 Diagram of a modified neck dissection. The skin and superficial fasciae have been removed, and the bold lines define the surgical boundaries that contain the nodal levels removed. The dissection preserves one or more of the following structures: the ipsilateral IJV, the SAN, the SCM, and the SMG. The lymph nodes removed include those in levels I, II, III, IV, and V.

SELECTIVE NECK DISSECTION

The various types of selective neck dissections are performed on patients at risk for early nodal metastases. These procedures are based on the concept of prophylactically removing those lymph node levels at greatest risk for spread in patients with N0 neck disease. They consist of en bloc removal of one or more of the nodal levels, depending on the location of the primary tumor and its known pattern of nodal metastasis. As previously mentioned, several studies have demonstrated that tumors in the oral cavity most frequently metastasize to level I, II, and III nodes. Tumors involving the oropharynx, hypopharynx, and supraglottic larynx most commonly metastasize to level II, III, and IV nodes. It has been found that whenever metastatic nodes were found in other areas of the neck with these primary tumors, there were always positive nodes in the stated regions most at risk.[2, 4, 19–21]

Recently, it has been suggested that the name of the type of SND be followed by the nodal levels removed. This approach clearly identifies the procedure performed.

Supraomohyoid Type of Selective Neck Dissection (I, II, III)

The supraomohyoid SND consists of en bloc removal of the lymph nodes in levels I, II, and III (Fig. 43-4). If the nodes in level IV are also removed, the procedure is referred to as an extended supraomohyoid SND. This procedure is indicated for patients with oral cavity cancers and N0 necks. These cancers are associated with at least a 20% risk of nodal metastasis. Neck dissection for floor of mouth cancers should remove nodes in levels I, II, and III; however, with carcinoma of the tongue, level IV nodes should also be included.

If there is palpable nodal disease (N+) in a patient with an oral cavity cancer, level IV and V nodes should also be removed. The exception to this rule is when intraoperative assessment reveals disease confined to levels I and II. In this situation, level I to IV nodes should be removed.

Surgical treatment of the contralateral neck is indicated in patients with cancers in the floor of the mouth, in the ventral surface of the tongue, and/or with midline tongue involvement in whom postoperative RT is not planned. In patients with oral cavity cancer, surgery on the contralateral neck is recommended if the patient has an N2C neck at presentation.[6] Whenever level I nodes are removed in these procedures, the ipsilateral SMG is also removed to control tumor spread.

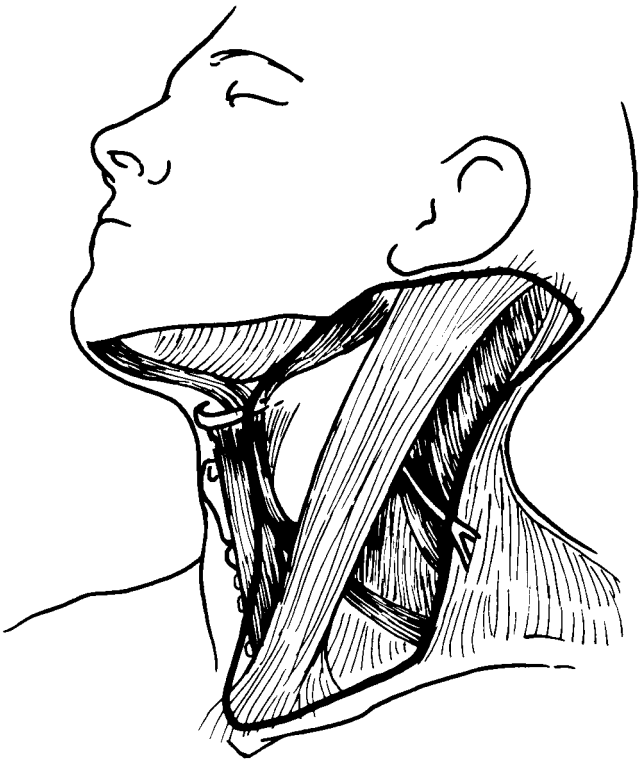
Copyright © 2003, Mosby, Inc. All rights reserved.

recommended in patients with cancers arising in the oropharynx, hypopharynx, and supraglottic larynx. Because these cancers involve the midline visceral structures that have bilateral lymphatic drainage, this type of neck dissection is usually performed bilaterally.[6] With very extensive level II, III, and IV nodal disease, level V should also be resected.

Posterolateral Type of Selective Neck Dissection (II, III, IV, V)

The posterolateral SND removes the nodes in levels II, III, IV, and V and the suboccipital and postauricular nodes. The perifacial (buccinator) and external jugular nodes may also be resected (Fig. 43-6). This procedure is used in the treatment of cutaneous malignancies and soft-tissue sarcomas arising in the posterior scalp, nuchal ridge, occiput, or posterior neck. The dissection is designed to remove the lymph node bearing fibrofatty tissue in the posterior and lateral compartments of the neck. Included in the dissection should be the intervening subdermal fat and underlying fascia between the nodal groups and the primary tumor. This latter dissection is designed to eliminate the nests of tumor cells that are characteristically associated with cutaneous malignancies.[6]



VIEW IMAGE

Anterior Compartment Type of Selective Neck Dissection (VI, VII)

The anterior compartment SND consists of en bloc removal of the nodes in level VI (Fig. 43-7). The procedure is indicated primarily for cancers arising in the thyroid gland, hypopharynx, cervical trachea, and cervical esophagus, as well as for those laryngeal cancers with subglottic disease. The dissection consists of en bloc removal of the cervical portions of the perithyroidal, pretracheal, and paratracheal nodes. In addition, the Delphian (precricoid node[s]) and the nodes along the course of the recurrent laryngeal nerves are resected. The boundaries of the dissection are the carotid sheaths laterally, the hyoid bone superiorly, and the suprasternal notch inferiorly. If there is known nodal disease at the level of the suprasternal notch, level VII nodes should also be resected. If the contralateral neck is N0 in patients with unilateral laryngeal and/or hypopharyngeal cancers, the dissection may be limited to the ipsilateral side. This reduces damage to the vascular supply to the parathyroid glands and eliminates the need to reimplant them.[6]

Extended Radical Neck Dissection (Additional Structures Removed)

The ERND refers to the removal of one or more additional lymph node groups or nonlymphatic structures, or both, not normally encompassed by an RND. Such nodal groups include the retropharyngeal, superior mediastinal (VII), perifacial (buccinator), and paratracheal (VI). Nonlymphatic structures include the carotid artery, hypoglossal

nerve (XII), vagus nerve (X), and paraspinal muscles. The additional lymphatic and nonlymphatic structures resected should be identified when describing the procedure.

RETROPHARYNGEAL NODAL DISEASE

Special mention should be made of the presence of retropharyngeal nodes in patients with pharyngeal wall cancers (Fig. 43-8). As many as 44% of patients with pharyngeal carcinomas have been found to have retropharyngeal nodes, and if surgery is to be performed, the dissection must be extended to include these nodes.[22] The retropharyngeal nodes are also at risk in patients with base of tongue, tonsil, soft palate, and retromolar trigone cancers when the tumor extends to involve the lateral and/or posterior oropharyngeal walls. The pretreatment imaging identification of such nodes lying medial to the internal carotid arteries near the skull base clearly signals the need for such a modification of the dissection boundaries. Alternatively, if RT is the treatment of choice, the routine fields must be modified to dose these nodes properly.

SURGERY: WITH AND WITHOUT RECONSTRUCTION

The surgical approaches directed to both the primary tumor site and any cervical nodal metastases can be divided into two general groups: those operations that simply remove the known disease, without a need for reconstruction, and those operations that resect the disease but require a reconstructive procedure to repair or close the defect and provide function and/or comesis.[18] With regard to the reconstructive techniques, it is only within the past two decades that great advances have occurred, which restore the patient to a more normal appearance, a better functional status, and ultimately a better quality of life.

Management of a surgical defect varies from healing by secondary intention to the complex transfer of tissue to the head and neck using microvascular techniques. When the surgical defect requires tissue transfer to provide proper closure, there are two major types of flaps available for use: pedicled and free flaps, both based on the blood supply to the skin coming from tiny perforating vessels on the surface of the underlying muscle that is nourished by a named artery and vein. The en bloc transfer of the needed skin and its underlying muscle, with intact perfusion of its vascular supply, ensures the viability of the transposed tissues. The myocutaneous flap consists of the rotation of regional skin and underlying muscle on the preserved vascular pedicle of the muscle. The free flap consists of skin, subcutaneous tissue, muscle, and even bone, as required for reconstruction, to be transferred from a distant site to the surgical field, with the blood supply to the flap being reestablished by microvascular anastomosis to local blood vessels.

When myocutaneous flaps are utilized in these reconstructions, the muscle used can be from the head and neck (i.e., temporalis, sternocleidomastoid, and levator scapulae) or from the chest wall or upper back (i.e., pectoralis major, trapezius, latissimus dorsi). The primary nutrient vessels to the involved muscle are preserved, and on imaging, the vascular attachment of the flap can usually be seen at the lower margin of the flap. In contrast, with the free flaps on imaging, no vascular pedicle is identified.[23, 24]

In general, myocutaneous flaps are utilized to reconstruct surgical soft-tissue defects. When bone needs to be replaced, a composite-free osteomyocutaneous flap is utilized. This usually occurs with reconstruction of the mandible and hard palate, and the flap sites harvested are most often from the pelvis, scapula, or fibula. Examples of postoperative CT and MR scans are shown in Figures 43-9 to 43-18.

RADIATION THERAPY

The decision as to the optimal treatment of cervical metastatic nodal disease depends on a number of factors including the extent and location of the primary tumor, the nodal levels involved, and the presence of extranodal disease in the neck. In addition, the medical condition and age of the patient play important roles in the final selection of treatment.[25] As previously mentioned, it was not until the past two decades that treatment options other than RND were considered as suitable alternatives. However, presently RT, with or without chemotherapy, is not only useful adjunctive therapy but has become an effective primary treatment approach.[25] Another consideration in the algorithm for the management of cervical nodes is that early-stage tumors can be treated comparably by surgery or RT, and the decision as to which modality to use for the treatment of the primary tumor and the neck is often determined by the fact that most centers favor utilization of a single treatment modality.

Evidence now supports the prophylactic treatment of an N0 neck, not only to decrease the clinical development of neck disease, but also to decrease the incidence of distant

VIEW IMAGE

metastases by controlling neck disease.[25] However, the likelihood of regional neck control also depends on control of the primary site, as reseeding of the neck may occur from an uncontrolled primary tumor.[26]

The effectiveness of RT for palpable nodal disease depends on a number of factors including nodal size, nodal fixation, and the number of nodes present. Small (less than 3 cm), solitary, mobile nodes respond best to RT. Compared to surgery, control of regional neck disease with RT for multiple large, fixed nodes is poor. Improved regional control rates have been noted with RT when the treatments are delivered without interruption, that is, continuous-course rather than split-course treatments. Interruption of treatments generally results from intolerance of the RT.[25] Such problems are often related to the dose delivered, which is determined by nodal size. Doses of 65 Gy are adequate to control nodal disease when the nodes are less than 1 cm. However, 70 Gy is suggested to control nodes of 1 to 2 cm, and 75 Gy is necessary for nodes of 2 to 3 cm. In addition, since adequate coverage of the neck is necessary for nodal control, larger fields require larger doses, and this results in decreased patient tolerance.

Trials of prophylactic RT performed 20 to 30 years ago revealed that doses of 20 Gy decreased neck recurrence rates compared to the decreases achieved with RND without RT. In 1987, the Radiation Therapy Oncology Group Trial 73-03 demonstrated that postoperative RT improved regional control and possibly survival compared to preoperative RT. Postoperative RT also allowed for better pathologic analysis of the surgical specimen, and most surgeons preferred to operate in a nonirradiated field.[25, 27] Nevertheless, preoperative RT remains an important treatment option. Although a good clinical response to RT suggests a favorable regional control rate, some poor clinical responders may achieve long-term regional control. Furthermore, high-dose, hyperfractionated preoperative RT may further improve regional control, especially in patients with advanced neck disease.[25, 28]

Postoperative RT appears to be necessary when macroscopic extranodal tumor extension and perineural invasion are present. Other indications include the finding of multiple involved nodes and large nodal size at surgery.

Data from the Memorial Sloan-Kettering Cancer Center and the Veterans Administration Cooperative Study on organ preservation using cisplatin-based chemotherapy followed by RT suggest that patients with clinically palpable nodal disease who have a complete clinical response after induction chemotherapy will achieve excellent regional control of their neck disease after high-dose RT, rendering RND unnecessary.[25, 29, 30] Neoadjuvant therapy is designed as an organ preservation treatment alternative to surgery for selected patients who have advanced laryngeal and hypopharyngeal carcinomas. Initially, these patients were first treated with chemotherapy, with the responders then given RT in a curative attempt. Presently, these patients are given concomitant chemotherapy and RT. In those cases that are good responders, either no surgery or limited neck dissection is necessary.

Improved control of advanced regional neck disease may also be achieved by the use of brachytherapy, which is the

intraoperative implantation of iodine-125 sutures, pins, catheters, or other radioactive substances after surgical excision of the disease. Both improved regional control and improved survival have been reported.[25, 31, 32]

ROUTINE POSTOPERATIVE AND POSTRADIATION IMAGING CHANGES

Any trauma to the neck, whether external beam irradiation, needle biopsy, or surgical manipulation, results in edema and hemorrhage of the local soft tissues secondary to either obstruction or rupture of vascular and lymphatic capillaries. With minimal trauma (i.e., needle biopsy), these changes are usually not identified on CT and MR images or are seen for less than 2 to 3 weeks as a localized inflammatory-type response. However, after surgery and RT, these soft-tissue changes are more extensive and may persist for months or years. In the immediate postoperative period, the imaging findings are further complicated by the possible presence of cellulitis, hemorrhage, and lymph or suppurative collections, with or without an enhancing rim. By 4 to 6 weeks after surgery, there is generally a noticeable decrease in these imaging findings as the neck starts to return to a near-normal posttreatment appearance. It is not known why in some patients these imaging posttreatment changes rapidly disappear, while other patients retain them for months or years. When postoperative RT is utilized, these findings persist much longer than if only surgery was performed.

On CT, the findings, primarily within the subcutaneous fat, consist of a rete-like (reticular) pattern of interconnecting thin strands that primarily represent obstructed venules and lymphatic capillaries. In addition, the attenuation of fat (primarily subcutaneous fat) is increased as interstitial fluid permeates these regions and the subcutaneous fat layer is thickened. On MR imaging, only the rete pattern and swelling of the fat are seen, as the fat otherwise appears normal in signal intensity.

With treatment and time, these changes start to resolve, in most cases by the end of the first postoperative month. However, in the immediate post-RT period or even during RT treatments, the soft-tissue swelling and rete pattern may not be well appreciated, often requiring about a month or more after cessation of treatments to be fully manifest on imaging. In addition to the soft-tissue swelling, the most notable imaging changes after neck RT are a mild diffuse swelling of the hypopharyngeal mucosa and supraglottic mucosal laryngeal surfaces and a thin zone of water attenuation (edema and phlegmon) in the retropharyngeal space behind the hypopharynx and lower oropharynx (Figs. 43-10, 43-17, and 43-18).[33–38]

After an SND, it may be difficult to determine that surgery was performed. Often the best imaging hint is a reduced fat volume in the fat deep to the SCM and, if appropriate, in the submandibular triangle of the neck. This reduced fat volume may make identification of nodal disease more difficult, and care should be taken to examine such necks very thoroughly.

The incision line can usually be identified on axial imaging studies because of an infolding of the skin line and often a localized area of subjacent scar tissue. Based purely on the imaging, a local recurrence could have the same appearance; however, as it is so close to the skin, clinical assessment usually confirms its benign etiology. By comparison, transverse skin incisions are most often not identified on axial images, especially in patients who have had thyroid surgery. In these cases, identification of the prior surgery is made by noting the absence of one or both lobes of the thyroid gland and the resulting medial location of the common carotid artery (and possibly the IJV) just lateral to the trachea (Fig. 43-13).

After a MND or a RND, there is flattening of the ipsilateral neck contour, nonvisualization of the ipsilateral nodes, and absence of some or all of the ipsilateral SCM,

Copyright © 2003, Mosby, Inc. All rights reserved.

SAN, SMG, and IJV. Identification of such surgery should not present a problem to the imager.

BASELINE SURVEILLANCE IMAGING

While it might seem desirable to delay a postoperative baseline scan as long as possible to allow the most complete resolution of these posttreatment findings, if one waits too long, there is a greater chance that a tumor recurrence may be present and misidentified as part of the normal posttreatment appearance of the patient. The time at which tumor recurrence develops is variable and depends upon such factors as host resistance, the presence of tumor-free margins at the time of surgery, and the biologic aggressiveness of the tumor. However, with tumor-free margins, it is rare for tumor to recur within 4 to 6 weeks after surgery.

Considering all of these factors, it is suggested that the baseline scan be obtained 4 to 6 weeks after surgery, as most of the postoperative changes have resolved, the new

FIGURE 43-12 Serial contrast-enhanced CT scans from cranial (**A**) to caudal (**D**) on a patient who has had a pharyngectomy and laryngectomy and bilateral radical neck dissections. Note the normal thin, uniform mucosal surface of the flap creating the surface of the neopharynx. Also note the normal circular/ovoid configuration of the fat of the flap as it forms the neopharynx and the sharp margin between the fat and the adjacent soft tissues of the neck. More caudally, note how the flap extends into the more superficial soft tissues of the neck and how, on the left side, the flap covers and protects the carotid artery.

anatomy is present, and it is unlikely that a tumor recurrence is grossly present.[23, 24] Similarly, if only RT is given, the 4- to 6-week posttreatment interval is also optimal to obtain a baseline imaging study.

When subsequent surveillance imaging studies are obtained and compared to the baseline examination, any soft-tissue fullness on the baseline study that has become progressively smaller is presumed to be related to post-treatment healing. Conversely, if a mass has enlarged, it must be considered recurrent disease until proven otherwise.[6, 17, 23, 24, 39–42]

An exception to this surveillance protocol is the patient receiving concurrent chemotherapy. Lack of growth and maintenance of configuration has been seen in these patients on serial scans for up to 18 months; however, at the completion of chemotherapy, tumor growth can occur.

Copyright © 2003, Mosby, Inc. All rights reserved.

Consequently, in patients receiving chemotherapy, the absence of change on serial surveillance scans does not necessarily indicate the absence of tumor. In general, chemotherapy protocols tend to be effective for longer periods of time with sarcomas than with carcinomas.

In some patients, the posttreatment soft-tissue changes may persist indefinitely, and without the ability to compare surveillance scans to a prior imaging study, the interpretation of the surveillance scans is difficult. The persistence of areas of thickening may be related to the development of what can best be described as vascularized scar. This tissue is not a true granulation tissue but rather a vascularized fibrotic tissue that enhances with contrast in a manner similar to cellular tumor. In addition, vascularized scar tissue has CT attenuation and MR signal intensities similar to those of recurrent tumor. On serial scans, the vascularized scar tends to either remain stable in size and configuration or to slowly decrease in size. This may be the only way, short of biopsy, to distinguish between such vascularized scar and recurrent tumor.[6, 17, 23, 24, 39–42] Examples of tumor recurrences and vascularized scar tissue are shown in Figures 43-19 to 43-34.

SURVEILLANCE PROTOCOL

Most tumor recurrences occur within 2 years after initial treatment, and most cancer deaths occur within 3 years of the initial diagnosis.[10, 24, 39] Thus, the patient is at greatest risk within the first 2 to 3 years after diagnosis and initial treatment. Consequently, surveillance imaging should be performed more often during this period. Most patients receive routine surveillance studies at 6-month intervals for the first year. However, those patients who have tumors with an aggressive histology or clinical course should probably receive scans at 4-month intervals for at least the first year. Yearly imaging examinations are then scheduled for at least 2 more years, although many patients continue with yearly scans indefinitely, as the presence of one upper aerodigestive malignancy raises the probability that a second tumor will develop.

Surveillance imaging should always be accompanied by a clinical examination. This recommended surveillance schedule presumes that the patient has no clinical evidence of a new mass, neurologic deficits, pain, or vascular compromise. The development of any of these signs and symptoms necessitates an immediate clinical examination and an imaging study. By following this policy, the radiologist and clinician are best able to identify early recurrent disease so that a further attempt at cure can still be made. While a cure is achieved in only a few of these patients, the literature supports the concept that early recognition and treatment of recurrent disease allows better palliation, often with a relatively good quality of life.

When an isolated recurrence occurs in a previously

FIGURE 43-13 Serial CT contrast-enhanced scans from cranial (**A**) to caudal (**B**) on a patient who has had a total laryngectomy and a partial pharyngectomy. Note the smooth outer contour (*arrows*) of the neopharynx that can be created either from a rotated flap or, as in this patient, with a portion of intestine. In **B**, also note that the left thyroid lobe has been resected and the right thyroid lobe reimplanted anterior to the normal thyroid bed. This allows the carotid arteries to move medially into the thyroid bed. Axial contrast-enhanced CT scan (**C**) on a patient who has had a total thyroidectomy and a right neck dissection. Note the absence of the thyroid gland and the medial location of the carotid arteries as they move into the thyroid bed.

VIEW IMAGE

treated neck in a patient with squamous cell carcinoma, factors that are associated with a less favorable outcome after aggressive salvage therapy include other serious medical problems, the patient's refusal of further treatment, development of the recurrence in the contralateral neck, development of the recurrence in the neck after a neck dissection, and a recurrence that measures >3 cm and/or is fixed.[43]

IMAGING SUSPICION OF A RECURRENCE

There are two tenets for the imaging identification of early tumor recurrence. First, if a flap was not used for reconstruction, then surgery removes tissue, and, except for edema, there should not be extra postoperative bulk or a mass in the operative site. If such fullness is seen, an explanation of the etiology of this tissue must be sought, as recurrent tumor must be considered the principal cause. Second, the most likely location for a tumor to recur is either in the operative bed or at the margin of the surgical site. With this in mind, attention must be paid to assessing regional muscle, fibrous, and vascularized soft tissue (Figs. 43-19 to 43-34).

Normal muscle tends to have a fairly linear or curvilinear configuration, with smooth contours. However, after surgery, muscle rotated within a flap may appear on end in an area where no such muscle is normally expected and may mimic a tumor mass. Apart from comparing attenuation values or signal intensities to those of adjacent normal muscle, the only way to distinguish such muscle from tumor may be the careful sequential tracing of the muscle path throughout the operative field. Most muscles manipulated during surgery tend to have mild enhancement, again potentially mimicking a tumor. Muscle within a flap also tends to be curvilinear in shape, as it is often wrapped or twisted around within the flap tissue to fill the operative defect. Localized bulges within a muscle are not normal and may represent hemorrhage or tumor.

The presence of any focal ''ovoid'' mass not identified on a previous surveillance scan in a postoperative neck must be suspicious for recurrence. This is especially true if the mass has infiltrative or spiculated margins. A useful sign on CT is the observation that tumor has an attenuation similar to that of muscle. Thus, if a suspected mass has an attenuation less

Copyright © 2003, Mosby, Inc. All rights reserved.

than that of muscle, it is unlikely to be carcinoma and often is related to edema.

The identification of a mass deep to a flap may be the first evidence of a recurrence. Due to the bulk of the flap, the often ''woody'' feel of the skin and subcutaneous tissues after irradiation, and the deep location of the disease, this region is usually inaccessible to clinical evaluation.

As stated, the major diagnostic imaging problem lies in differentiating a recurrent tumor mass from dense scar and vascularized scar, both of which may have infiltrative margins and can be indistinguishable from tumor on both CT and MR imaging. The progressive decrease in T2-weighted signal intensity of a soft tissue area as seen on serial surveillance MR scans, strongly suggests the presence of dense scar. If the patient has recent pain or discomfort in the region, tumor recurrence is the most likely diagnosis, provided that there is no other evidence of local infection. Thus, such local pain would negate waiting up to 6 months

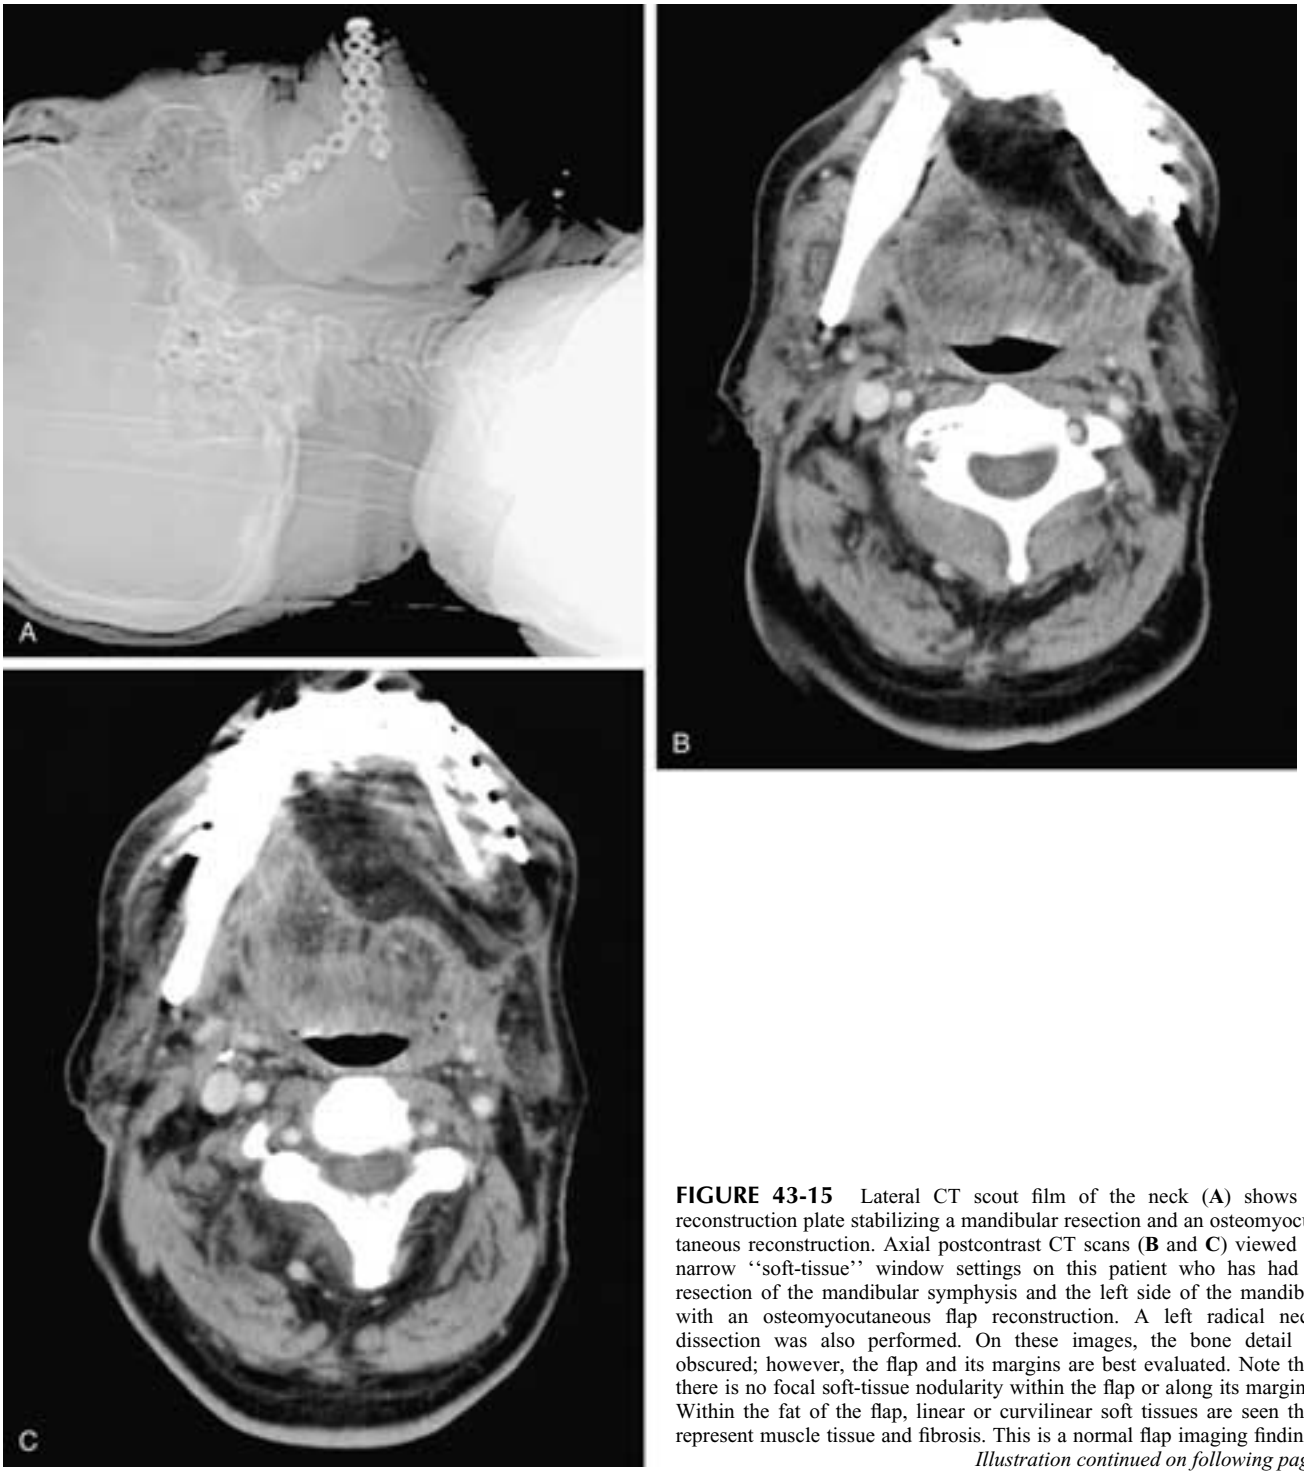

FIGURE 43-15 Lateral CT scout film of the neck (**A**) shows a reconstruction plate stabilizing a mandibular resection and an osteomyocutaneous reconstruction. Axial postcontrast CT scans (**B** and **C**) viewed at narrow ''soft-tissue'' window settings on this patient who has had a resection of the mandibular symphysis and the left side of the mandible with an osteomyocutaneous flap reconstruction. A left radical neck dissection was also performed. On these images, the bone detail is obscured; however, the flap and its margins are best evaluated. Note that there is no focal soft-tissue nodularity within the flap or along its margins. Within the fat of the flap, linear or curvilinear soft tissues are seen that represent muscle tissue and fibrosis. This is a normal flap imaging finding.

FIGURE 43-15 *Continued.* In **D** and **E**, the same images as **C** and **D** are shown at wide ''bone'' window settings. Note that the anterior edge of the native right mandible is sharp, with no evidence of erosion. The small low-attenuation areas with dense margins seen in the aspect of the right mandible were related to fixation screws. Also note that two transplanted bones have no evidence of erosion. This is a normal imaging appearance for this operative procedure.

to see if the mass identified on a particular study has grown and a CT-guided fine needle aspiration biopsy should be performed as soon as possible.[44] Alternative suggestions have been to utilize PET, thallium-201, and MR spectroscopy (see Chapter 45).

With specific regard to metastatic lymph nodes in patients with head and neck carcinomas who undergo concurrent chemotherapy and RT, it has been suggested that when there is a nodal volume reduction of greater than 90%, the metastatic node has been sterilized.[45] This may affect the need for further neck dissections in such patients.

BIOPSY OF SUSPECTED RECURRENCE SEEN ON IMAGING

Once a potential recurrence is seen on a surveillance scan, a CT or ultrasound-guided fine needle aspiration biopsy needs to be performed as soon as possible. Although a 22-gauge needle is often recommended, a 25-gauge spinal needle is easier to steer for accurate placement in deeply situated masses. A cytopathologist should be present at the biopsy to assess the adequacy of the specimen obtained utilizing an air-dried quick stain technique. A maximum of five passes may be required until an adequate specimen is obtained. The samples are subsequently evaluated with Papanicolaou-stained slides and cell block analysis. There are few complications with this procedure.[46–53]

THE IMAGING DETECTION OF VASCULAR COMPLICATIONS

Thombosis of the IJV or the carotid artery may occur from ligation or other intraoperative manipulation.[54] It is not rare on surveillance imaging to identify thrombosis of these vessels, especially the carotid artery (Fig. 43-35A). Usually this is a clinically silent event. Arterial stents from unrelated prior surgery can also occasionally be seen on surveillance imaging (Fig. 43-35B). On CT and MR imaging, arteritis may be seen as thickening and enhancement of the arterial wall. In documenting this potentially serious side effect of neck irradiation, an increased frequency of carotid artery wall thickening has been identified utilizing ultrasound in young patients with Hodgkin's disease treated by RT.[55] RT-related arteritis can also lead to complications during endarterectomy and other vascular surgery, and irradiated patients also can develop radiation-accelerated atherosclerosis (Fig. 43-36).[56–59]

With specific reference to the IJV, examination with color Doppler ultrasound has found that the vein remained patent in 88% of patients after an MND, in 57% of patients

Copyright © 2003, Mosby, Inc. All rights reserved.

treated with RT alone, and in only 18% of patients receiving MND and RT.[1] Examination of the IJV in patients after MND and SND showed that in 26.4% of these patients there was evidence of thrombosis within the first postoperative week. However, on long-term follow-up, the incidence of thrombosis was only 5.8%, suggesting that some veins recanalize.[60]

THE IMAGING DETECTION OF OSSEOUS COMPLICATIONS

When a primary tumor involves the mandible, some type of bone resection is performed. This may vary from a marginal resection to a segmental or total mandibulectomy. Currently, the trend is to perform a primary repair of the osseous defect at the time of resection by using a free-composite flap containing bone (osteomyocutaneous flap). Consequently, postoperative imaging visualizes both native mandible and transplanted bone, the latter usually harvested from the scapula, pelvis, or fibula. Many of these patients are irradiated postoperatively, and mandibular radionecrosis develops in 2% to 3% of the patients. Distinction between radionecrosis and recurrent tumor may be impossible on CT and MR imaging studies. The imaged bone can have areas of sclerosis, rarefaction, and sequestration, all of which can be seen with both radionecrosis and tumor (Fig. 43-37). It is therefore essential to examine carefully the bony margins of

Text continued on page 2262

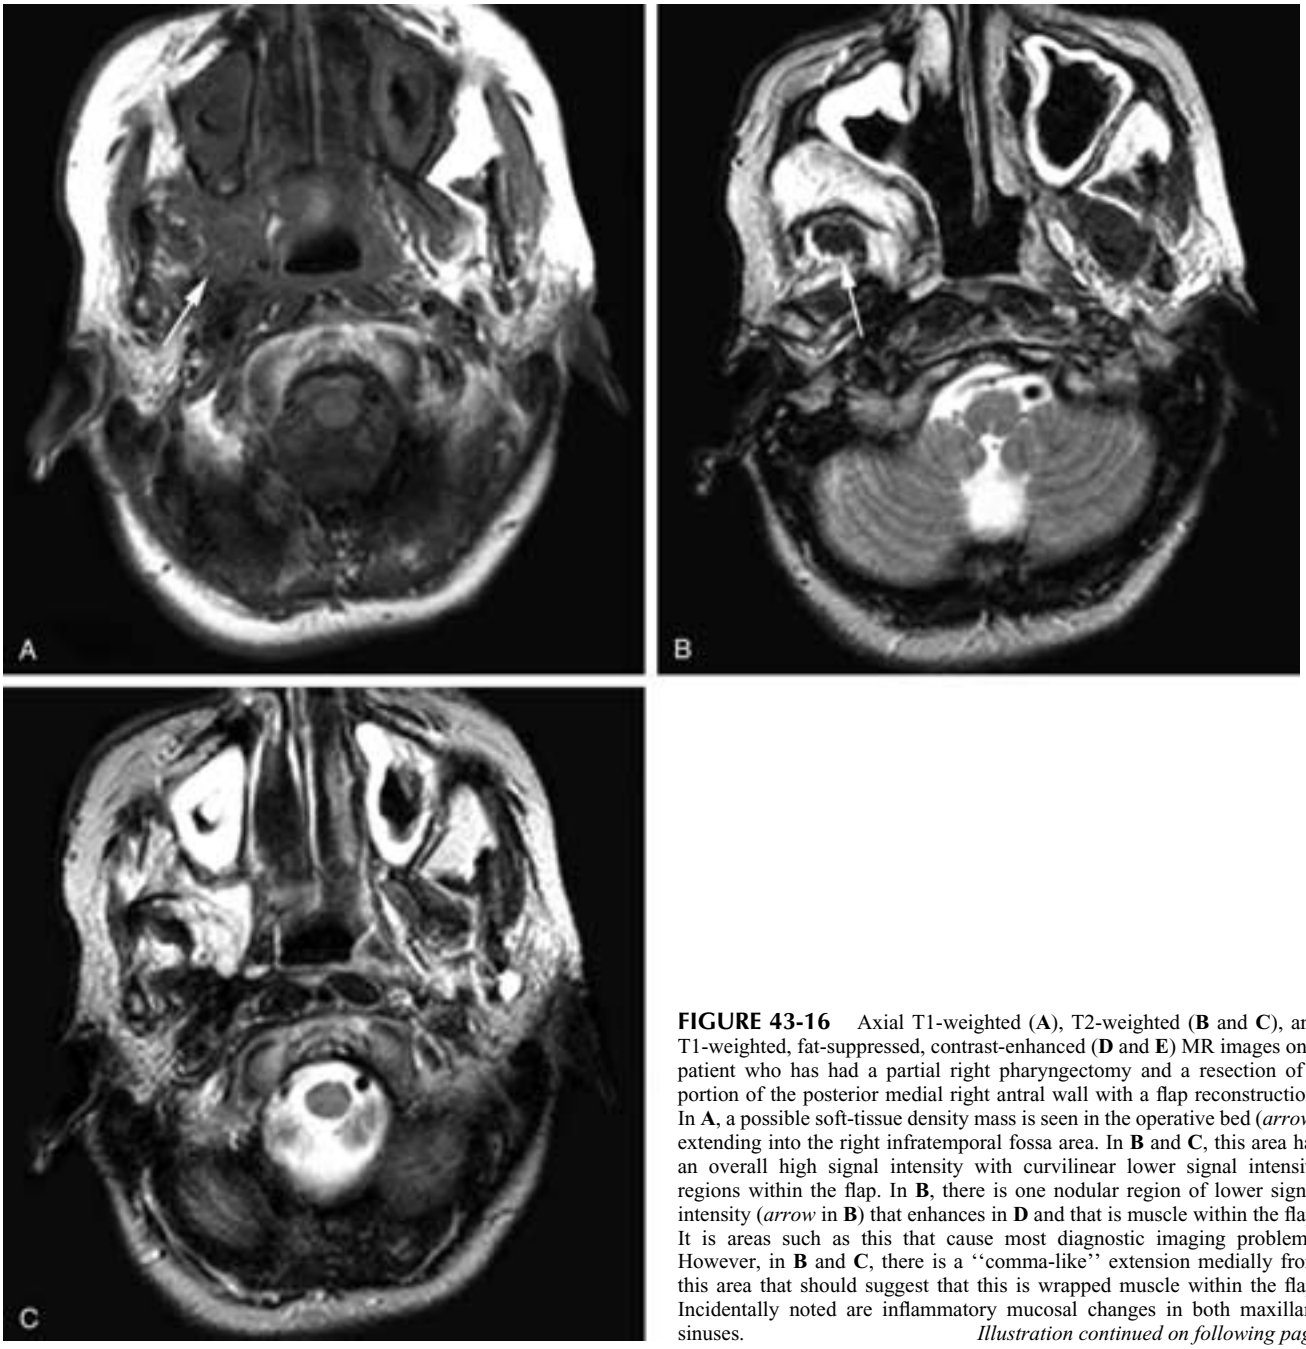

FIGURE 43-16 Axial T1-weighted (**A**), T2-weighted (**B** and **C**), and T1-weighted, fat-suppressed, contrast-enhanced (**D** and **E**) MR images on a patient who has had a partial right pharyngectomy and a resection of a portion of the posterior medial right antral wall with a flap reconstruction. In **A**, a possible soft-tissue density mass is seen in the operative bed (*arrow*) extending into the right infratemporal fossa area. In **B** and **C**, this area has an overall high signal intensity with curvilinear lower signal intensity regions within the flap. In **B**, there is one nodular region of lower signal intensity (*arrow* in **B**) that enhances in **D** and that is muscle within the flap. It is areas such as this that cause most diagnostic imaging problems. However, in **B** and **C**, there is a ''comma-like'' extension medially from this area that should suggest that this is wrapped muscle within the flap. Incidentally noted are inflammatory mucosal changes in both maxillary sinuses.

VIEW IMAGE

FIGURE 43-16 *Continued.* In **D** and **E**, areas of muscle and inflammation enhance, often further confusing the MR diagnosis. Often, it is only by fine needle aspiration–guided biopsy or by comparison to other studies that an early recurrence in such areas can be eliminated from diagnostic consideration.

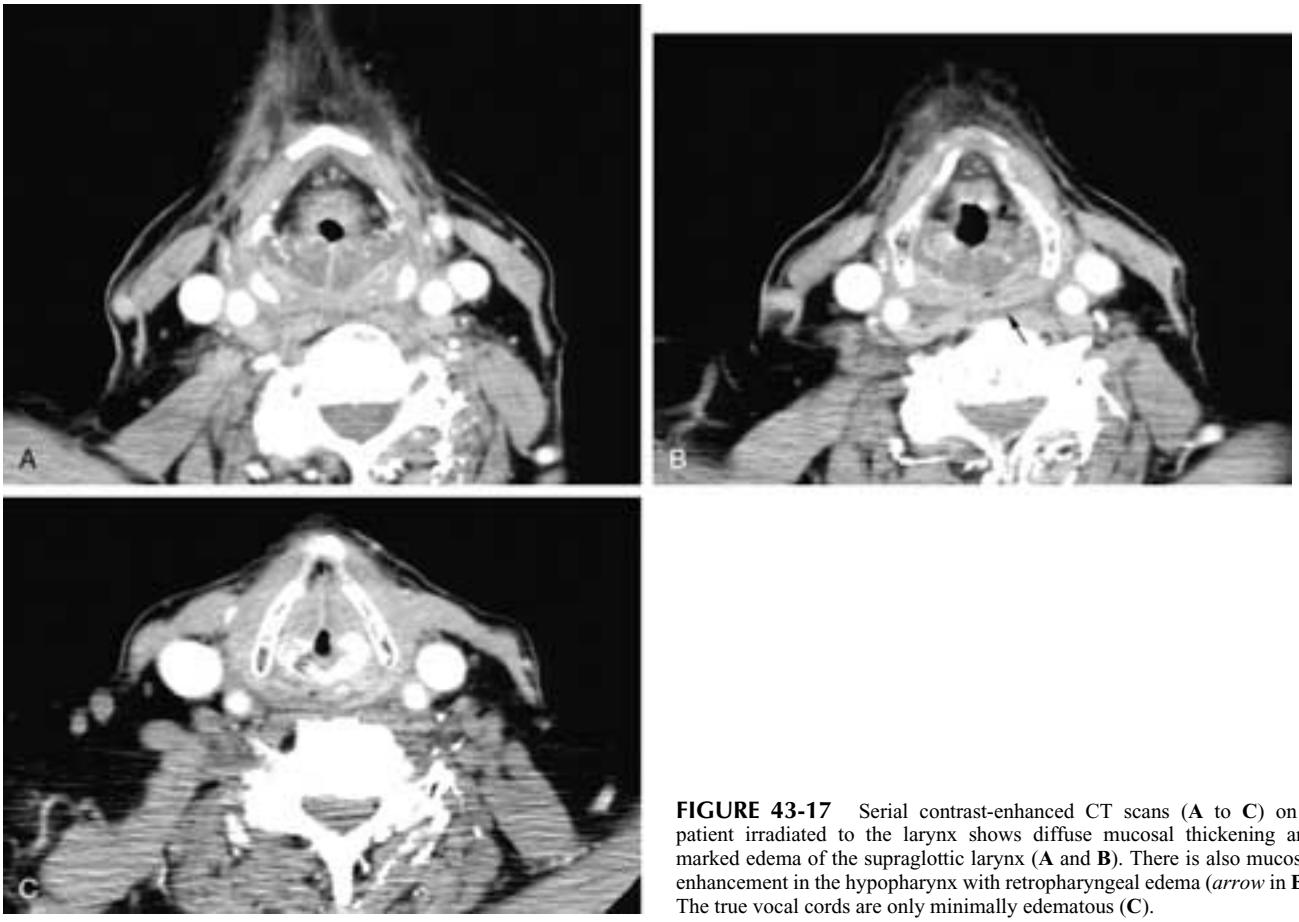

FIGURE 43-17 Serial contrast-enhanced CT scans (**A** to **C**) on a patient irradiated to the larynx shows diffuse mucosal thickening and marked edema of the supraglottic larynx (**A** and **B**). There is also mucosal enhancement in the hypopharynx with retropharyngeal edema (*arrow* in **B**). The true vocal cords are only minimally edematous (**C**).

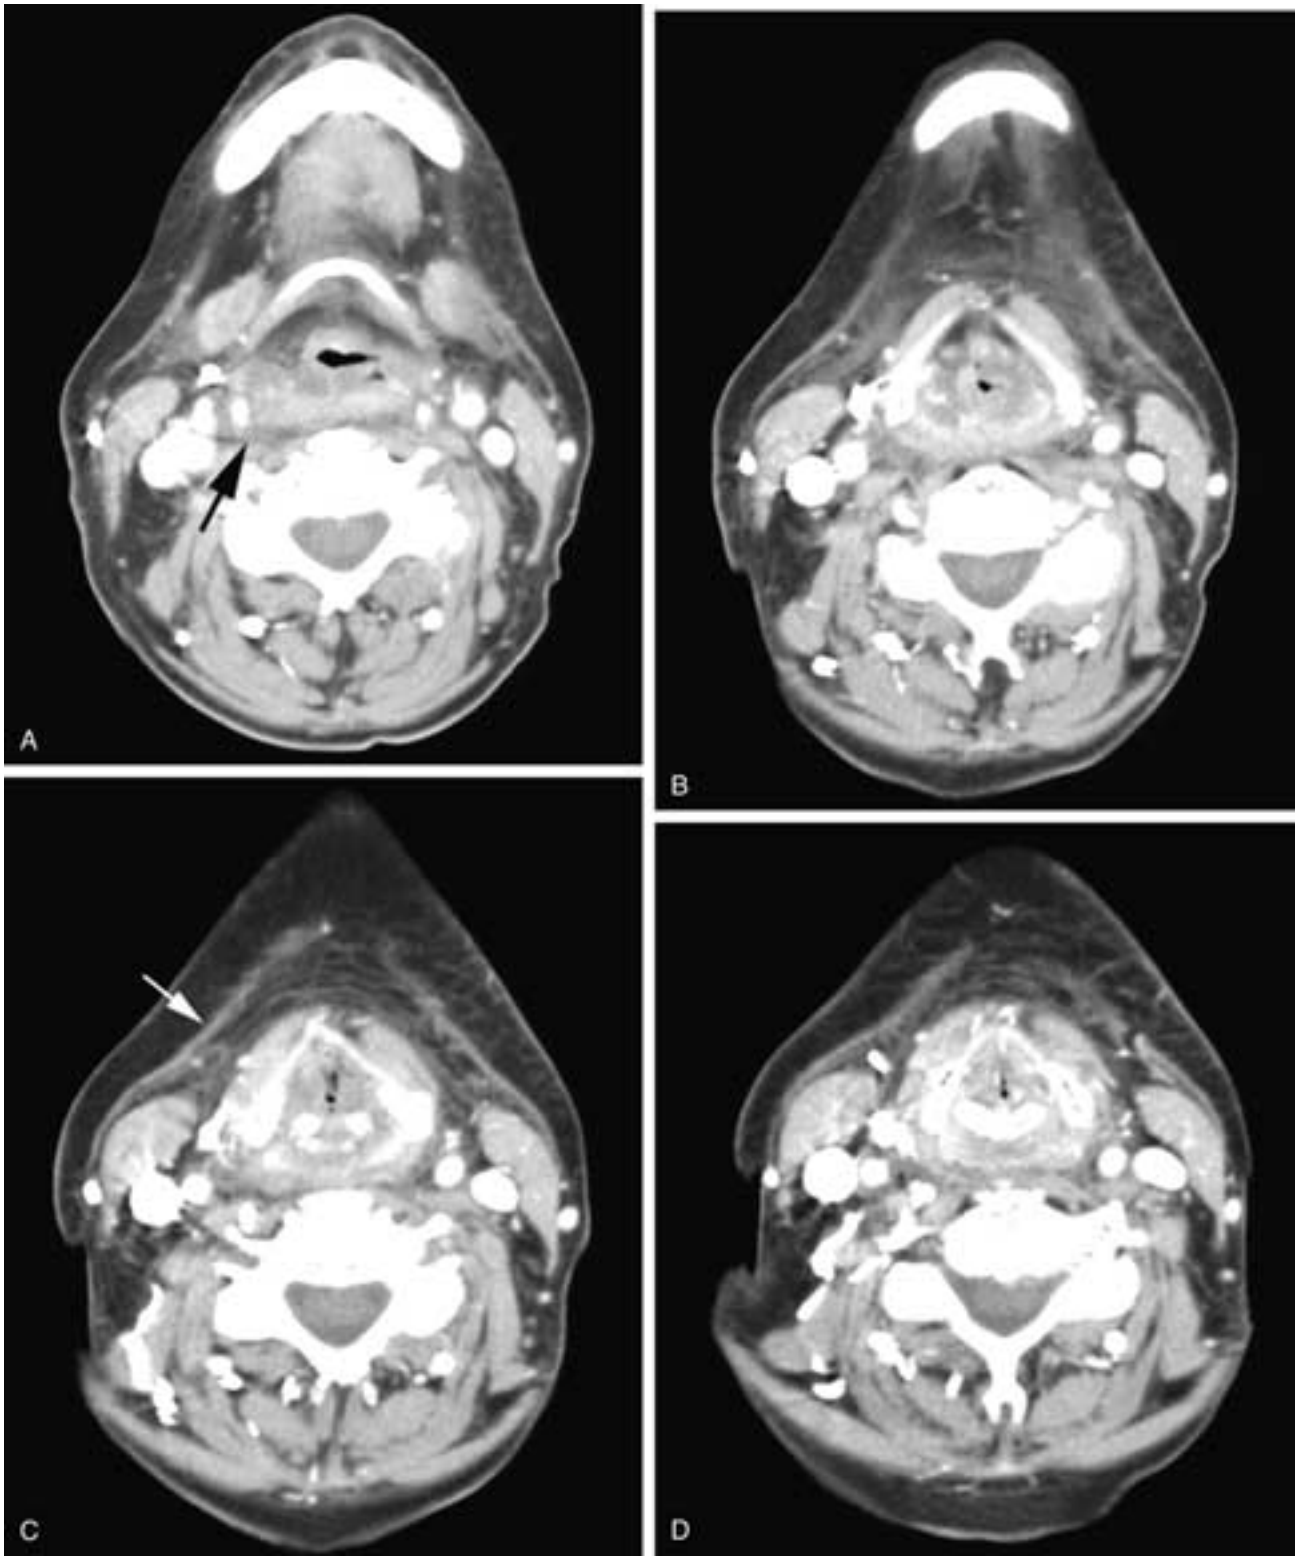

FIGURE 43-18 Serial axial contrast-enhanced CT scan from cranial (**A**) to caudal (**D**) in a patient who received RT to the neck. There is marked thickening of the mucosal surfaces, not only in the supraglottic larynx (**A** and **B**) but also in the glottic (**C**) and subglottic (**D**) larynx. This is a more pronounced reaction than normal (see Fig. 43-10). Note that the attenuation of the supraglottic laryngeal soft tissues is less than that of muscle, suggesting that it represents edema. Also note the retropharyngeal edema (arrow in **A**) usually seen in irradiated patients (see Fig. 43-10). In addition, there are edematous, inflammatory-type changes in the superficial subcutaneous fat with thickening of the platysma (*arrow* in **C**). Despite the apparent airway narrowing on imaging, many of these patients have no dyspnea.

In **B**, the squamous cell carcinoma recurrence has infiltrated the entire operative bed.

both the remaining native and transplanted bone in the operative field. In addition, at the site of these changes there may be ulceration, necrosis, and inflammation of the soft tissues. Often it is only by biopsy or local resection that the distinction between tumor and infection can finally be established.[61–63]

POST–NECK DISSECTION CHYLOUS FISTULA

A postoperative chylous fistula occurs in about 1% to 2% of neck dissection patients. Most of these fistulas occur when level IV nodes are dissected and there is the potential for injury to the thoracic duct. With CT and MR imaging, there is the appearance of a cystic mass with the characteristics of water. The cyst is almost always located in the lower left neck near the carotid sheath and the region of the thoracic duct (Fig. 43-38).

POSTTRAUMATIC NEUROMA

The development of a traumatic neuroma after neck surgery is an uncommon event. These lesions are not true neoplasms but rather reparative-type pseudotumors. When a peripheral nerve is disrupted at surgery, the distal end undergoes Wallerian degeneration while the proximal end initiates a proliferative reparative-type response. If there is only a small gap between the nerve ends, healing occurs. However, if there is a large gap, or if the gap is filled with scar, blood, or inflammatory or granulation-type tissue, the nerve ends cannot meet and a haphazard growth of the axons occurs, creating the traumatic neuroma. Most of these tumors are less than 2 cm in diameter, and they tend to occur along the dorsal margin of the incision line and involve cutaneous nerves from the cervical plexus.[64–73] Typically, there is localized pain or discomfort, with a ''trigger'' point often present. Fine needle aspiration biopsy of these superficial lesions is difficult because of their painful nature. These lesions can be observed for years; however, if the patient is very symptomatic, surgical excision is recommended.

Imaging reveals a mass with a relatively low attenuation central region; however, without clinical correlation, CT cannot confidently differentiate it from a localized implant-type recurrence or scarring (Fig. 43-39).

DERMAL METASTASIS

Metastasis to the skin from head and neck mucosal carcinomas is rare, developing in about 1% of cases. The median time to occurrence is 6 months, and 90% of the patients die of their disease within a median period of 3 months following diagnosis.[74] The development of skin metastasis is most closely related to the presence of two or more cervical metastases and/or the presence of extracapsular nodal spread in the cervical metastases. Similar risk factors have been identified for the development of distant metastases to other sites. Such metastases occur with greater frequency in immunocompromised patients, such as those

with HIV infection or chronic lymphocytic leukemia, or in cardiac transplant patients.[74–78] In HIV patients, rarely such dermal metastasis may occur in very aggressively behaving carcinomas prior to the identification of cervical nodal metastasis (Fig. 43-40).

NEWER TECHNIQUES

A discussion of the use of PET, thallium-201, and MR spectroscopy to better differentiate tumor from a nontumorous mass appears in Chapter 45. In the future, these techniques may offer the next echelon of diagnostic testing, beyond or in combination with routine CT and MR imaging.[18, 79–97]

VIEW IMAGE

INTRODUCTION

Basic Mechanisms of Entering and Exiting the Cell Division Cycle

Knowledge of the genetics of tumor development and metastasis may not be essential to the interpretation of all radiology studies. However, many of these imaging examinations are performed on patients who have malignancies, and the informed radiologist should understand the way in which these tumors develop. In addition, genetics-based imaging, a field now in its infancy, should become considerably more important in the near future. This chapter will review the current concepts of the genetics of tumors and metastasis. An understanding of this chapter requires a certain amount of knowledge regarding the basic biology of the cell cycle. While a thorough review of the cell cycle is beyond the scope of this chapter, a brief review is provided in the following paragraph that should facilitate absorption of concepts and terminology in the remainder of the chapter. In addition, a brief glossary appears at the end of this chapter.

Tumors generally arise through clonal expansion beginning with a single cell that has become aberrant, that is, transformed into a neoplastic state. It is important to note, however, that neoplasia does not just represent uncontrolled cell proliferation but may also represent failure of a cell to differentiate properly and, for that matter, failure to die under appropriate circumstances. Thus, many of the alterations that lead to transformation involve pathways controlling the cell division cycle and its relations to differentiation and to programmed cell death, termed *apoptosis*. The cell cycle is commonly described in terms of the phases G1, S, G2, and M. Gap1, or G1, is the gap between mitosis, M, and DNA synthesis, S. During G1, genes are activated and proteins synthesized to prepare the cell for DNA replication. S-phase is the period during which all of the DNA of a cell is replicated once and only once. Gap2, or G2, is the gap between DNA synthesis and mitosis. During G2, genes are activated and proteins synthesized to prepare the cell for mitosis, M, or cell division, at which time the duplicated DNA is distributed equally to each of the two daughter cells. Cells that are proliferating repeat these phases in that order. The cell cycle includes several checkpoints, which are referred to throughout this chapter. At these points, in response to aberrant progression a cell may exit the cycle. For example, G1 includes a ''start'' point at approximately midphase. Once a cell has traversed the start point, it is committed to undergo DNA replication. In response to signals indicating DNA damage, however, a cell may not traverse the start point. Such cells cease to proliferate, and most such cells undergo apoptosis. The start checkpoint is thus an important point at which cells with mutated DNA may be prevented from becoming cancerous. As discussed later in this chapter, several protein products of tumor suppressor genes participate in pathways impinging on start and other checkpoints. Another way for cells to exit the cell cycle is to enter the state known as G0, G-zero. The G0 state is frequently called quiescent since cells in it are not proliferating. In G0, however, cells may be active in various synthetic processes. Most differentiated cells in the body are in G0. Cells may leave the division cycle at start to enter G0. Conversely, cells in G0 may, in response to proliferative signals, reenter the cell cycle, and such reentry occurs at the start point in mid-G1. The proliferative capacity of a normal cell is not infinite. It is generally accepted that nontransformed cells of most tissues can divide 50 to 60 times before undergoing senescence. Senescence is a state in which cells live and may continue to grow, although they have lost their ability to proliferate. Neoplastic cells evade senescence and thus become immortal. Senescence is not considered in detail in this chapter, although it is presented in relation to the concept of renewal of telomeres, which are the ends of the linear DNA of chromosomes. As discussed, telomere renewal is important in the establishment of immortality in tumor cells. Understanding the relationship between controls over the cell cycle and its exit points sets the stage for an understanding of the genetic changes that lead to neoplasia.

Frequently, a given gene has the same abbreviation as the protein it encodes. In this chapter, in order to facilitate a distinction, gene names are italicized, while the names of corresponding proteins are not.

Gene Alterations Define Neoplasia

The revolution in molecular biology that accompanied the onset of gene cloning has now allowed the enumeration of certain genetic principles that are common to all cancers. These principles can be generalized as follows: (1) All cancers are caused by successive mutations in multiple genes that allow a cell to evade or override controls over a variety of processes that govern normal cell proliferation, adhesion, and mortality. (2) While certain of these mutations can be inherited, leading to a predisposition to cancer, the bulk of the mutations are acquired through action of environmental factors, including products of normal metabolism. (3) While gene mutations affecting a small, well-defined set of regulatory gene categories are necessary for and sufficient to induce neoplasia, mutations in many other genes affect tumor growth, metastasis, and the response to therapy.

Historically, our knowledge of the dominantly acting oncogenes came first because many of these genes were discovered as the transforming genes of acutely transforming retroviruses. A notable example is the *src* gene, the transforming gene of Rous sarcoma virus, which causes tumors in chickens. The Rous virus was discovered in 1911. However, the actual identification of the *src* gene did not occur until the elucidation of the genetic roles of DNA and RNA, as well as the understanding of the structure and replication of retroviruses in the 1950s and 1960s. With the discovery of the enzyme reverse transcriptase, the stage was set for rapid advances in the understanding of tumor genetics. Advances were also greatly facilitated by the discovery of restriction endonucleases, which allowed the development of the technology of molecular cloning in the mid-1970s.

As mentioned, traditionally the genes mutated in oncogenesis were categorized as either dominantly acting oncogenes or tumor suppressor genes. However, this neat

Copyright © 2003, Mosby, Inc. All rights reserved.

categorization has recently been blurred by discoveries of the multifunctionality of many proteins, so that genes encoding certain proteins can take on aspects of either oncogenes or tumor suppressor genes. In addition, there are genes that cause instability, and while these genes do not contribute to the maintenance of a malignant phenotype, they lead to other gene changes that do. That is, our view of oncogenes and tumor suppressor genes has evolved from a perception of them as separate categories to one that views them as a continuum, with stages between the extreme positions of recessive loss of function and dominant gain of function. It is now understood that certain genes, when mutated, may gain a function that contributes to cancer while losing other functions that may protect against cancer. In addition, certain mutations of tumor suppressor genes can confer a dominant negative phenotype on the encoded protein. Such a mutation would thus resemble a gain-of-function mutation characteristic of a dominantly acting oncogene. The *p53* gene is a notable example of this, having originally been considered a dominantly acting oncogene but later, with enhanced understanding of the types of mutations that can affect the gene, having been categorized as a tumor suppressor gene.

It is now generally recognized that combinations of genes must be sequentially altered to allow the progression toward cancer.[1] All cancers have alterations in oncogenes that confer advantages on specific cells to evade normal proliferative controls in order to form expanding clonal populations of cells. In addition, all cancers must have alterations in tumor suppressor genes to inactivate the ability of the products of these genes to confer a protective effect against evasion of growth controls. Our present knowledge is beginning to allow a generalization of the overall complex functions in which the products of these oncogenes and tumor suppressor genes are involved. The sequential involvement of an array of genes raises the question of how many mutational steps it takes to cause any given cancer. Initially, much of the work in this area came from in vitro studies on cultured cells. Many of the early oncogenes were identified as such by their ability to transform these cells to form tumors in immunologically compromised mice (see the section on Detection of Oncogenes in Human Tumors).

Do these in vitro studies indicate that only one or two genetic changes accompany the progreion to cancer in humans? Not necessarily, as studies of tumorigenesis in transgenic mice have indicated the necessity for multiple rate-limiting steps. Renan[2] considered the age-dependant diagnosis of many cancers in humans and suggested that four to seven stochastic, rate-limiting genetic alterations are involved. Studies of colon cancer by Vogelstein and colleagues[1] indicated that genetic changes accompany a series of premalignant states that ultimately culminate in metastatic cancer. In addition, further genetic changes are known to alter the ability of a tumor to respond to treatment. The ultimate summary of the studies on cell transformation, animal models, and statistical analyses of human tumors is that the development of a tumor proceeds through a series of genetic changes, each of which confers an advantage on a population of cells that allows that population to receive each successive genetic alteration more readily.

Characteristics Common to All Neoplasia Conferred by a Variety of Genetic Alterations

It is clear that various neoplasias can be caused by acquired mutations in multitudes of different cellular genes. The accumulation of data regarding the genes affected now allows investigators to discern patterns in the phenotypic characteristics that result from these changes, and it is evident that there is a set of acquired characteristics that are common to the development of most, if not all, cancers. In a review of the hallmarks of cancer, Hanahan and Weinberg[3] have enumerated six essential physiologic characteristics that are, taken together, sufficient to dictate malignant growth. These characteristics, which result from the wide variety of gene alterations, are self-sufficiency in growth signals, insensitivity to growth-inhibitory signals, evasion of programmed cell death (apoptosis), replicative immortality, sustained angiogenesis, and the capacity for tissue invasion and metastasis. These characteristics are summarized in Figure 44-1. The following discussion of oncogenes and tumor suppressor genes will demonstrate that most changes in dominantly acting oncogenes serve to confer on cells a self-sufficiency in growth signaling. Many such changes lead to growth signaling pathways that are constitutive and no longer reliant on induction by an extracellular signal. Most tumor suppressor gene products participate in pathways that are growth inhibitory or that lead cells with damaged DNA toward apoptosis. Acquisition of replicative immortality requires changes that allow a cell to regenerate chromosome telomeric repeats, tandemly repeated nucleotide sequences at the ends of chromosomes that ordinarily become progressively shorter with each round of DNA replication. Not all neoplasias require angiogenesis, and not

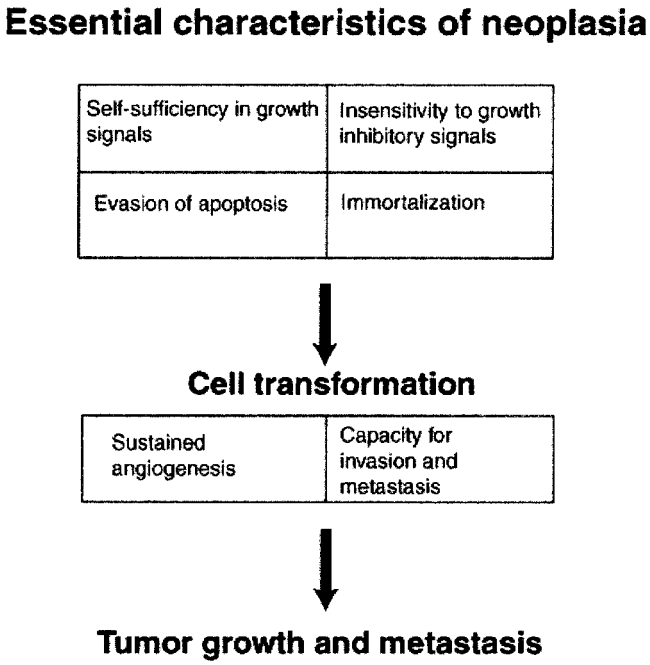

FIGURE 44-1 Six characteristics sufficient to dictate malignant growth. The characteristics of cells (large rectangle) and tumors (small rectangle) that can confer malignant tumor formation are described in detail by Hanahan and Weinberg.[3]

all are invasive or metastatic. Cells of virtually all neoplasias that produce a tumor mass, however, can undergo genetic alterations that bestow these characteristics on them. Such alterations may allow cells to produce factors that promote new blood vessel growth, or they may inactivate cadherins or integrins to allow cells to escape their usual sites of tethering. Clearly, not all of the genes altered in the progression to cancer fall neatly into the categories of dominantly acting oncogenes or tumor suppressor genes. Nonetheless, a discussion of these two broad classes of genes is informative in terms of understanding the mechanisms by which cancer cells acquire abnormal mechanisms of proliferation.

DOMINANTLY ACTING ONCOGENES

An oncogene is a cellular gene, the expression of which contributes in a dominant fashion to the development of cancer. Oncogenes of tumors arise through somatic mutation of normal cellular genes. Such genes perform various functions that contribute to the normal phenotype of cells. However, when they are mutated, they gain a function that confers on them the ability to avoid or to subvert a normal growth pattern. The functions of many of these normal genes, frequently referred to as proto-oncogenes, are not known. Most oncogenes have been discovered by their transforming characteristics and have thus been most thoroughly studied in their mutated, oncogenic forms. The oncogenes discussed here, as distinct from the tumor suppressor genes (which require both alleles to be mutated), require only one allele to be mutated to produce their oncogenic effects.

Viral Oncogenes

Many cellular oncogenes were first discovered by their homology to the transforming genes of various acutely transforming retroviruses. For example, the *myc* oncogene is the transforming gene of MC29 myelocytomatosis virus, which infects chickens. The *ErbB* oncogene is the transforming gene of Avian erythroblastosis virus, which also infects chickens. The *ras* oncogene is the transforming gene of rat sarcoma virus, and a similar viral oncogene is found in the Harvey murine sarcoma virus that infects mice. When hybridized to the DNA of host cells, the viral genomes were found to contain sequences that were also present in the genome of the host cell. It is now clear that the acutely transforming retroviruses gained their transforming genes through the transduction of genes normally present in uninfected host cells. Retroviruses that contain such an oncogene are capable of transforming cells in animal tissues with very high efficiency.

Not all retroviruses are oncogenic, and many oncogenic retroviruses do not contain transforming genes. All the genes just described, and many others mentioned in Table 44-1, are very homologous to their human counterparts. It is, in fact, rare for any human cancer to be associated with retroviral infection. The only human cancer directly caused by a retrovirus is human T-cell leukemia, the etiologic agent of which is the virus HTLV-1.

Detection of Oncogenes in Human Tumors

The characteristic that facilitated the early discovery of oncogenes versus tumor suppressor genes is the ability of the former to transform cells in tissue culture on DNA transfection. The ability to clone genomic libraries of DNA from tumor cells, to transfect noncancerous human cells in tissue culture, and to rescue the resulting transforming genes has been a standard means of detecting oncogenes for many years. In most early experiments, the mouse NIH3T3 cell line was a standard tool for such transformation studies. These cells are an immortalized mouse line. When transformed with DNA including an oncogene, they grow as anchorage-independent foci in soft agar, and plasmid rescue techniques can then be used to reextract and clone the transforming genes of such foci.

The immortalized NIH3T3 cells may already possess one or more altered genes contributing to a transformed phenotype. This type of assay obviously detects dominantly acting oncogenes and thus excludes genes in which the transforming mutation produces a loss of function. An early experiment of Robert Weinberg and coworkers showed that c-*myc* and H-*ras* can cooperate in transforming nonimmortalized mouse cells.[3] In this experiment, NIH3T3 cells were transformed by the transfection of H-*ras* alone. The nonimmortalized fibroblasts were, however, not transformed by H-*ras* alone. Nor did transfection with c-*myc* alone induce transformation. However, when the nonimmortalized fibroblasts were transfected with c-*myc*, they became immortalized and were subsequently transformed by transfection with H-*ras*. This experiment illustrates the concept that alteration of one oncogene may confer an advantage on a cell that facilitates transformation by a successive oncogene.

Human cells have been notoriously more difficult to transform with combinations of oncogenes than have mouse cells. Recently, however, transformation of nonimmortalized human cells has been achieved with combinations of oncogenes and tumor suppressor genes in further experiments by Weinberg and coworkers.[4] These experiments reinforce the point that dominantly acting oncogenes are critical, but not sufficient, components in the sequential progression of gene changes that lead to cancer.

Oncogenes Are Activated in Cells in a Variety of Ways

Oncogenes are activated in cancer cells in a variety of ways, all of which represent different forms of mutagenesis. In each case, the DNA sequence of a proto-oncogene or its transcriptional regulatory region is altered, but the means of alteration may be responsible for different effects on the activity of the protein ultimately expressed.

Insertional Mutagenesis

One means of oncogene activation is genomic insertion of a retroviral promoter, which can then activate the transcription of a particular downstream proto-oncogene while not necessarily altering the protein product of that gene. This mechanism of mutagenesis was first discovered with respect to the avian c-*myc* gene, the transcription of

which was observed to be activated from an inserted avian leukosis virus retroviral LTR promoter.

Another related but distinct mechanism of activation is genomic integration of an acutely transforming retrovirus. In this case, the virus carries its own activated oncogene with it, under the control of its LTR promoter. This is the mechanism of oncogenic transformation effected by acutely transforming retroviruses in animals. In yet another insertional mechanism, a retrovirus that does not necessarily contain a transforming gene may insert in a coding region or a regulatory region of a particular gene, disrupting production of the product of that gene.

Mutational Alteration of Gene Transcription

A proto-oncogene can become an oncogene through changes in its transcriptional regulation that cause it to be ectopically expressed. That is, the sequence within a gene regulatory region may be disrupted, causing the gene to be activated in the wrong place or at the wrong time. This type of activation frequently accompanies chromosome rearrangements, as exemplified by the c-*myc* gene in some cases of Burkitt's lymphoma, in which the transcription of the gene is activated, whereas the protein product of the gene remains unaffected. In many cases of Burkitt's lymphoma the c-*myc* gene undergoes a well-characterized translocation from its position on chromosome 8 to a position on chromosome 14, where it is subject to transcriptional activation by powerful immunoglobulin gene enhancers. In that mechanism, an ectopic expression of the gene is induced while the actual protein product of the gene remains normal.

Mutational Alteration of the Protein Coding Sequence

One mechanism of oncogene activation is mutation to alter the protein product of a particular proto-oncogene. For example, point mutations in the *ras* gene at codon 12 are known to result in an increased affinity of the *ras* protein for GTP, leading to activation of growth signal transduction pathways. Mutation to alter either gene regulation or protein structure may be induced by ionizing radiation as well as by the formation of DNA adducts resulting from exposure to chemical carcinogens. It has been noted that the vast majority of cancers are caused by exposure to chemical carcinogens. While these carcinogens certainly include many synthetically produced or released chemicals, they may also include chemicals generated by activities such as ingesting and metabolizing food. For example, oxygen free radicals generated as a normal metabolic by-product are believed to be responsible for most accumulating, inevitable DNA damage.

Chromosome Translocation to Generate an Aberrant Fusion Protein

Chromosome translocation frequently puts the product of one gene in a position to form an aberrant fusion protein

Copyright © 2003, Mosby, Inc. All rights reserved.

with the product of another gene. A thoroughly studied example of this mechanism is the chromosome 9:22 translocation that results in formation of a BCR-Abl fusion protein in chronic myelogenous leukemia (CML). In that case, the tyrosine kinase activity of Abl is altered, subject to characteristics of its BCR fusion. This mechanism is frequently associated with alteration in the characteristics of a variety of transcription factors, each of which may alter the course of cell differentiation, leading to cancer.

Selective Gene Amplification

One frequent mechanism of oncogene activation is selective gene amplification. In this mechanism, a chromosome region including, but not limited to, the relevant oncogene is multiply replicated relative to the genomic DNA. It is not fully understood how one segment of a chromosome is replicated relative to its flanking DNA sequences, but many investigators believe the process involves generation of a large extrachromosomal circular segment of DNA, through an aberrant recombination event, which can replicate autonomously. In cultured cells at an early passage following an amplification event, many small extrachromosomal segments containing the amplified region can be seen in metaphase spreads, and these appear almost as tiny chromosomes. These amplification products are termed *double minutes*. At a later stage following amplification, the amplified region can be visualized as a chromosomally integrated, homogeneously staining region (HSR). It is not known whether the HSR represents reintegration of extrachromosomally amplified material. Amplification has the effect of increasing the protein product of any active gene in the amplified region. It is known that in certain cases amplification arises in response to selective pressure. For example, in cancer cells treated with methotrexate or aminopterin, the dihydrofolate reductase gene, *DHFR*, may be amplified. This has the effect of reducing the effect of the chemotherapy and thus represents a survival mechanism for cancer cells. Examples of amplified oncogenes include the *myc* gene family members c-*myc*, l-*myc* and n-*myc*, each of which has been found to be amplified in small cell lung carcinoma. If one member of this family is amplified, other members of the family generally are not, leading to the notion of redundant intracellular function for the protein products of those genes. The *myc* gene family members are also amplified in several other cancers. c-*myc* is amplified in colon and breast carcinomas. n-*myc* is amplified in neuroblastoma and is associated with a poor prognosis.[5] Another example of selective amplification is the *ErbB-2* gene in breast cancer. As in the case of c-*myc* and breast cancer, amplification of *ErbB-2* is seen to occur at a late stage in cancer development and is associated with a poor prognosis.

Growth Factors and Growth Factor Receptors as Oncogenes

Most oncogenes are altered forms of genes that serve a normal function in pathways that convey a signal from outside of the cell to the cell nucleus in order to stimulate proliferation. The sequences of several oncogenes resemble those of extracellular growth factors, and the sequences of several more resemble those of growth factor receptors. For example, the sequence of the N-terminal 109 amino acids of the β-chain of platelet-derived growth factor (PDGF) is nearly identical to that of the protein $p28^{sis}$, the product of the transforming gene, *v-Sis* of the simian sarcoma virus. On the other hand, the *v-Erb-B* protein has sequence homology to the transmembrane and cytoplasmic domains of the epidermal growth factor (EGF) receptor. The cytoplasmic domain of the EGF receptor was revealed to possess tyrosine kinase activity, and it was subsequently shown that binding of the receptor to its ligand results in autophosphorylation of tyrosine residues in the cytoplasmic domain. This phosphorylation of tyrosine residues is a recurring theme among signal transduction proteins that can become oncogenes. The first tyrosine kinase to be discovered, in fact, was the *Src* protein of Rous sarcoma virus. Src is not itself a growth factor receptor, but rather a protein active near the cell membrane in signal transduction. It is now known that there are multiple growth factor receptors that utilize autophosphorylation of tyrosine residues to mediate signal transduction. These receptors are termed *receptor tyrosine kinases* (RTKs).

The RTKs are transmembrane proteins that contain an extracellular ligand-binding domain, a transmembrane domain, and cytoplasmic tyrosine kinase and carboxy-tail domains. The RTKs are capable of some fluidity within the cell membrane. It is believed that in response to ligand binding the receptors form dimers or higher oligomers, triggering autophosphorylation of the intracellular cytoplasmic domains. The tyrosine kinase activity of the receptors is essential for initiating an intracellular signal cascade mechanism.

Oncogene members of the RTK family can be activated by a variety of genetic alterations. Several such alterations involve the extracellular ligand-binding region of receptors, in which case they may create a receptor molecule that is constitutively active even in the absence of ligand. As mentioned, the *v-Erb-B* oncogene is a truncated form of the EGF receptor, lacking the ligand-binding domain. The *v-Ros* oncogene also has a large deletion of the ligand-binding domain. In other RTK oncogenes, however, mutations in either the transmembrane or tyrosine kinase domains have been observed to enhance the transforming potential. As noted, the *Erb-B2* gene is amplified in certain cases of breast cancer. This has the effect of increasing the number of cell surface receptors, thereby enhancing the response of the breast cell to the relevant growth factor ligand.

Autocrine and Paracrine Loops

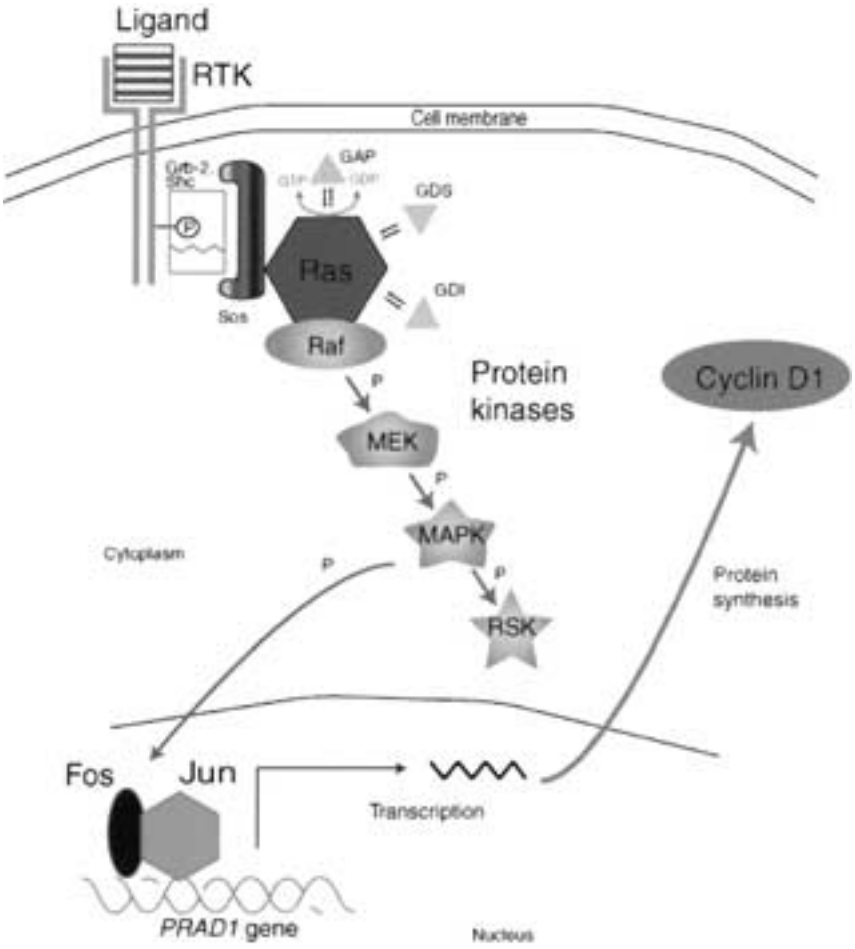
The interplay between growth factors and receptors can create situations highly conducive to tumor growth.[6] One example of this is the autocrine loop, which can arise when a cell produces a growth factor to which its own receptors respond. If, for example, a cell has an activated *Sis* oncogene and PDGF receptors on its cell surface, then it will overproduce a growth factor to which its own receptors respond by signaling for increased proliferation. A similar loop can exist if a cell overproduces a growth factor receptor that responds to a factor that is also produced by the cell. That may be the case in cells that possess an amplified *Erb-B2* gene. It is now recognized that paracrine loops may

Copyright © 2003, Mosby, Inc. All rights reserved.

be very important in the development of certain solid tumors. A paracrine loop can exist when two different cell types within a tissue each respond to a growth factor produced by the other. It is important to note that only one of the two cell types may have an activated oncogene and that thus only one of the types may constitute the tumor. This type of paracrine loop highlights the fact that normal cells are a component of many tumors and that the presence of such cells may be an important factor in tumor development.

Oncogenes in Intracellular Signal Transduction Pathways

The binding of a growth factor to its cell surface receptor triggers an intracellular response that culminates in a signal molecule entering the cell nucleus and activating gene transcription and/or DNA replication. This process of conveying a signal from the cell surface to the nucleus is called signal transduction. Several different pathways of signal transduction have now been identified, and they all have one feature in common: they rely on cascades of protein phosphorylation reactions involving protein kinases located at different positions in the cell. One such pathway, the Ras-MAP kinase pathway, is illustrated in Figure 44-2. This pathway is notable because several components of it are genetically altered in a variety of neoplasms. One component, Ras, is so frequently altered that it will be considered in detail in the next section. In this pathway, Grb-2 and Shc are adaptor proteins that recognize and bind to phosphorylated tyrosine residues in the intracellular domains of an activated RTK. Sos (son of sevenless) is a protein that is recruited to the inner surface of the cell membrane by its association with Grb-2. Sos is, in turn, a guanine-nucleotide exchange factor that activates Ras. Sos promotes the release of GDP by Ras and the subsequent binding of GPT, which configures Ras for active signal transduction. Several proteins can affect the Ras-GTP interaction. One such set of proteins are called GAP proteins or GTPase-activating proteins. These proteins play an inhibitory role in Ras activation by promoting GTP breakdown. One important GAP protein is neurofibromin, encoded by the neurofibromatosis tumor suppressor gene, *NF-1*. Activated Ras binds to and activates the serine-threonine protein kinase, Raf. The details of this activation are not completely known, but the activation appears to require participation of additional cellular proteins. A truncated form of Raf has been identified as a retroviral oncogene in animals. Raf phosphorylates and activates mitogen/extracellular signal-activated kinase (MEK), which, in turn, phosphorylates and activates mitogen-activated protein kinase (MAPK). Members of the MAPK family phosphorylate and activate transcription factors, exemplified in Figure 44-2 by Fos and Jun, which act in the cell nucleus to activate transcription. In this



VIEW IMAGE

FIGURE 44-2 The Ras-Map kinase pathway for intracellular growth factor signal transduction. The figure depicts signal transduction initiated by binding of a generalized growth factor to a dimerized receptor tyrosine kinase (RTK) at the cell plasma membrane. Ras is recruited to the inner surface of the membrane by the proteins shown in response to internal phosphorylation of tyrosine in the RTK. In its active GTP-bound form, Ras interacts with and activates the protein kinase Raf, initiating a cascade of protein phosphorylation events denoted by *P*. A GTPase-activating protein, GAP, interconverts active and inactive Ras forms. Mitogen-activated kinase (MAPK) can phosphorylate several transcription factors that enter the nucleus, as exemplified here by Fos and Jun, which together activate transcription of several genes, including the *PRAD1* gene, which encodes the protein cyclin D1. The protein kinase RSK is involved in translational aspects of protein synthesis. Mutation of genes encoding several proteins in this pathway can lead to self-sufficiency of growth signaling independence of the extracellular factor. (See Color Plate 1)

Copyright © 2003, Mosby, Inc. All rights reserved.

figure the gene *PRAD-1* is shown being activated. *PRAD-1*, itself oncogenically mutated in some cancers, encodes the protein cyclin D1, which plays a role in traversing the G1-S boundary in the cell cycle. Other transcription factors besides Fos and Jun may also be phosphorylated by MAPK. While activated Fos and Jun are capable of oncogenic transformation of cells in culture, they have not yet been linked to any human tumor. The activated protein kinase RSK phosphorylates certain substrates that facilitate protein translation. It is notable that this particular signal transduction pathway involves both tyrosine protein kinases (RTK) and serine-threonine protein kinases (MEK, MAPK, and RSK). Several other similar pathways are at various stages of elucidation, and certain of these may also be activated by Ras.

Two signaling pathways that are independent of Ras and that are known to be involved in certain cancers have recently been characterized to some degree. These are the Wnt pathway and the Hedgehog/Patched pathway. The Wnt proteins are members of a large family of ligands that mediate signaling related to tissue development. Wnt binds to the receptor Frizzled, triggering a cascade that culminates in translocation of the protein β-Catenin to the cell nucleus. β-Catenin had previously been identified as a protein involved in forming links between the intracellular domains of cadherins and the cytoskeleton, and its activity in the nucleus was thus surprising. In the nucleus, β-catenin interacts with the TCF/LEF transcription factor to activate genes involved in cell growth. The *Wnt* oncogene in mice is activated by integration of mouse mammary tumor virus, but human *Wnt* has not yet been linked to any tumor. The β-catenin gene, however, is mutated in several neoplasms including colon carcinoma and melanomas. The Hedgehog/Patched pathway is also involved in tissue development. Its arcane nomenclature stems from the fact that the pathway was largely worked out in *Drosophila*, where gene mutations can frequently have dramatic phenotypes. In *Drosophila* the Wnt and Hedgehog/Patched pathways frequently oppose each other in the development of polarized tissue structures. The secreted ligand Hedgehog binds to the receptor Smoothened, which has multiple transmembrane domains, triggering a cascade leading to cell growth. Smoothened activity is normally inhibited by another protein, Patched, and binding of Hedgehog relieves that inhibition. Mutations in the human homolog of Patched are detected in the hereditary nevoid basal cell carcinoma.

Ras Gene Activation in Multiple Neoplasms

The *Ras* genes are paradigmatic examples of genes that undergo dominant gain of function related to oncogenic transformation as a result of mutation of one allele. Members of the *Ras* gene family are mutated in approximately 30% of all human tumors and are thus the most frequently encountered oncogenes. In addition to their frequent mutation in lung and colon cancer, *Ras* mutations are detected in more than 90% of cases of pancreatic cancer. Among the known members of the *Ras* gene family are H-*ras* and K-*ras*, both of which are homologous to genes originally discovered as retroviral transforming genes. H-*ras* encodes a 21 kDa protein that, as described in the last section, is a GTP-binding signal transduction protein. Binding of GTP to Ras induces a conformational change in the protein that activates it for signal transduction to downstream proteins. Ras also hydrolyzes GTP to GDP, and bound GDP is inhibitory to activation. Most mutations in Ras genes are point mutations in codons that inhibit the ability of Ras to hydrolyze GTP. Codons 12 and 61 are the ones most frequently mutated. Little is known about differences in the functions of various Ras family members, but they appear to play important roles in different cell types. H-*ras* is most frequently mutated in colon cancer, and K-*ras* is most frequently mutated in pancreatic cancer. N-*ras* has been detected in neuroblastoma. Intriguingly, certain tumors have no *Ras* mutations. For example, no primary neuronal tumors have been found with *Ras* mutations. In many of these tumors, however, inactivating mutations are detected in the *NF-1* protein, neurofibromin, which is inhibitory to Ras activation. Therefore, activated *Ras* may be an important factor in development of these tumors as well.

The c-*myc* Oncogene in Burkitt's Lymphoma

The c-*myc* gene is located near the telomeres of the long arms of chromosome 8, at band 8q24. It consists of three exons that encode a protein that serves, among other possible functions, as a transcription factor. The Myc protein, together with a partner protein, Max, activates several genes involved in stimulating cell proliferation. Myc also plays a role in immortalization of cells, that is, allowing the cells to escape senescence after several rounds of cell division. Mutations in c-*myc* in the B-cell tumor, Burkitt's lymphoma, involve chromosome translocations. As opposed to mutations in *Ras* genes, mutations in c-*myc* frequently do not alter the protein structure at all. In approximately 75% of cases of Burkitt's lymphoma, the c-*myc* gene is translocated to the long arm of chromosome 14, to band 14q32. In these cases the c-*myc* gene is placed in the transcriptional control region of the immunoglobulin heavy chain (C_μ) gene. In 25% of cases a portion of either chromosome 2 or 22 is translocated to chromosome 8, and in these cases c-*myc* is placed in the transcriptional control region of immunoglobulin light chain loci. In other words, in virtually every case of Burkitt's lymphoma, the c-*myc* gene, which is normally minimally active in B cells, is placed under the control of a control region promoting high transcriptional activity, that is, the control region of a gene making antibodies for the B cells. Thus, activation of the c-*myc* gene usually involves increased production of the Myc protein rather than a change in the structure of the encoded protein. In Africa, Burkitt's lymphoma occurs in a geographic belt that coincides with a belt of Epstein-Barr virus (EBV) infection, and most cases of Burkitt's lymphoma involve B cells infected with that virus. For a long time it was suspected that EBV was a causative agent of Burkitt's lymphoma. In the United States, however, most cases of Burkitt's lymphoma do not involve EBV infection, although all cases show translocations involving c-*myc*. It is now believed that EBV helps to promote the development of Burkitt's lymphoma by promoting clonal expansion of populations of B cells. This may provide a favorable environment for expansion of a clone containing, or about to contain, a critical chromosome 8 translocation.

Translocations That Create Oncogenic Fusion Proteins

The Philadelphia Chromosome

In more than 90% of cases of chronic myelogenous leukemia (CML), cytogenetics reveals the presence of a small, readily identifiable chromosome known as the Philadelphia chromosome. This chromosome is also present in approximately 20% of cases of acute lymphocytic leukemia (ALL) and 5% of acute myelogenous leukemia (AML). This aberrant chromosome is now known to be the result of a translocation between chromosomes 9 and 22. In this translocation, the C-terminal portion of the coding region of the c-*abl* gene, located near the telomeres of chromosome 9, is translocated to a region of chromosome 22 called the breakpoint cluster region (bcr). This translocation is an example of a phenomenon now known to be very widespread in neoplasia, that is, the generation of an oncogenic fusion protein. The N terminus of this new chaemeric protein is a portion of a protein of unknown function called bcr, and the C terminus is that portion of c-*abl* containing tyrosine kinase activity. In most cases of CML a bcr-abl fusion protein of 210 kDa is generated, while in most cases of ALL the fusion protein is 190 kDa. In both cases, the bcr-abl fusion protein has enhanced tyrosine kinase activity compared to that of intact Abl. The normal cellular functions of Abl are not completely known, but as tyrosine kinases are important in intracellular signaling, it is presumed that enhanced kinase activity would lead to enhanced downstream signaling effects.

Translocations Involving Transcription Factors

Recently, several chromosome translocations that create oncogenic fusion proteins in various leukemias have been characterized. Intriguingly, many of these involve transcription factors. In pre-B-cell lymphoblastic leukemia a t(1:19) translocation creates the E2A-PBX1 fusion protein, in which the transcriptional activation domain from E2A is fused to the DNA-binding homeodomain of PBX1. This allows E2A to strongly activate transcription from promoter regions containing the PBX1 binding site. In a very similar situation, the gene encoding another homeoprotein, hrx, is disrupted by translocations at 11q23 occurring in myeloid and lymphoid leukemias. In these cases, hrx may be fused with a wide variety of other proteins. It is believed that most of the fusion partners of hrx possess dimerization domains that can enhance DNA-binding effects of the hrx portion of the protein.

TUMOR SUPPRESSOR GENES

A tumor suppressor gene is defined as a gene in which both alleles must be inactivated in order for cancer to develop. Although tumor suppressor genes are frequently called recessive oncogenes, a *predisposition* to cancer is inherited as a dominant phenotype. The proteins encoded by tumor suppressor genes generally function to confer a protective effect against cancer. Mutations thus cause a loss of function. This is in distinct contrast to dominantly acting oncogenes, which encode proteins that gain a function, usually not related to the original function of the protein, that leads to cancer.

Familial Cancer Syndromes

Mutations in tumor suppressor genes are responsible for inherited cancer syndromes. This phenomenon is explained by the *two-hit* hypothesis of Knudsen.[7] In that scenario, a mutation in one allele of a tumor suppressor gene is inherited through the germ line. This does not cause cancer, but since every cell of the inheriting individual carries one mutated allele, it becomes statistically more likely that a second mutation will be acquired in the remaining allele. Most, but not all, familial cancer syndromes involve several kinds of cancer. It remains to be explained why different tumor suppressor genes predispose to specific kinds of cancers.

Retinoblastoma and RB

Retinoblastoma is the most common malignant intraocular tumor of childhood. While it is rare, it accounts for nearly 1% of all childhood neoplasms. The disease is believed to originate in developing cells of the cone lineage. Retinoblastoma occurs in either a hereditary form or a sporadic form. In the hereditary form, aberrations can be detected in chromosome band 13q14 in every somatic cell of the body, indicating germ line transmission of a defective allele. In the tumor cells, both alleles of the target gene at this band, termed the *RB* gene, are defective. In the sporadic form of retinoblastoma, somatic cells do not reveal *RB* aberrations, but again, the tumor cells possess two defective *RB* alleles. The differences between the hereditary and sporadic forms of retinoblastoma are satisfactorily accounted for by the two-hit hypothesis put forth by Knudsen and summarized in Figure 44-3.

Approximately 40% of all retinoblastoma cases are hereditary, and in these cases the disease is usually bilateral, that is, affecting both eyes of an individual. In the hereditary form, the affected individual does not inherit the tumor but rather a predisposition to acquiring the tumor. That predisposition is transmitted in the form of one defective *RB* allele. That inherited defect is the first hit in the two-hit progression. Evidently, the possession of one normal *RB* allele provides sufficient protein to retain its tumor suppressive activities. Hit two is an environmentally acquired defect in the remaining *RB* allele, and this occurs in cells giving rise to the tumor. It remains mysterious why cells in the retina preferentially acquire hit two since, after all, every cell of the body possesses hit one. It is quite conceivable that cells of the retina respond to light radiation in ways that, as an unintended by-product, facilitate mutagenesis. This is consistent with the observation that many hereditary retinoblastomas are bilateral, that is, that the statistical probability of acquiring hit two in a retinal cell is so high that the event can occur twice in the same individual. In the sporadic form of retinoblastoma, hits one and two are both acquired. The sporadic forms may involve bilateral tumors, but most frequently they are unilateral. Of course, the probability of acquiring two hits in the *RB* gene is much lower than that of acquiring one hit. This accounts for the fact that the incidence of sporadic retinoblastoma is very low, affecting about 1 in 30,000 people.

Copyright © 2003, Mosby, Inc. All rights reserved.

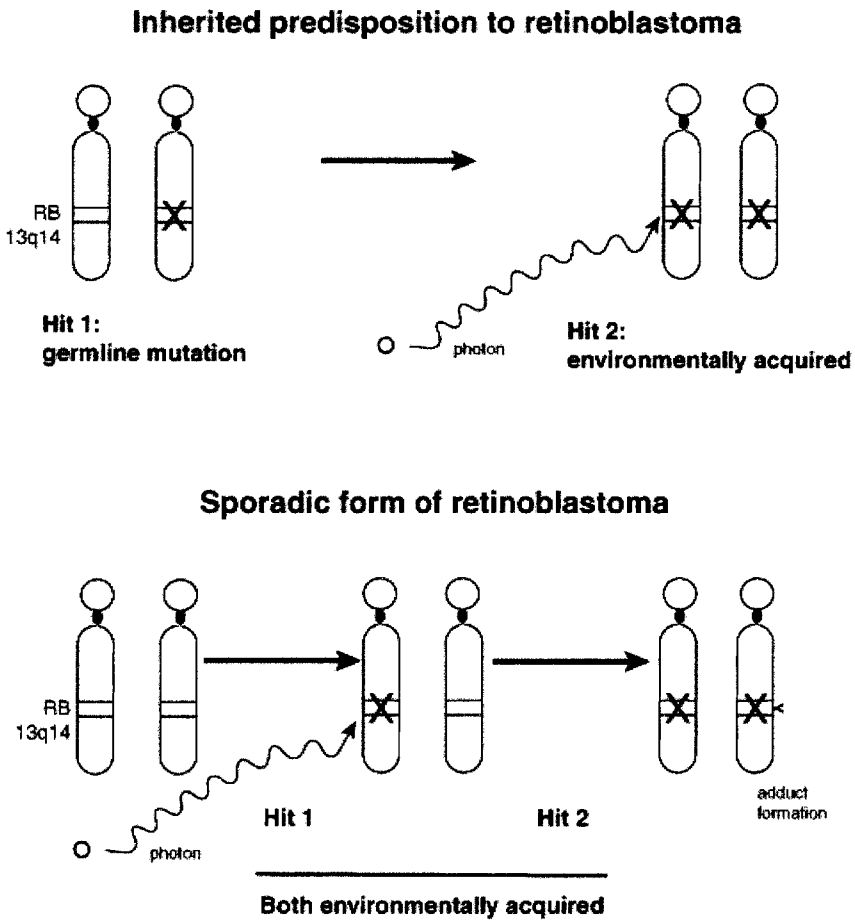

FIGURE 44-3 The two-hit hypothesis of tumor suppressor gene inactivation. This hypothesis was first promulgated by Alfred Knudsen[7] to explain the inheritance of a predisposition to neoplasia in familial neoplastic syndromes. It is exemplified here by inactivation of the *RB* gene on chromosome 13 in retinoblastoma. The essence of this hypothesis is that some people inherit an inactivating mutation of one allele of a tumor suppressor gene. Note that they thus dominantly inherit a predisposition to neoplasia, not the neoplasia itself. The predisposition is due to the fact that only one additional environmental hit is required for transformation.

VIEW IMAGE

Defects in *RB* are not exclusively associated with retinoblastoma. Retinoblastoma is a familial cancer syndrome potentially involving multiple tumors, and people who have had ocular tumors removed remain at risk for additional tumors, most notably osteosarcoma and mammary carcinoma. In addition, defects in the *RB* gene have been detected in a wide variety of cancers not associated with retinoblastoma. Defects in the structure or expression of the Rb protein have been found in a high percentage of both small-cell and non-small-cell lung carcinomas. Such defects have also been found in approximately 22% of all mammary carcinomas.

Li-Fraumeni Syndrome and p53

Li-Fraumeni syndrome is an inherited predisposition to develop a wide variety of cancers.[8] Comparable to the relationship described above between retinoblastoma and a mutated *RB* gene, the predisposition to cancer in Li-Fraumeni syndrome results from inheritance of a single mutated *p53* gene at chromosome band 17p13. Cancers in different organs thus develop via acquired mutations in the remaining *p53* allele, consistent with the two-hit hypothesis of Knudsen. Of all known tumor suppressor genes, *p53* is implicated in the widest variety of neoplasms, including high percentages of the three most common cancers: those of the lung, colon, and breast. The p53 protein is mutated or absent in a majority of cases of small-cell lung carcinoma. Similarly, p53 is inactivated in approximately 75% of cases of colorectal carcinoma. p53 has also been implicated in hepatocellular carcinoma, glial cell tumors of the brain, certain cases of malignant mesothelioma, and many additional neoplasms.

The gene encoding p53 was actually discovered prior to that encoding Rb, but it was not initially recognized as a tumor suppressor gene. In part this was due to the fact that certain mutations of p53 confer upon it a dominant-negative activity. That is, structural alterations can confer upon the mutated p53 protein the ability to interfere with activity of the protein encoded by the remaining normal allele. In that situation, mutation of p53 more closely resembles that of a dominantly acting oncogene than that of a tumor suppressor gene. The p53 protein is a transcription factor involved in pathways of response to DNA damage. As such, it either protects a cell against oncogenic transformation or ensures that a cell with excessive DNA damage undergoes programmed cell death. As will be described subsequently, several oncogenic DNA viruses encode proteins that bind to and inactivate p53 and/or Rb. They presumably do so by mimicking the protein-binding capacities of normal cellular proteins. Figure 44-4 summarizes the relationship between inactivation of p53 by mutations and by interaction with viral proteins, both of which target regions in the p53 DNA-binding domains.

Li-Fraumeni syndrome was recognized as a familial cancer syndrome only in the mid-1980s.[8] The reason for this slow recognition is simply that the wide variety of cancers

Copyright © 2003, Mosby, Inc. All rights reserved.

for which a predisposition is inherited obscures the familial relationship. For example, breast cancer in one family member may not be perceived as related to, say, brain tumor in a cousin. The functional activities of tumor suppressor gene products, including p53, are being intensively studied, and results are yielding important information regarding potential courses of therapy. Using Rb and p53 as examples, these activities are discussed in some detail below.

Guardians and Gatekeepers

The protein products of tumor suppressor genes have commonly been characterized in terms of their classification as either *guardians* or *gatekeepers*. These two broad categories reflect the protective roles of many tumor suppressor gene products. The underlying concept is that guardians prevent the accumulation of DNA damage that would lead to oncogenic transformation, whereas gatekeepers prevent cells that have accumulated such damage from passing through critical cell cycle checkpoints. While useful in considering protein functions, our now detailed knowledge of cell cycle regulatory pathways renders this classification a bit simplistic. The multiple functions of certain tumor suppressor gene products can blur the distinction between these classes. For example, the p53 protein could be considered either a guardian or a gatekeeper. It is a transcription factor, the activity of which is enhanced by DNA damage. The p53 protein activates a variety of cellular processes leading to DNA repair or, in the case of extensive DNA damage, leading to exit of the cell cycle through apoptosis. Thus, p53 guards against a highly mutated cell progressing to cancer. On the other hand, one gene induced by p53 is that encoding the CDK inhibitor, p21. Since p21 inhibits phosphorylation of the retinoblastoma protein, Rb, it can prevent the G1-S transition. Thus, transcriptional activating activity of p53 could also qualify it as a gatekeeper. Rb could be considered a gatekeeper since in its hypophosphorylated form it binds several regulatory proteins and prevents them from mediating the entry into S-phase. In G1 of the cell cycle, or in response to several growth signals, Rb becomes hyperphosphorylated, upon which it releases regulatory proteins that promote entry to S-phase. The phosphorylation of Rb is sensitive to signals stemming from DNA damage. Thus, Rb controls passage through an important checkpoint for cell proliferation. On the other hand, since several proteins regulating Rb phosphorylation are sensitive to DNA damage, this pathway could be perceived as guarding against accumulation of such damage. Figure 44-5 summarizes certain interactive aspects of Rb- and p53-related pathways of cell cycle control.

The Retinoblastoma Protein, Rb, and Cell Cycle Control

RB is the first gene to be characterized as a tumor suppressor gene. It had been known for decades that childhood retinoblastoma is associated with aberrations at chromosome band 13q14. In the mid-1980s the gene was

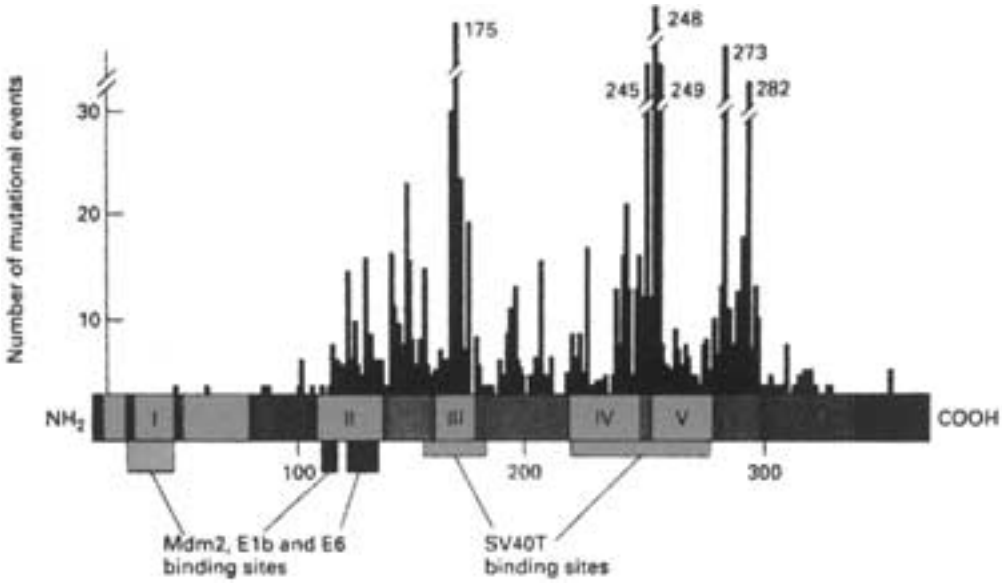

FIGURE 44-4 Distribution of mutations in the *p53* tumor suppressor gene in various tumors. The p53 protein is schematized, and amino acids are enumerated on the x-axis.[19] On the y-axis, numbers of mutations at each amino acid position are presented as recorded in a variety of tumors. The majority of mutations occur in the central DNA-binding domains of p53. Note that regions in these domains are also targeted for binding by viral proteins that inactivate p53. E1b is an adenoviral protein, E6 is a papilloma viral protein, and the SV40 large T antigen is a simian virus 40 protein. The site specificity of the mutations is due in part to the environmental agents that caused them. For example, certain sites are preferentially mutated by aflatoxin B1 in hepatocellular carcinoma, and other sites are preferentially observed in lung adenocarcinoma, presumably mutated by benzo-a-pyrene or other agents in cigarette smoke. (From Denissenko MF, Pao A, Tang M, Pfeifer GE. Preferential formation of benzo [a]pyrene adducts at lung cancer mutational hotspots in P53. Science 1996;274:430. Copyright 1996 American Association for the Advancement of Science.) (See Color Plate 2)

VIEW IMAGE

FIGURE 44-5 Involvement of several tumor suppressor gene products in pathways leading to cessation of cell growth or to apoptosis in response to DNA damage. Processes leading to activated cell proliferation, that is, entry to S-phase of the cell cycle, are indicated in green. Processes inhibiting cell proliferation are indicated in red. In response to DNA damage, such as that caused by ionizing radiation, for example, the ATM protein kinase phosphorylates and activates p53. The p53 protein, in turn, through effects on gene transcription, activates pathways leading to either apoptosis or cessation of cell growth. Transcription of the *p21* gene is activated by p53. The p21 protein is an inhibitor of both CDK2, necessary for initiation of DNA replication, and CDK4, which catalyzes phosphorylation of Rb. Hyperphosphorylation of Rb is necessary to trigger events leading to the G1-S transition. Two different products of another tumor suppressor gene, *p16/ARF*, play important roles in inhibiting cell proliferation. ARF binds to MDM2 and prevents it from targeting p53 for proteolytic destruction. The p16 protein specifically inhibits CDK4 kinase activity, preventing phosphorylation of Rb. Several proteins are indicated in magenta. It is believed that at least one of the four genes encoding these proteins, *ARF/p16*, *cyclin D1*, *p53*, and *Rb*, is mutated in every neoplasia. (See Color Plate 3)

identified and sequenced by W.-H. Lee and colleagues, revealing its product to be a protein of approximately 110 kDa.[9, 10] The phosphorylation of Rb is cell cycle dependent. In mid-G1, phosphorylation is begun by the cyclin D1/CDK4 protein kinase. Rb is then further phosphorylated by other D cyclins and CDKs and by cyclin E/CDK2. Rb, when hyperphosphorylated, releases a transcription factor, E2F1, which activates several genes necessary for entry into S-phase. Another important function of Rb is to repress transcription by binding to transcription factors, such as E2F1, when they are bound to gene promoters. To do this, Rb attracts the enzyme histone deacetylase, which configures chromatin to be inactive. Rb phosphorylation is inhibited by the protein p21, and the p21 gene is in turn upregulated by p53. Thus, there is an intimate link between the pathways regulated by Rb and p53. The product of another tumor suppressor gene, $p16^{INK4}$, also inhibits Rb phosphorylation. Both p21 and p16 block phosphorylation by the protein kinase CDK4, which is regulated by cyclin D1. Cyclin D1, in turn, is upregulated by the Ras-MAP kinase pathway, thereby promoting passage through the G1 start point of the cell cycle. It is believed that at least one of the following four genes is disrupted in virtually every form of cancer: *RB*, *p53*, $p16^{INK4}$, or *PRAD1* (the last encodes cyclin D1).

The p53 Protein and DNA Damage

The *p53* gene is the tumor suppressor gene most frequently mutated in cancer. The activity of the p53 protein is modulated by DNA damage. Association of p53 with another protein, MDM2, targets p53 for destruction. However, p53 is stabilized by phosphorylation catalyzed by

Copyright © 2003, Mosby, Inc. All rights reserved.

the protein kinase ATM. ATM may be a signal-transducing link between DNA repair enzymes, activated by DNA damage, and pathways activated by p53.[11] The *ATM* gene is itself a tumor suppressor gene mutated in many cases of breast cancer. Another protein, ARF, also stabilizes p53, in this case by inhibiting the action of MDM2. ARF is a gene product encoded by an alternate frame of the *p16* locus, and thus *ARF* is also a tumor suppressor gene. The protective functions of both p16 and ARF may be lost by a single mutation in the *p16/ARF* locus. The p53 protein, as a transcription factor, upregulates the gene encoding p21, which is an inhibitor of both CDK2 and CDK4 kinases. Thus, in response to DNA damage, pathways inhibiting cell cycle progression are activated by p53. The p53 protein also upregulates the gene for BAX, a protein activating caspase pathways leading to apoptosis.

Another aspect of p53 activity may serve to facilitate DNA repair. The p21 protein, upregulated by p53, performs an additional function separate from its ability to inhibit CDK kinases. p21 also binds to the protein PCNA and modulates its activity. PCNA is a processivity factor for DNA polymerase, and it may function in DNA recombination/repair pathways. The activities of the p53 protein are thus ordered in two somewhat disparate directions. Some functions are directed toward DNA repair, a process that facilitates cell survival. Other functions of p53 are directed toward eliminating cells with excessive DNA damage through apoptosis. The regulatory mechanisms through which p53 activities are directed to either DNA repair or apoptosis have yet to be fully elucidated.

Genome Instability Syndromes

Hereditary Nonpolyposis Colon Cancer

One class of tumor suppressor genes does not fit neatly into either the guardian or gatekeeper category. Several genes in this class encode proteins, the loss of function of which through mutation leads to genome instability. Frequently, these proteins are involved in DNA repair. For example, the *MSH2* and *MLH1* genes, mutated in hereditary nonpolyposis colon cancer, carry out steps in DNA mismatch repair. This disease is an inherited predisposition to colon adenocarcinoma that is not associated with familial polyposis. When both alleles of these genes are inactivated, the rate of mutation in an affected cell can increase up to 1000-fold. Thus, generations of affected cells accumulate mutations, ultimately culminating in oncogenic transformation. Any mutated gene that results in such genome instability is said to confer a mutator phenotype. Such genes constitute an unusual class of tumor suppressor genes since two mutated alleles can be inherited. In that case, the predisposition to cancer can be inherited in a recessive fashion.

Bloom and Werner Syndromes

Two genome instability syndromes, Bloom syndrome and Werner syndrome, are highly interesting because the mutated genes encode DNA helicases of the recQ family. The two genes are termed *BLM* and *WRN*, respectively. Bloom syndrome is associated with multiple leukemias and gastrointestinal cancers, and Werner syndrome is associated with multiple sarcomas. The enzymatic nature of the BLM and WRN helicases is to unwind DNA in a processive, ATP-dependent manner. While the exact functions of these two proteins are not known, such unwinding is an important aspect of DNA replication, recombination, and repair. Disruption of the *WRN* gene also leads to many changes characteristic of premature aging, including wrinkling, cardiovascular changes, cataracts, and others. Such changes due to inactivation of a single gene highlight the relevance of accumulating DNA damage to the aging process.

A Variety of Tumor Suppressor Genes Regulating Protective Mechanisms

Presently, *RB* and *p53* are the two most thoroughly characterized tumor suppressor genes and two of the most commonly mutated genes in all neoplasms. In fact, mutations or deletions in *p53* are currently the genetic aberrations most widely detected in cancer. In addition, as discussed with regard to viral causes of cancer, inactivation of the products of these two genes is sufficient to allow DNA tumor viruses' oncogenic potential. Nonetheless, the list of known tumor suppressor genes is expanding rapidly, and we are just beginning to appreciate the extent to which certain other such genes may be involved in neoplastic transformation. These genes encode proteins involved in highly diverse cell activities. In general, these processes confer a protective effect against neoplastic transformation, either by protecting the genome from damage or by ensuring that a cell with potential oncogenic damage does not continue to grow. The following discussion and the list in Table 44-1 are not compendia of known tumor suppressor genes, since that number is growing constantly, but rather a discussion of selected genes the functions of which are enhancing our understanding of tumor suppressive pathways. While the familial syndromes associated with defects in these genes include various cancers, in many cases they are not limited to cancer.

The Gene Mutated in Ataxia-Telangiectasia, ATM

The gene mutated in the genetic disorder ataxia-telangiectasia (AT), is critical in providing a protective effect against ionizing radiation. AT is characterized by cerebellar ataxia, enhanced sensitivity to ionizing radiation, immunodeficiency, and the evasion of cell cycle checkpoints leading to a predisposition to cancer. The gene *ATM*, for AT mutated, has been identified as a major tumor suppressor gene for breast cancer. The ATM protein is a protein kinase with multiple substrates within the cell. Cells cultured from individuals with AT are defective in the G1/S cell cycle checkpoint activated by radiation damage. This defect has been shown to be a consequence of a defective p53 response pathway. In this pathway, cells with extensive DNA damage are directed toward leaving the cell cycle and undergoing apoptosis. ATM phosphorylates p53 on serine residue 15, and this phosphorylation contributes to the activation of p53 and to its stabilization by countering the ability of protein MDM2 to target p53 for degradation. ATM phosphorylation of other cellular substrates is also undoubtedly important since the AT cells display a highly complex phenotype.

Copyright © 2003, Mosby, Inc. All rights reserved.

Transfection of AT cells to overexpress ATM restores the normal phosphorylation of p53 in response to ionizing radiation. Clearly, tumors with defects in the *ATM* or *p53* genes will show a reduced ability to respond positively to the therapeutic effects of radiation.

ARF *and* p16: *Unusual Overlapping Tumor Suppressor Genes*

The *INK4a-ARF* locus, at chromosome band 9q21, encodes two proteins, mRNAs, which are transcribed in the same direction from a single promoter. The two proteins, however, are completely distinct since they are generated from alternate reading frames, depending upon mRNA splicing. The proteins, p16(INK4) and p19(ARF), each display growth inhibitory properties, the first by influencing Rb checkpoint control and the second by influencing p53-mediated growth arrest. P16(INK4a) is an inhibitor of CDK4 and can prevent cyclin D1/CDK4 from phosphorylating Rb and thus from mediating the G1/S transition. The *INK4a* gene has been identified as a tumor suppressor gene in many cancers including melanomas. Mutations in the *INK4a* gene are capable of simultaneously inactivating ARF. ARF binds directly to both p53 and MDM2 and stabilizes p53 with regard to degradation. ARF can bind to p53-DNA complexes and can enhance induction of the CDK inhibitor, p21(CIP1). p21 inhibits both CDK4 and CDK2 and thus contributes to inhibition of cell proliferation. The overall effect of inactivation of the *INK4a-ARF* locus is to help the cell evade arrest at the G1/S checkpoint, and subsequent apoptosis, in response to DNA damage, including that arising from ionizing radiation.

BRCA1 *and* BRCA2 *in Breast and Ovarian Cancer*

These genes are notable because they are responsible for a high percentage of cancers specific for women. The two protein products, which are not homologous, frequently colocalize together, and they may function together. BRCA1 is probably a multifunctional protein. Evidence suggests that it can act as a transcription factor and that it is involved in upregulating the *p21* gene, thus paralleling p53. Alternatively, BRCA1 and BRCA2 may function in DNA recombinational repair. BRCA1 and BRCA2 both colocalize with Rad51 on the presynapsing regions of synapsing chromosomes in female meiosis.[12] Rad 51 is a human homolog of the bacterial RecA protein, which mediates strand invasion in recombination. BRCA1 may also affect ubiquitin ligation, a process involved in protein degredation, with resulting effects on chromatin structure. *BRCA1* and *BRCA2* are classic tumor suppressor genes in that the predisposition to cancer through mutation is inherited in a dominant fashion. Genetic inactivation of both *BRCA1* alleles in mice causes embryonic mortality. Figure 44-6 is a fluorescence photomicrograph demonstrating BRCA1 located in both basal (b) and luminal (l) epithelial cells of a breast tissue explant. High levels of BRCA1 are found in mitotic cells (*arrows*), as might be consistent with a role in recombination/repair. Yellow shows colocalization with vimentin, a basal cell marker, at the upper left and, with cytokeratin 19, a luminal cell marker, at the lower right. Staining for each of the latter two proteins is green.

NF-1 *and Von Recklinghausen's Neurofibromatosis*

The *NF-1* gene, located at chromosome band 17q11, encodes a protein, neurofibromin, which is an important GTPase-activating protein (GAP) inhibiting the activity of Ras proteins. Inactivation of this gene can thus lead to enhanced Ras pathway signaling in affected cells. Mutation in the *NF-1* gene leads to an inherited predisposition to Von Recklinghausen's neurofibromatosis, characterized by multiple nodules of peripheral nerve cell growth.

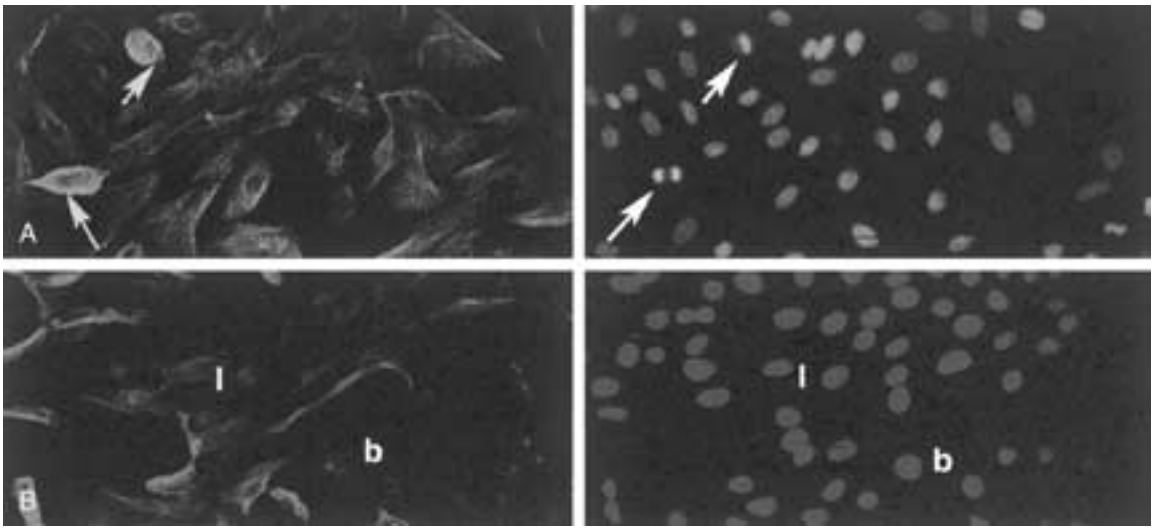

FIGURE 44-6 Presence of the breast cancer tumor suppressor gene product BRCA1 in both basal and luminal epithelial cells of the breast. BRCA1 is detected in the nuclei of both basal and luminal cell types when using double immunofluorescence labeling. *Left panel*: **A**, Edge of the basal outgrowth costained with MAbs to BRCA1 (red) and vimentin (green). **B**, Edge of luminal outgrowth costained with MAbs to BRCA1 (red) and cytokeratin 19 (green). *Right panel*: **A** and **B**, DAPI counterstain of the same fields of cells. Note: photo mask was left in the light path to help orient fields and is visible in some of the photographs. *b*, Basal; *l*, luminal. Arrows are identified in text. (Daniel DC. Dual immunofluorescence labeling with cell-specific markers localizes BRCA1 in both basal and luminal epithelial cells in primary outgrowth from noncancerous mammary ductal and alveolar preparations. Cell Tissue Res (1999) 298:481.) (See Color Plate 4)

PTEN: *A Tumor Suppressor Gene Encoding a Phosphatase*

The chromosome band region 10q23 is frequently altered in several neoplasms, including melanomas, endometrial carcinoma, and prostate tumors. A tumor suppressor gene in this region has recently been identified as a phosphatase that can dephosphorylate the intracellular second messengers phosphatidylinositol 3,4,5-trisphosphate and phosphatidylinositol 3,4-bisphosphate. These lipid phosphate molecules are phosphorylated in the phosphoinositol 3-kinase (PI-3 kinase) pathway, a growth signaling pathway distinct from the Ras-MAP kinase pathway, and their dephosphorylation exerts a growth inhibitory effect. Thus far, *PTEN* is the only phosphatase identified as a tumor suppressor.

WT-1 *and* WT-2 *and Wilms' Tumor*

Two genes on chromosome 11 are linked to an inherited predisposition to Wilms' tumor of the kidney. The *WT-1* gene, located at band 11p13, is a transcription factor containing a zinc finger, a chelated zinc amino acid motif that is usually involved in DNA binding. *WT-1* binds to a GC-rich DNA element and can act as either a transcriptional activator or a repressor, depending on its interaction with other factors. *WT-1* is expressed in developing kidney, testis, and ovary. Genitourinary tissues are thought to be sites of origin of Wilms' tumor. Less is known about the function of the *WT-2* gene, located at band 11p15.5, but inactivation of this gene is linked to Beckwith-Wiedemann syndrome, a familial neoplastic syndrome that includes kidney, adrenocortical, and liver tumors.

CIRCUMVENTING APOPTOSIS

It is clear that many of the genetic changes leading to cancer are involved in the circumvention of normal pathways leading to apoptosis. Apoptosis is programmed cell death. It is a process frequently accompanying normal tissue differentiation, in which case it is genetically controlled. Figure 44-7 shows apoptosis, darkly stained via an assay for DNA fragmentation, at a highly specific stage of mouse testicular development. Apoptosis is also invoked in the cellular response to DNA damage, and in this case it is an important protector from the development of neoplasia. Several reports have documented pathways of the apoptotic response of cells to ionizing radiation. In response to DNA damage, p53 upregulates the p21 CDK inhibitor and upregulates BAX, which through a convoluted pathway ultimately triggers a cascade of caspases, which are involved in proteolytic activity. Upregulation of p21 by p53 also blocks the cell cycle at the G1/S boundary. This is because p21 inhibits the CDK4- and CDK2-catalyzed phosphorylation of Rb and replicative enzymes responsible for entry into S-phase. Certain elements of the pathways of apoptosis relevant to ionizing radiation are depicted in Figure 44-4. The effects of p53 on DNA replication may also involve CDK2 inhibition at the onset of S-phase. CDK2 has been implicated in phosphorylation of MCM4, a protein that is part of a putative DNA helicase complex, consisting of MCMs 4, 6, and 7, that is required for initiation of DNA replication. MCM intranuclear levels are highly cell-cycle regulated, and reports indicate that MCM protein levels are

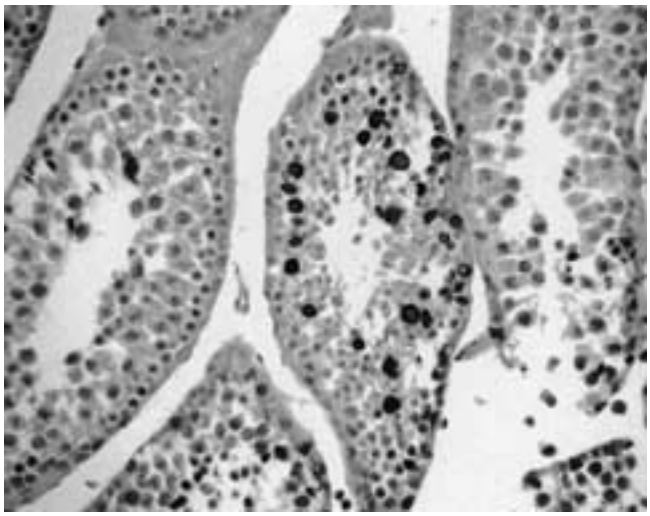

FIGURE 44-7 Apoptosis is highly stage-specific in normal spermatogenesis in the mouse. Shown is a section from normal mouse testis approximately 20 days after birth. Staining for apoptosis, or programmed cell death, is done by the TUNEL assay, which detects DNA fragmentation. This is early in spermatogenesis, but cells develop toward the center of the seminiferous tubule. Note that darkly stained apoptotic cells are visualized in a specific layer in development. Note also how apoptosis, which affects specific cells in a defined region, differs from necrosis, a nonprogrammed form of cell death that usually affects multiple contiguous cells in a focus. (See Color Plate 5)

VIEW IMAGE

preferentially elevated in oncogenically transformed cells. An example of selectively elevated MCM7 in ovarian cancer can be seen in Figure 44-8. In this case, the slower-growing cells of ovarian cysts are not stained, whereas the more aggressive malignant cells are.

It should be clear from the presented pathways that many of the tumor suppressor genes commonly altered in

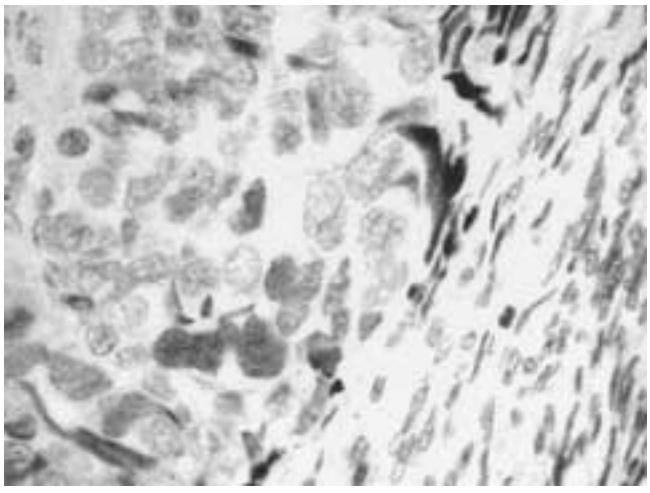

FIGURE 44-8 DNA replication protein MCM7 as a marker for ovarian cancer. Many recently developed tumor cell markers are proteins involved in DNA replication. MCM7 is part of an MCM 4, 6, 7 DNA complex essential for initiation of DNA replication. Its levels are cell-cycle regulated. Staining, visualized as red-brown, was with anti-MCM7 antibody and secondary antibody coupled to horseradish peroxidase. Note the high percentage of large tumor cells with mottled nuclear staining as opposed to the lack of staining of adjacent normal ovarian tissue on the right. (See Color Plate 6)

neoplasia are participants in apoptotic mechanisms. The importance of such alteration to treatment is becoming ever more clear. For example, if a tumor possesses inactive p53, one should carefully evaluate any treatment strategy that involves radiation or chemotherapeutic agents that damage DNA. If apoptosis were absent from tumor cells, such treatments would not be effective. Visually, apoptosis is characterized by chromatin aggregation around the inside of the nuclear membrane, nuclear fragmentation, and ultimately cell fragmentation. It is a process completely distinct from necrosis, another visually identifiable presentation of cell death. Necrosis involves general degrading of cell features, and it is not programmed. Necrosis usually involves all cells immediate to a traumatic focus, whereas apoptosis involves selected cells within a tissue area.

TELOMERASE AND ONCOGENIC TRANSFORMATION

It had been notably difficult to transform primary human cells to oncogenicity by transfecting them with activated oncogenes. As described in this chapter, such transformation could be achieved with mouse cells. Human cells, however, do not respond the same way. Recently, an important experiment was performed by R.A. Weinberg and colleagues.[4] They were able to transform primary human cells in culture by adding to them genes encoding SV40 large T antigen, which binds Rb and p53 and inhibits their activities; activated Ras, which provides a continuously active growth signal transduction pathway; and the catalytic subunit of human telomerase. Telomerase was the key to the success of this experiment.[13] The ends of chromosomes, termed *telomeres*, consist of long repeats of the sequence (in humans) of CCCTAA and TTAGGG. It is now known that the lengths of these repeats in mouse cells are considerably different from those in human cells, and thus the mechanisms for their maintenance may also differ. Continuously growing cells require telomerase for the following reason. The DNA of mammalian chromosomes is linear, and the telomeres can thus not replicate fully through normal DNA synthesis in each replication cycle because there is no position for a primer for the last Okazaki fragment to elongate the 3′ end. Multiple rounds of replication would therefore literally erode the ends of chromosomes. Telomerase can ameliorate this problem by supplying a template in the form of an RNA sequence bound to the protein.[13] Telomerase, denoted hTERT, essentially acts as a reverse transcriptase, using its RNA moiety as a template to synthesize blocks of DNA to elongate repeats at the 3′ overhang of one strand of the DNA end. In cells not oncogenically transformed, telomerase activity is absent or nearly so. Such cells can divide only a finite number of times before undergoing senescence. Telomere maintenance is required for indefinite proliferation. Thus, the acquisition of telomerase activity is a step in cell immortalization, which is itself a step in oncogenic transformation. Research indicates that there exist other, nontelomerase-dependent mechanisms for telomere maintenance. Telomerase, however, appears to be preferentially utilized in neoplasia since its levels are elevated in a high percentage of all tumor cells.

INTERACTION OF TUMOR SUPPRESSOR GENE PRODUCTS WITH PROTEINS ENCODED BY ONCOGENIC DNA VIRUSES

The importance of the Rb-p53 linked pathways for protection against cancer is highlighted by the action of certain DNA tumor viruses. Large T antigen of SV40 binds to both Rb and p53, inhibiting their actions. The E7 protein of human papilloma virus, linked to cervical cancer, binds to Rb, whereas the E6 protein binds to p53. Similarly, the E1A protein of adenovirus binds to Rb, whereas the E1B protein binds to p53. Thus, all of these DNA viruses, each capable of oncogenic transformation of cells, at least in culture, subvert the cells' protective mechanisms by similar means. Not all of these viruses have been firmly linked to cancer in humans. Nonetheless, there are firm links for certain viruses and ample reason to continue to monitor the potential links for others.

Human Papilloma Viruses and Cervical Cancer

Human papilloma virus (HPV) is a large circular DNA virus implicated in the formation of many types of benign warts. There are more than 50 known strains of HPV, most of which are capable of causing genital warts in women that are sexually transmitted. A small percentage of these strains have been firmly linked to the development of cervical carcinoma. Strain types 16 and 18 account for most cases in which cancer has developed from HPV-induced warts.[14] Recent epidemiologic studies have indicated that sequences representing these strains can be detected in as many as 33% of college women. Clearly, HPV is a major sexually transmitted disease. It is also clear, however, that a far smaller percentage of college women develop cervical cancer, underscoring the belief that, in addition to inactivation of tumor suppressor gene products, other genetic changes are also instrumental in the progression to cancer. All strains of HPV produce the E6 and E7 proteins, which bind to p53 and Rb, respectively. Why then do only a few strains cause cancer? The transforming proteins of HPV strains 16 and 18 have a higher affinity for their respective tumor suppressor gene products than do the proteins of their counterparts linked to benign warts. It is believed that binding of the viral proteins to the tumor suppressor gene products targets the latter for degradation within cells, a process that is thus more efficient in cells infected by types 16 and 18. It is interesting that Rb and p53 are thus far the only tumor suppressor gene products known to be inactivated by DNA transforming viruses. Thus, simultaneous inactivation of these two proteins may be capable of the subversion of cellular protective pathways sufficient to allow oncogenic transformation.

Are SV40 or Other Papovaviruses Involved in Human Cancer?

Simian virus 40 (SV40) is a circular DNA virus that is known to cause kidney tumors in monkeys and is capable of

Copyright © 2003, Mosby, Inc. All rights reserved.

oncogenic transformation of cultured human cells. As discussed above, the transforming protein of SV40 is the large T antigen, which interacts with both Rb and p53. Whether SV40 is capable of causing tumors in humans is a very important question since as many as 30 million Americans may have been injected with live SV40 virus in the 1950s. That situation came about because the first preparations of the Salk polio vaccine were made from monkey cells that, unknown at the time, harbored SV40 infection. A large-scale study concluded in 1998 that there was no correlation between the presence of SV40 DNA sequences in serum and several types of cancer.[15] These data were less conclusive for certain relatively rare forms of cancer, for which only a few subjects were analyzed. Nonetheless, the data clearly show that SV40, taken alone as a risk factor, is not a major cause of cancer in humans and that a perceived rise in the rates of certain forms of cancer since the 1950s cannot be attributed solely to SV40. Ongoing studies will determine whether SV40 may be significant when considered together with other known risk factors.

Two papovaviruses related to SV40 are known to infect humans, and both of these produce T antigen closely related to that of SV40. Sequences of the polyoma virus BK (BKV) have been detected in kidney and urine but are not known to cause any disease. Sequences of the polyoma virus JC (JCV) have been detected in nearly 93% of people over the age of 17, and JCV is known to be associated with a human disease. JCV is the etiologic agent of progressive multifocal leukoencephalopathy (PML). PML was formerly very rare, affecting primarily immunocompromised individuals, but with the onset of the AIDS epidemic, PML has been diagnosed in nearly 4% of people with AIDS, in whom it has nearly always been fatal. Antiretroviral therapy has recently reduced the mortality due to PML. In the disease, JCV infection of oligodendroglial cells in the central nervous system leads to progressive demyelination and loss of neuronal function. Recent results indicate that the presence of HIV in the brain may play a major role in activating JCV infection. JCV has recently been linked to certain brain tumors in individuals who do not have AIDS, as JCV sequences were detected in tumor tissues of medulloblastomas and pituitary tumors but not in adjacent normal tissue. This detection does not establish causality, but if the connection remains firm, it may point to new routes of therapy for these usually intractable cancers.

Hepatitis Virus Types B and C and Hepatocellular Carcinoma

Infection with either hepatitis B or C virus confers an increased risk of hepatocellular carcinoma. Hepatitis C, however, is more strongly linked since nearly 20% of people with chronic hepatitis C infection develop cancer within 10 years. Thus far, no transforming protein of any hepatitis virus has been shown to interact with and inactivate a tumor suppressor gene product as, say, the E6 and E7 proteins of papilloma viruses do. With hepatitis C, the development of liver carcinoma is believed to be due to the nature of the chronic infection. At a low level, the virus is constantly damaging liver tissue that is constantly being regenerated. This regeneration involves proliferative expansion of selected cells, and it would provide a favorable environment for expansion of clones of cells with oncogenic mutations. It takes many years for most individuals with chronic hepatitis C to develop hepatocellular carcinoma. Thus, it is likely that the expansion of cells due to regeneration predisposes cells to acquire additional genetic alterations.

NEOPLASIA IN AIDS

There are certain malignancies that were formerly rarely encountered but, with the onset of AIDS, are now so strongly associated with that disease that they are virtually signatures of it. In general, cancer in AIDS involves difficult treatment decisions, primarily because the usual chemotherapeutic or radiologic options, frequently immunosuppressive, may not be suitable. In addition, patients may be under treatment for HIV infection, which may comprise highly aggressive antiretroviral therapy (HAART), which includes a combination of inhibitors of viral proteases and replicative enzymes. Treatment of neoplasia in AIDS may require consideration not only of the viral nature of AIDS, but also of certain of the cancers characteristic of it.

Kaposi's Sarcoma and HHV8

Kaposi's sarcoma (KS), a malignant neoplasm of endothelial cell origin, is the most common neoplasm preferentially associated with AIDS. Prior to the AIDS epidemic, it was considered a sporadic disease affecting primarily European Jewish males, usually after the seventh decade of life. With the advent of AIDS, however, KS has become virtually epidemic, especially among HIV-infected homosexual males. It is now recognized that there are different variants of KS and that HIV infection may play a direct role in the prevalence of KS in AIDS. In the classic sporadic form of KS, lesions occur as purple to brown nodules largely confined to the skin in the lower extremities. KS has been found in highly immunosuppressed individuals other than those with AIDS—for example, in organ transplant patients; in these cases, nodules are not localized to skin or to the lower extremities. KS nodules in AIDS patients are extremely widespread and may occur in viscera including the GI tract and lungs. Mucosal lesions are also common in AIDS, as seen in Figure 44-9, and nodules are frequently seen in the nasopharyngeal mucosa. The incidence of KS in HIV-1-infected individuals is more than 100-fold higher than in people with other types of acquired immunosuppression.

Human herpesvirus 8 (HHV8) has now been linked to the development of KS, but the etiologic nature of this link remains to be fully explained. Less than 20% of the general population is seropositive for HHV8, and infection by this agent is essentially latent, involving endothelial cells, B lymphocytes, and certain epithelial cells. HIV-1, in contrast, infects classes of T lymphocytes, macrophages, and certain glial cells of the CNS. Recent research suggests that there is potential for a reciprocal interaction between these two viruses. HIV-1-induced cytokines can have a direct stimula-

VIEW IMAGE

FIGURE 44-9 Nasopharyngeal lesion of KS, linked to HHV8, in an individual with AIDS. (Micrograph courtesy of Dr. H. Lummerman, Department of Pathology, Mount Sinai School of Medicine.)

tory effect on endothelial cell growth. In addition, the Tat protein encoded by HIV-1, a potent transcriptional regulator, is secreted by infected cells and has been demonstrated to be incorporated by neighboring cells in functional form. Tat directly activates growth factor receptors in endothelial cells. Tat can also interact with HHV8-encoded proteins to reciprocally and synergistically activate the gene expression of both viruses. In a majority of cases, KS regresses partially or completely in response to HAART. Such regression does not allow a distinction between immunosuppression versus a role for HIV in the mechanism of KS origin since HAART both increases $CD4^+$ T-cell counts and decreases the HIV viral load.

Primary Central Nervous System Lymphoma and Epstein-Barr Virus

Non-Hodgkin's lymphomas are the second most common neoplasm encountered in AIDS. They are found in AIDS patients more than 100-fold more frequently than in the general population. Of these lymphomas, primary central nervous system lymphoma (PCNSL) is preferentially associated with AIDS, affecting more than 3% of HIV-infected individuals. PCNSL is essentially a signature of AIDS, as it occurs in AIDS patients more than 3000-fold more frequently than in the general population. PCNSL is also seen in immunosuppressed transplant patients, occurring nearly 35-fold more frequently than in the general population. In North America, PCNSL cases are generally $CD20^+$, parenchymal B-cell lymphomas. Brain masses are most easily diagnosed by enhanced-contrast CT, MR imaging, and brain biopsy. Recent advances in CT imaging, particularly the use of single photon emission computed tomography using thallium 201, have reduced the necessity for brain biopsy. Intriguingly, PCNSL is associated with activation of a circular DNA virus, as is KS. Recent studies indicate that virtually all PCNSL tumors are positive for the genome of EBV, a herpes-like virus. EBV, latent in most people, can be activated in B cells, where it most notably causes mononucleosis. Infection of B cells in PCNSL is apparently latent. PCNSL lesions typically consist of masses of immunoblastic or plasmacytic B cells in a perivascular cuffing pattern, as seen in Figure 44-10. Histologic examination frequently shows the aggressive large cell subtype, as seen in Figure 44-10, in which staining employs an anti-EBV protein antibody. The histology in PCNSL is very different from that in Burkitt's lymphoma, in which a smaller, non-cleaved B-cell subtype is more common. In keeping with this observation, and with an EBV etiology, PCNSL does not involve translocations of the c-*myc* gene, as does Burkitt's lymphoma. The incidence of PCNSL decreased after the introduction of HAART. This may be due to restored immunocompetence preventing the onset of the disease. It may also, however, be due to a decreased HIV viral load in the brain.

GENES INVOLVED IN MULTIPLE STEPS OF METASTASIS

The ability to spread to distant sites in the body greatly enhances the lethality of most solid tumors. For such metastases to be successful, a cancer cell must detach from its original tumor location, invade a blood or lymphatic vessel, travel to a distant and compatible site in the body, exit the blood or lymphatic system, in many cases reattach to adjacent cells and/or to the extracellular matrix, and, finally, begin clonal proliferation.[16] Much recent work has been devoted to identifying the genes involved in each of these steps in metastasis. Cells that are not oncogenically transformed do not ordinarily form colonies when they are not attached to the extracellular matrix. Several dominantly acting oncogenes can confer the property of anchorage-

independent growth on cells. For example, activating mutations in members of the *ras* gene family confer a variety of morphologic and cell-cycle regulatory changes that result in anchorage-independent growth. Several proteases are important for the processes of detachment from the matrix and from adjacent cells. The protease plasmin is involved in release from the basement membrane, and it is activated by a protease called plasminogen activator. Overexpression of plasminogen activator in cells enhances their metastatic potential. Integrins are cell surface receptors that mediate interactions between cells and between cells and the extracellular matrix. Integrins are frequently upregulated in cells with high metastatic potential. Similarly, the expression of proteins of the immunoglobulin superfamily, such as ICAM1, correlates positively with high metastatic potential. In contrast, expression of cadherins and catenins is frequently downregulated in metastatic cells. Cadherins are cell-cell adhesion molecules that are calcium-dependent transmembrane glycoproteins, and catenins form links between the intracellular domains of cadherins and the cytoskeleton.

TUMOR ANGIOGENESIS

Tumor Size Restricted by Blood Supply

All solid tumors must recruit a blood supply to promote expansion. Stimulation of the growth of new capillaries from existing blood vessels is termed *angiogenesis*. Folkman and Beckner first hypothesized that virtually all solid tumors are restricted in size to approximately 2 mm in diameter prior to the onset of angiogenesis.[17] It is now recognized that most such tumors arise in the absence of angiogenesis and exist as lesions in situ, after which a small percentage acquire an angiogenic phenotype. The vast majority of in situ carcinomas remain as microscopic lesions throughout the individual's life. The remaining small percentage progress to engendering new blood vessels. This angiogenic switch is critical at both ends of the metastatic cascade, described in the previous section. Newly developed tumor blood vessel endothelium is generally hyperpermeable relative to that of nontumor tissue. Thus, a high percentage of cells from a primary tumor are capable of entering the blood supply, thus initiating metastasis. Once metastatic cells colonize a new site, the resulting tumor is restricted in size until the angiogenic switch triggers the growth of new blood vessels. There are essentially four ways in which the angiogenic switch may be activated. The most common mechanism is that an avascular carcinoma can stimulate neovascularization in an adjacent vascular bed. Secondly, endothelial precursor cells in the blood can colonize an avascular tumor. Thirdly, cells in a tumor can induce fibroblasts or myeloid cells adjacent to or within the tumor to produce angiogenic factors. Finally, preexisting blood vessels can provide axes of growth for a developing tumor. Each of these cellular angiogenic mechanisms may involve the participation of multiple gene products. At this point, more than 20 genes encoding factors capable of modulating angiogenesis, either positively or negatively, have been identified.

Activation in Tumors of Genes Encoding Angiogenic Growth Factors

In response to hypoxia, cells in a tumor are known to induce genes encoding a host of angiogenic peptide growth factors. Well-characterized factors at this time include vascular endothelial growth factor (VEGF), platelet-derived endothelial cell growth factor (PD-ECGF), and acidic and basic fibroblast growth factors (aFGF, bFGF). To stimulate neovascularization, the tumor must produce sufficient angiogenic growth factors to overcome the action of the body's naturally produced angiogenesis inhibitors, such as angiostatin. The angiogenic growth factors diffuse toward existing blood vessels, at which point they initiate a cascade of molecular events, as exemplified here by VEGF. VEGF binds at the endothelial cell surface to any of a number of cognate VEGF receptor molecules, which are similar to the transmembrane receptors previously described for various growth factors. This binding triggers receptor dimerization and activation of intracellular signal transduction pathways, including tyrosine phosphorylation and the MAP kinase pathway, leading to increased cell proliferation. This proliferation results in the creation of a new mother vessel, which is hyperpermeable. The mother vessels are transient and rapidly differentiate into new arteries and veins. This differentiation requires participation of an intriguing class of transmembrane ligands and receptors, the ephrins and Ephs. The interaction at the endothelial cell surface between ephrin-B2 and Eph-B4 has been implicated in the patterned development of arterial-venous boundaries.

Imaging of Tumor Angiogenesis

Angiogenesis is of particular relevance with regard to imaging solid tumors since many existing imaging methods are dependent on visualization of the vascular system.[17, 18] Furthermore, size is a critical factor in imaging a tumor; angiogenic tumors are frequently of detectable size, whereas nonangiogenic tumors are not. A variety of therapeutic strategies aimed at inhibiting tumor angiogenesis are presently being developed, and the use of imaging to monitor such therapy will become an increasingly important consideration. All major existing imaging technologies have been useful in capturing parameters related to tumor vascularity. CT, ultrasound, and positron emission tomography (PET), employed with contrast-enhancing agents or radioactive tracers, are capable of documenting blood volume, blood flow, and mean transit time. MR imaging and PET have been particularly useful in defining the permeability of the tumor vascular system.

Recently, certain novel imaging strategies have been developed to specifically target angiogenic endothelial cells. Angiogenic endothelial cells express cell surface integrin molecules possessing an Arg-Gly-Asp (RGD) motif. Monoclonal antibodies have been prepared that target these integrins and that are linked to paramagnetic liposomes in order to essentially create an imaging system directed at the cell surface of developing endothelial cells. These liposomes may also carry a cargo in the form of an antiangiogenic factor or a cytotoxic agent.

FUTURE OF CANCER TREATMENT

Although the knowledge of tumor genetics is vast, it is approaching a turning point with regard to clinically useful application. With the sequence of the human genome completely elucidated, investigators will soon have a working knowledge, if not a functional understanding, of all of the genes altered in neoplasia. Thus, work will shift from the basic task of identifying the genes involved in neoplasia to the perhaps more difficult task of applying this knowledge to treat neoplasia. The nature of experimental investigation will thus shift from its present focus on genomics toward a focus on understanding the interactions of proteins encoded by genes involved in neoplasia and to an understanding of the pathways in which these proteins function. The treatment of cancer will then progress with the use of ever more specific inhibitors of protein-protein interactions and enzyme activities.

GLOSSARY

Allele one of two gene copies, each of which is inherited from one or both parents of the individual. These alleles may or may not be identical.

Apoptosis programmed cell death. Apoptosis occurs normally during tissue development. It also occurs in response to signals indicating cell or DNA damage and thus represents an important mechanism for preventing neoplasia.

CDK acronym for cyclin-dependent kinase. A class of protein kinases dependent for their activity on association with another protein, called a cyclin, the presence of which is specific for a certain phase or phases of the cell division cycle. Each CDK interacts with specific cyclins.

Checkpoint when used in relation to the cell division cycle, a time point at which a cell may, in response to certain signals, particularly for cell or DNA damage, exit the cycle.

Cyclins a class of proteins that interact with CDK protein kinases to stimulate their activity. Cyclins are degraded at a specific point in the cell cycle and synthesized at another point. They are thus available to activate a particular CDK in a cell cycle–dependent manner. Each cyclin activates specific CDKs.

Dimer a compound produced by the combination of two like molecules, without loss of atoms.

Helicase an enzyme that unwinds DNA or RNA in an energy (i.e., ATP)-dependent, processive fashion. Processive means that the enzyme can proceed to unwind the polynucleotide duplex for a significant distance.

Ligand an entity that interacts with a receptor to modulate the signaling pathway stemming from that receptor.

LTR an acronym for long terminal repeat, a repeated sequence at the ends of a linear retroviral RNA molecule. The LTR contains a promoter for regulating transcription of the viral RNA molecule once integrated into the DNA of the host genome.

Oncogene a cellular gene, the expression of which contributes in a dominant fashion to the development of cancer. Oncogenes of tumors arise through somatic mutation of normal cellular genes, termed *proto-oncogenes*. The mutated gene may thus gain a function unrelated to the function of the original proto-oncogene.

Promoter a DNA sequence, generally upstream of a gene, that contains elements binding proteins that regulate expression of the gene.

Protein kinase an enzyme that catalyzes the transfer of a phosphate group from ATP to an amino acid in another protein, termed its *substrate*. Each protein kinase has specific protein substrates.

Protein phosphatase an enzyme that catalyzes the removal of a phosphate group from another protein that has been phosphorylated by a protein kinase.

Proto-oncogene a normal cellular gene that, when mutated, becomes an oncogene. The product of a proto-oncogene may serve a cellular function unrelated to growth control or cancer. Mutation of only one allele creates a protein with newly acquired oncogenic properties.

Retrovirus an RNA virus that must be reverse-transcribed to make DNA, which then integrates into the host genome.

Telomere either end of the continuous DNA strand that comprises a chromatid of each chromosome. Each human telomere consists of multiple repeats of the sequence TTAGGG. These repeats must be replicated in a special manner to maintain telomere length over multiple cell divisions.

Copyright © 2003, Mosby, Inc. All rights reserved.

Transduction the process, requiring DNA recombination, by which a virus infecting a cell incorporates all or part of a cellular gene, thus becoming a part of the virus and conferring on it new viral properties.

Translocation an event, requiring DNA recombination, in which DNA of part of one chromosome is transferred to another chromosome. This may involve an exchange of DNA sequences between chromosomes. If the translocation DNA breakpoints lie in two different genes, the event can generate a fusion gene encoding a protein with the N terminus of one of the two original genes and the C terminus of the other. Several oncogenes have been generated by translocation.

Tumor suppressor gene a gene of which both alleles must be inactivated in order for cancer to develop. Although tumor suppressor genes are frequently called recessive oncogenes, a *predisposition* to cancer is inherited as a dominant phenotype. To lead to neoplasia in a familial cancer syndrome, one inactivated allele of a tumor suppressor gene is inherited at birth and the other allele is subsequently inactivated environmentally.

INTRODUCTION

The past 15 years have witnessed dramatic changes in the imaging of a variety of head and neck disorders. Although initially the emphasis of imaging was on morphologic analysis, the areas of most active recent investigation have involved metabolic and functional imaging techniques. The primary goal of head and neck imaging has always been to provide anatomic information that accurately maps a lesion, especially in areas where the clinician cannot directly use palpation. However, the early results of the new metabolic imaging techniques suggest that they may be more useful than cross-sectional anatomic imaging in improving the radiologist's ability to accurately identify recurrent tumor, monitor treatment, and identify cervical metastases. This chapter will review the most promising of these metabolic techniques and discuss their potential clinical applications.

POSITRON EMISSION TOMOGRAPHY

Introduction

Unlike computed tomography (CT) and magnetic resonance (MR) imaging, which depict structural anatomy, positron emission tomography (PET) is a functional imaging technique that depicts tissue metabolic activity. As most tumors show increased glycolytic activity compared with nonneoplastic tissues, ^{18}F-labeled fluorodeoxyglucose, a glucose analogue, has proven to be a very useful marker of tumor activity in many parts of the body, including the head and neck. In this chapter, the basic physics and technical aspects of PET will be reviewed, as will the radiopharmaceuticals that have been applied most commonly in the head and neck. The performance of PET in the evaluation of the patient with head and neck cancer will then be discussed.

Technical Aspects

Positron Emission

PET imaging relies on the use of radioisotopes that are unstable, because their nuclei contain an excess of protons, and that decay with emission of positively charged particles (positrons). These radioisotopes are cyclotron produced and short-lived. The emitted positrons travel only a short distance (1 to 2 mm) in tissue before combining with a negatively charged electron. This collision results in mutual annihilation, with conversion of mass to energy and the emission of two 511-keV photons directed approximately 180° to one another. These photons are more penetrating than positrons and exit the body easily, so that they can then be detected with a scanner.

These events (annihilation and photon emission) establish the fundamental physical limitations on the resolution of PET imaging. First, the annihilation event does not occur at the site of the decaying radionuclide, but rather at a distance that is determined by both the density of the subject matter and the energy of the emitted positron. Second, the two annihilation photons are not emitted in perfect collinearity, this divergence being dictated by the rules of conservation of momentum.[1] The combination of these two factors leads to a degree of unsharpness that is on the order of 2 to 3 mm.

Radiopharmaceuticals

The metabolism of cancer cells is altered compared to that of normal cells of the same tissue origin. In cancer cells, both glucose metabolism and the rate of protein synthesis are increased. In addition, in order to meet the needs of actively proliferating cells, there is an increased need for fatty acids and nucleic acids. Short-lived positron emitters such as ^{18}F and ^{11}C can be used to label a wide range of biologic substrates without altering their character, and these substrates can be used to study a variety of physiologic processes. A range of physiologic tracers has been developed for PET imaging, the most widely used of which is 2-[^{18}F]fluoro-2-deoxy-D-glucose (FDG).

^{18}F-Fluorodeoxyglucose

FDG is a glucose analogue with a fluorine-for-hydroxyl substitution on a D-glucose substrate. It is the most commonly used radiopharmaceutical in PET imaging. ^{18}F is cyclotron-produced and has a half-life of 110 minutes, making its use feasible for sites that do not have an on-site cyclotron. A typical dose of FDG in the adult patient is on the order of 370 MBq (10 mCi). FDG is taken up by glucose transporters and phosphorylated by hexokinase to FDG-6-phosphate, but further metabolism is then blocked by the presence of the extra hydroxyl moiety. FDG-6-phosphate therefore accumulates in the cell and provides a marker for glucose uptake and utilization. Because FDG and serum glucose compete for uptake, patients should fast for at least 4 hours prior to an FDG PET study. As neoplastic cells characteristically have high rates of glycolysis even in the presence of oxygen, contrast between tumors and normal tissue is high.[2] Uptake of glucose and FDG into malignant cells is facilitated by increased expression of glucose transporter molecules at the cell surface, and activity of hexokinase has also been shown to be significantly higher in malignant cells.[3, 4] Tumor concentration of FDG generally reaches a peak at 30 minutes, remains relatively constant for up to 60 minutes, and then slowly declines.[4] It must be recognized that nonneoplastic but rapidly metabolizing cells such as macrophages may also accumulate FDG[5]; therefore, accumulation of FDG is not specific for neoplastic cells.

^{11}C-Labeled Amino Acids

Another family of radiopharmaceuticals that has been investigated for oncologic imaging is the ^{11}C-labeled amino acids, notably ^{11}C-methionine and ^{11}C-tyrosine. As the half-life of ^{11}C is only 20 minutes, this label can only be used with an on-site cyclotron. Methionine is an essential amino acid needed for protein synthesis, polyamine synthesis, transmethylation reactions, and the transsulfuration pathway.[6] ^{11}C-tyrosine also is an essential amino acid required for protein synthesis.[7] Malignant transformation accelerates these syntheses and reactions, making labeled amino acids potentially useful markers of tumor activity.

^{11}C-Labeled Thymidine

^{11}C-labeled thymidine PET has been suggested as a way to assess tumor proliferation in vivo.[8] Determination of the proliferative capacity of tumors is increasingly used in

Copyright © 2003, Mosby, Inc. All rights reserved.

clinical trials of head and neck tumors to select patients for particular therapies. Thymidine is one of the building blocks of DNA, and in vivo measurement of its incorporation into DNA offers a potential means to quantify proliferative activity.

Scanner/Detectors

The distribution of positron-emitting radionuclides in vivo cannot be imaged directly because of the positron's short range in matter. PET imaging therefore relies, as previously described, on the detection of photons traveling at 180° to each other, which represent the footprints of annihilation reactions. The system is set up so that an event is registered only when two oppositely located detectors record the arrival of a photon within some finite resolving time, establishing a ''coincidence'' event. An image consists of true coincidences as well as signals resulting from random false coincidences, which are a major contributor to system noise and which tend to degrade the image. The detectors used in PET consist of a scintillator (typically bismuth-germanate, or BGO), photomultiplier tubes, and an amplifier. A mechanical gantry holds the detector system and shielding, as well as septa that are used between detectors for interplane shielding in multiple ring detector systems.[9]

The most common design for a PET scanner makes use of multiple rings of detectors that produce multiple slices simultaneously. Some scanners can be operated in either a high-resolution mode or a high-sensitivity mode.[10] In the high-sensitivity mode, direct slices include coincidence events recorded not only from directly opposing crystals, but also from the two crossing planes of neighboring crystals. In the high-resolution mode, the direct slices include only events from directly opposing crystals. Similarly, for cross-planes, coincidence paths are accepted in four crossing planes for the high-sensitivity mode, but only from the two nearest cross-planes in the high-resolution mode. In the high-resolution mode, a PET gantry with n rings of detectors provides $2n$-1 slices through utilization of cross-coincidences between two adjacent rings.

Three types of resolution of a PET scanner are typically defined: radial, tangential, and axial. Radial resolution, also called in-slice resolution, is best at the center of the field of view and poorest at the periphery. Tangential resolution is measured in-plane, but tangential to a radial line, and is also best in the center of the field. Axial resolution is measured along the long axis and depends upon detector size, interdetector spacing in the axial direction, and type of collimation.

Image Generation

The data acquired in PET are a function of at least two variables: the distribution of the source of annihilation photons included in the field of view and the modulation of the above by the attenuation of photons that occurs between their source and the detectors.[1] An attenuation correction must be made for each data point recorded. An attenuation correction factor can be applied to each scan projection or, more commonly, transmission attenuation can be measured with an external source and this correction can be applied to the data. Correction is usually made by acquiring ''transmission'' images that measure the attenuation of 500 keV radiation in the subject (usually from a rotating ^{68}Ge source), and this information is used to correct the emission data before reconstruction.

Transverse tomographic images are reconstructed from a series of measurements taken from different angles around the object to be imaged. The two main reconstruction methods by which activity distribution is estimated from the coincidence measurements of annihilation events are filtered backprojection and statistical model-based iterative reconstruction. Reconstruction algorithms are necessary since the position of an annihilation event can be placed along a straight line joining two detectors, but no information is available as to the location of the event along that line. In filtered backprojection, a choice of reconstruction filter offers a trade-off between resolution and noise in the reconstructed images.[11] Filtered backprojection also suffers from ''spray'' or ''starburst'' artifact (Fig. 45-1). The ability of iterative reconstruction algorithms to take account of the statistical nature of the acquired data by incorporating models such as resolution, attenuation, and scatter during the reconstruction process can, in general, improve the quality of the reconstructed image compared to that of filtered backprojection.[12] Iterative reconstruction also allows whole-body attenuation-corrected images to be obtained in a reasonable length of time.[13] In the future, with improved temporal resolution and computing power, the difference in arrival time of two photons will allow the exact location of the originating event to be deduced (so-called time-of-flight PET), and events will be directly located along a line between two detectors rather than being placed using an algorithm. At present, images are generally displayed and interpreted directly on a computer console, which allows simultaneous viewing of axial, sagittal, and coronal planes, as well as the ability to rotate images.

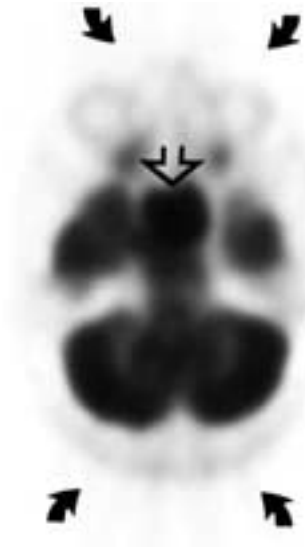

FIGURE 45-1 An FDG PET examination performed on a patient with nasopharyngeal carcinoma and reconstructed with filtered backprojection demonstrates a focus of intense activity in the nasopharynx (*open arrow*). Note that spray artifact is prominent around the periphery of the image (*arrows*).

VIEW IMAGE

FIGURE 45-2 Multiple FDG PET images show the normal distribution of tracer accumulation in the head and upper neck. Normal activity is demonstrated in the (**A**) nasopharynx (*thin arrow*) and parotid glands (*thick arrow*), (**B**) soft palate (*straight arrow*), (**C**) palatine tonsils (*arrow*), and (**D**) submandibular glands (*curved arrow*), sublingual glands (*straight arrow*), and lingual tonsils (*open arrow*). Note that the maxillary sinuses, maxilla, and mandible are photopenic. Faint activity is seen in the spinal cord on all images (*curved arrow* in **B**).

Quantification/Standardized Uptake Value

Attenuation correction allows results to be quantified. Quantified results are generally presented as the standardized uptake value (SUV), which is the amount of radiotracer in a region (as measured by a PET scanner) normalized by the injected dose and the patient's body mass. The general equation is:

$$\text{SUV} = \frac{\text{injected dose (nCi)/body weight (g)}}{\text{tissue concentration (nCi/g)}}$$

SUVs are widely reported but are subject to multiple sources of variability, which are often not accounted for in reported studies.[14] Among these sources of variability are (1) patient's body composition and habitus, which are not accounted for by weight; (2) lack of standardization of the uptake period, the time from tracer injection to PET scanning; (3) actual plasma glucose level at the time of scanning; (4) recovery coefficients and partial volume effects; and (5) region of interest effects. Attempts have been made to reduce the variability of the SUV using other constants such as K_i, the net influx constant, but these can be problematic as well.[15] Recently, SUVs based on lean body mass (SUV_{lbm}) and body surface area (SUV_{bsa}) have been investigated as weight-independent indices of FDG uptake, with SUV_{lbm} appearing to be more appropriate for quantifying FDG uptake in order to avoid overestimation of glucose utilization in obese patients.[16] For clinical purposes, a visual analysis of the images is usually sufficient,[17] but quantification may be useful in particular clinical circumstances (e.g., predicting the response to chemoradiotherapy) and certainly in more basic research.[18]

Image Registration

Although highly sensitive, PET does not provide the same definition of anatomic detail that is provided by CT or MR imaging and therefore does not necessarily allow precise localization of pathology or determination of exactly what structures are involved by a pathologic process. Computerized coregistration of PET and CT/MR images helps circumvent this limitation and provides additional clinically relevant information.[19] One method of registration makes use of an iterative surface-fit algorithm that performs the scaling, translation, and rotation of one of the surfaces and obtains the best fit of the two surfaces under comparison after manual alignment.[20] Anatomic landmarks such as the nasal profile or curvature of the brain may be used to guide the registration, or external markers may be placed. The development of combined CT/PET scanners should reduce the difficulty of anatomic correlation (Fig. 45-2).[21]

Imaging FDG Metabolism Without a Dedicated PET Scanner

Positron emission events are imaged most efficiently and with highest resolution using a dedicated PET scanner with full-ring bismuth germanate crystal block detectors. However, as these scanners are of limited availability, interest has focused on the ability of conventional or modified gamma cameras to image positron emission events. Conventional multiheaded single photon emission computed tomography (SPECT) cameras are in widespread use, but attempts to image FDG using these cameras fitted with high-energy collimators have proved to be of limited value due to low spatial resolution and low sensitivity.[22, 23] This poor performance is a consequence of limited efficiency for the detection of 511-keV photons using a camera optimized for detection of 140-keV photons, as well as constraints imposed on system spatial resolution as a result of physical collimation of high-energy photons. Results are improved by operating a modified gamma camera fitted with thicker (1.6 cm versus the usual 0.95 cm) NaI crystals in

Copyright © 2003, Mosby, Inc. All rights reserved.

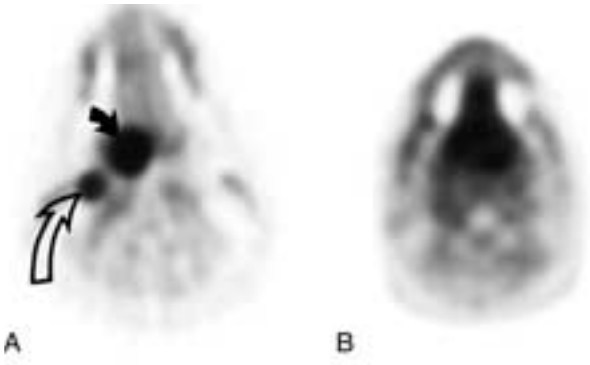
coincidence mode. In this situation, there are limitations due to the count rate, as well as a substantial contribution of accidental coincidences.[22] Several recent studies, however, have demonstrated that a dual-head camera with PET capability is sensitive in the detection of primary head and neck cancers and accurate in the preoperative assessment of lymph node metastases and detection of local recurrences.[24–26]

Clinical Applications

The literature on the role of PET in head and neck oncology is rapidly expanding. The vast majority of these studies are FDG-based, and these will be the focus of this chapter.

Normal Appearance in the Head and Neck

Before interpreting the abnormal, it is important to have a firm understanding of the normal distribution of FDG in the body and, in particular, in the head and neck region. On a whole body scan, the most intense activity is in the brain, followed by the myocardium, renal collecting systems, and bladder. There is moderate activity in the liver, spleen, and bone marrow and variable activity in the bowel, breast (reflecting the amount of proliferative glandular breast tissue), and muscle.[27] In the head and neck, there is marked accumulation of FDG in the floor of the mouth, generally attributed to the sublingual glands, and in the lymphoid tissue of Waldeyer's ring. Moderate activity is present in the parotid and submandibular glands, as well as in the extraocular muscles. Mild activity is also present in the nasal turbinates (Fig. 45-3). The thyroid gland may demonstrate striking FDG uptake, especially if it is goitrous. Striated muscle uptake is usually mild unless the patient is talking or has recently exerted the neck or shoulder muscles. Bones and fat are photopenic.[28]



VIEW IMAGE

FIGURE 45-3 A 73-year-old man with SCC of the base of the tongue underwent staging evaluation with FDG PET. **A**, An initial pretreatment scan shows intense tracer accumulation in the base of the tongue (*solid arrow*) and in a metastatic right upper jugular lymph node (*open arrow*). This older scan, reconstructed using filtered backprojection, also shows mild spray artifact. **B**, A follow-up scan obtained 6 months after completion of radiation therapy demonstrates resolution of focal uptake at the base of the tongue and the cervical lymph node, but there is a mild generalized increase in soft-tissue uptake, as is typically seen following radiation therapy. Note the absence of spray artifact on this image reconstructed using an iterative method.

VIEW IMAGE

FIGURE 45-4 An FDG PET scan was performed in a patient with a small (5-mm), superficial, moderately well differentiated SCC of the left posterior buccal mucosa and retromolar trigone. The primary lesion is seen (*arrow*).

Postirradiated Appearance

Radiation therapy causes little or no change in normal uptake patterns of FDG in the head and neck except for a mild generalized increase in soft-tissue uptake (Fig. 45-4). In a series of 11 patients with squamous cell carcinoma (SCC) of the head and neck studied before, during, and after a 6-week course of radiation therapy, Rege et al. found that the average metabolic ratio in the tonsils, nasal turbinates, soft palate, and gingiva did not change significantly with treatment, while FDG uptake decreased dramatically in SCC.[29] The salivary glands also maintained normal FDG uptake, though their function was decreased following radiation therapy.

Head and Neck Cancer

FDG PET has a number of proven and potential roles in the assessment of patients with head and neck cancer, the majority of whom have SCC. FDG PET has been used to look for unknown primary lesions and second primaries, to stage disease prior to therapy, to detect residual and/or recurrent disease after therapy, to assess the response to therapy, and to detect distant metastases. The performance of FDG PET in each of these areas will now be reviewed.

Unknown Primary/ Second Primary

FDG PET detects more than 95% of SCCs with a volume of 1 cc (Fig. 45-5), with uptake seemingly unrelated to the histologic grade of the tumor.[30–32] Small superficial lesions may go undetected by FDG PET but can often be seen endoscopically.[33] About 5% of patients with SCC present solely with evidence of cervical nodal metastases and no identifiable primary lesion on head and neck examination. Anatomic imaging with CT/MR and endoscopy with random biopsy of likely primary sites (nasopharynx, tonsil, base of the tongue, pyriform sinus) will identify primary sites in 10% to 20% of these patients.[34] If no primary tumor site is found on CT/MR imaging, or on endoscopy with biopsy, then there are three basic therapeutic approaches: (1) a patient may undergo neck dissection followed by watchful waiting (controversial); or (2) neck dissection followed by radiation therapy to one or both sides of the neck and all possible primary tumor sites, including the nasopharynx; or (3) radiation therapy to all likely primary sites and the neck, followed by consideration of a neck dissection. The

FIGURE 45-5 A 44-year-old man presented with a right neck mass, and SCC was diagnosed on fine needle aspiration. The clinical examination was unremarkable, as was routine imaging. **A**, An FDG PET scan shows a focus of markedly increased FDG uptake in the area of the right tonsil (*arrow*). Asymmetric activity in the floor of the mouth is of uncertain significance. **B**, The contrast-enhanced CT image at this level shows no appreciable tonsillar asymmetry. Multiple biopsies of the right tonsil yielded a diagnosis of SCC, and the patient underwent radiation therapy.

identification of a primary site allows for more focused treatment that reduces morbidity and is therefore of considerable benefit to the patient. Such focused treatment is also associated with a better 5-year survival.

The reported success of FDG PET in identifying unknown primary lesions in patients presenting with metastatic cervical adenopathy is variable but promising. A number of series that have assessed 4 to 18 patients have reported successful location of unknown primary lesions in 20% to 50% of cases, with most of these lesions not seen on conventional anatomic imaging (Fig. 45-6).[31, 35–39] It should be noted that one of these series made use of FDG SPECT rather than FDG PET, with good success.[36] In one series, a 4-mm lesion was missed with PET and found endoscopically, and in another series a nasopharyngeal primary was identified at postradiation therapy follow-up PET.[35, 38] There was also a 20% to 30% rate of presumed false-positive diagnoses, assuming that biopsy is the gold standard.[36, 37] This latter assumption is not necessarily valid, as biopsy is operator dependent and may miss small or deep submucosal deposits. Of interest, in each series there were a number of patients in whom no primary site was ever identified by PET, endoscopic biopsy, or clinical follow-up. It is assumed that (1) some small primary tumors might have been eliminated by the body's own immune surveillance system, or (2) that these tumors might have been cured by radiation therapy (assuming that this is the treatment approach taken), or (3) that a prior now-forgotten SCC of the skin may be the actual primary site. The fact that a number of primary lesions are never identified by any method makes it difficult to calculate values for sensitivity and specificity.

One recent study reported a much poorer performance for FDG PET in the search for an unknown primary, with a primary site correctly identified in only 1/13 patients and apparent false-positive results in 6/13 patients.[40] Suggested reasons for the discrepancy between this and other studies include relatively poor resolution of the PET system being used (though SPECT has even lower resolution), the small size of two of the primary lesions identified by endoscopy and biopsy, and the possibility that biopsy sampling errors

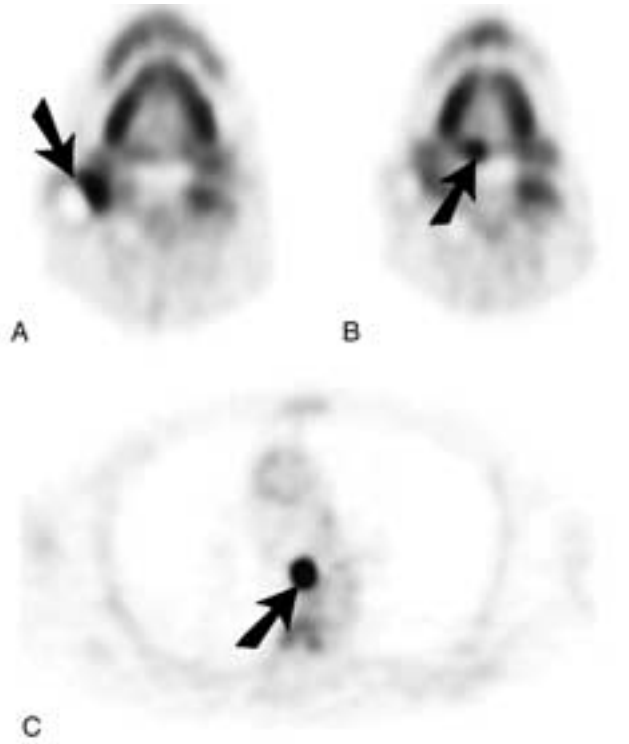

FIGURE 45-6 A 59-year-old man presented with a right neck mass, and fine needle aspiration was consistent with SCC. No primary lesion was noted on careful mucosal examination. A CT scan showed a mixed cystic and solid nodal mass, but no primary lesion was detected. An FDG PET scan was obtained to look for occult primary lesions and to focus the endoscopic examination. **A**, The right neck mass shows focal accumulation of FDG adjacent to a photopenic area, consistent with the known partially necrotic nodal mass (*arrow*). **B**, A slightly more inferior image shows focal activity at the right base of the tongue (*arrow*). No palpable abnormality was present at this location. **C**, An image through the chest shows intense focal activity in the region of the esophagus (*arrow*). Endoscopic biopsies of both sites subsequently showed SCC, with the nodal metastasis presumed to be related to the primary lesion at the base of the tongue. The patient received radiation treatment to both primary sites and the neck. (From Fischbein N, Anzai Y, Mukherji SK. Application of new imaging techniques for the evaluation of squamous cell carcinoma of the head and neck. Semin US CT MRI 1999;20:187–212.)

FIGURE 45-7 A 58-year-old woman presented with dysphagia and was found on examination to have extensive involvement of the epiglottis by SCC. MR showed no clearly pathologic adenopathy, but FDG PET demonstrated suspicious areas of tracer uptake bilaterally (*arrows*). The patient underwent total laryngectomy, partial glossectomy, and bilateral modified radical neck dissections. Pathologically, both nodes contained small foci of tumor on the order of 3 to 4 mm in diameter.

could lead to apparent false-positive FDG PET results. In the search for an unknown primary, it is always preferable that imaging studies (CT, MR, FDG PET) be done before endoscopy and biopsy; otherwise, sites of recent tissue sampling may be mistaken for tumor on postbiopsy images. Furthermore, the imaging evaluation may help to focus the endoscopic evaluation on the area most likely to yield positive material. If a larger volume of sample can be obtained from suspicious areas, the diagnostic yield may be increased over that of more limited, speculative biopsies.

The issue of second primary lesions is also relevant for patients with head and neck cancer, as these patients, many of whom use tobacco and alcohol, are at risk for synchronous or metachronous lesions of the head and neck, lung, or esophagus. The risk of second primary lesions in patients with head and neck cancer has been estimated at 4% per year, with second primary sites being predominantly located in the oral cavity, pharynx or larynx (40%), lungs (31%), and esophagus (9%).[41] The issue of whether to include the chest is relevant for sites for which whole-body scans are not routinely done. The added value of including the chest and abdomen has been debated, particularly given FDG PET's sensitivity to inflammatory as well as neoplastic conditions, leading to more imaging tests to sort out false-positive results.[42] Stokkel et al., however, studied 68 patients with head and neck cancer using dual-head FDG PET of the head, neck, and chest.[24] In 12 patients (18%), a second simultaneous primary malignant tumor was found, only five of which were detected by clinical or routine radiologic examination. Our own experience suggests that inclusion of the chest and abdomen is useful in the evaluation of patients with head and neck cancer (Fig. 45-7).

Nodal Staging

The staging of the neck is an essential task for the head and neck surgeon, radiation therapist, and oncologist. As most primary tumor sites in the head and neck have a relatively high incidence of nodal metastases, the neck must always be evaluated when a therapeutic plan is developed. Staging is generally done by a combination of clinical palpation and anatomic imaging. Clinical palpation is limited by the patient's body habitus, inaccessibility of certain nodal groups to palpation (e.g., retropharyngeal nodes), and tissue changes induced by prior therapy.

CT and MR imaging allow assessment of areas that cannot be palpated, and they can demonstrate areas of focal necrosis that confirm metastatic nodal disease (see Chapter 36). However, both techniques are limited by the fact that normal-sized, nonnecrotic nodes may harbor foci of tumor, while enlarged nodes may be reactive rather than neoplastic. Size criteria for determination of nodal metastases have been extensively reviewed in the literature and are also discussed in Chapter 36.[43] The performance of CT and MR for detecting metastatic foci in nonnecrotic nodes varies with the size criteria selected for assessing a node as abnormal. If a node equal to or greater than 5 mm is considered abnormal using CT and MR imaging, there is a sensitivity of 92% to 98% but a specificity of only 13% to 20%. When a 10-mm node is considered abnormal, the sensitivity is reduced to 81% to 88% and the specificity increases to 39% to 48%.[43] FDG PET affords another opportunity to detect metastatic nodes based on abnormal accumulation of FDG by foci of tumor.

The sensitivity of FDG PET for the detection of cervical nodal metastases in head and neck cancer ranges from 50% to 100% in various series[44–51] (Table 45-1). FDG PET can detect tumor-involved lymph nodes as small as 4 mm (Fig. 45-8), though below this level, lesions can certainly be missed. As histopathologic studies have shown that more than 40% of all lymph node metastases may be localized in lymph nodes smaller than 1 cm, a number of metastatic foci will certainly go undetected by any imaging method.[52] The specificity of FDG PET in detecting cervical nodal metastases ranges from 80% to 100%, with false positives due to reactive rather than neoplastic nodes. A recent study that prospectively compared FDG PET with conventional imaging modalities (CT, MR, ultrasound) in lymph node staging of head and neck cancer found that FDG PET had a sensitivity and specificity of 90% and 94% respectively, compared to 82% and 85% for CT, 80% and 79% for MR, and 72% and

FIGURE 45-8 A 63-year-old man underwent radiation therapy for SCC of the larynx. Six months following completion of therapy, he had persistent severe pain and occasional hemoptysis. Endoscopic examination demonstrated marked diffuse mucosal edema and erythema. **A**, An axial T1-weighted, postgadolinium, fat-saturated MR image demonstrates marked laryngeal edema and moderate enhancement without a focal abnormality. **B**, The FDG PET scan demonstrates a focus of intense activity in the larynx and no evidence of pathologic nodes. Mild diffuse soft-tissue activity is due to prior radiation therapy. Because of persistent symptoms and the suspicious PET scan, a laryngectomy was performed. SCC was demonstrated at pathologic examination.

70% for ultrasound.[44] In this study, regional lymph nodes were considered pathologic on conventional imaging if they were more than 12 mm in diameter or if there were other signs of malignancy such as central necrosis.

A particular setting in which FDG PET has been evaluated is in the management of the so-called N0 neck. The N0 neck shows no evidence of pathologic lymphadenopathy by clinical or conventional radiographic evaluation. However, N0 patients may harbor subclinical metastatic foci in as many as 20% to 30% of cases, and therefore the neck is often treated surgically or with radiation therapy in order to eradicate subclinical disease.[53] If a negative PET could be considered reassuring enough that a ''watchful waiting'' approach could be safely adopted, then the neck could be spared treatment in the N0 patient. Myers and Wax looked at 11 N0 patients with SCC of the oral cavity who underwent 19 neck dissections and found that FDG PET had 100% sensitivity and specificity for the presence or absence of disease in the neck.[51] Given that FDG PET is relatively insensitive to metastatic foci smaller than 3 to 4 mm, these numbers will likely fall as more patients are studied. However, it is probable that FDG PET will come to play an important role in the selection of therapeutic approach in the cancer patient with an N0 neck. The ability of PET to detect smaller foci of disease than either CT or MR imaging increases the likelihood that an apparently N0 neck is, in fact, truly N0. This information may make a watchful waiting approach more acceptable to both patient and physician.

Residual/Recurrent Disease

Following surgery and/or radiation therapy, it can be difficult to detect residual or recurrent tumor clinically, though findings such as the presence of a mass, increasing pain, or soft-tissue necrosis may suggest a recurrence. Disease may also be difficult to detect on posttherapeutic CT and MR imaging studies due to edema, scarring, and flap reconstruction.[54, 55] However, earlier detection of persistent or recurrent tumor may allow institution of more timely and more effective salvage therapy. Biopsy of suspicious areas can be performed, but biopsy of an irradiated area may precipitate tissue necrosis.[56] This is a particular problem in the larynx, where chondronecrosis may necessitate laryngectomy. Biopsy is also not a perfect gold standard, as failure to biopsy deeply enough or in the correct location may cause a focus of tumor located in desmoplastic, poorly vascularized tissue to be missed. FDG PET can be very effective in this setting, as it is not limited by anatomic distortion, as are CT and MR imaging, and the PET result may be useful to guide fine needle biopsy.[57, 58]

The performance of FDG PET in the detection of residual/recurrent disease following primary therapy has been assessed by multiple groups[57, 58] (Table 45-2). Sensitivity for detection of disease generally ranges from 80% to 100%, while specificity ranges from 43% to 100%. The high sensitivity suggests that disease is unlikely to be missed if present (Fig. 45-9), though false positives are a significant issue necessitating close clinical and imaging correlation. A negative result is generally highly reassuring, as the negative predictive value of FDG PET has been shown to be high.[26, 59] At present, most FDG PET scans that are performed in patients at risk for recurrent disease are performed because of clinical suspicion of disease. The role of FDG PET in routine surveillance of the posttherapy head and neck cancer patient has not yet been determined, though it has been suggested as a natural (and cost-effective) extension of the above results.[57] Stokkel et al. suggest that in patients suspected of having recurrent laryngeal or hypopharyngeal cancer in whom FDG PET is negative, endoscopy may be omitted for at least 6 months and possibly up to a year, resulting in a considerable cost saving.[26] At present, several institutions are beginning to move in this direction, with patients undergoing regular clinical follow-up, baseline posttherapy (surgery and/or irradiation) imaging, and serial

Copyright © 2003, Mosby, Inc. All rights reserved.

FDG PET. Additional anatomic imaging is performed if the findings on FDG PET require correlation.

Response to Therapy

In those cases where radiation therapy, alone or in combination with chemotherapy, is used as the initial therapy for SCC of the head and neck, PET may be useful to monitor the response to therapy and potentially to predict which patients will have a durable response. This should be particularly useful in the context of organ preservation protocols, where the concern about missing the window of opportunity for surgical salvage is always present.

Greven et al. evaluated a group of patients both before and after radiation therapy.[63] FDG PET scans obtained 1 month after high-dose radiation therapy showed decreased uptake in all tumors identified on the pretherapy scans. There was persistent disease in 3/16 patients who had normal posttherapy scans, while 6/6 patients with decreased but persistent uptake all had persistent disease. Thus, on FDG PET scans obtained 1 month following high-dose radiation therapy, a negative scan was not an accurate indicator of disease status, though a positive scan suggests that persistent disease is likely. By 4 months posttherapy, negative scans became more reliable. However, some surgeons fear that by this time, the surgical window of opportunity may have been missed. Similar early post–radiation therapy findings were reported by Lindholm et al. using ^{11}C-methionine, with high uptake on the scan suggesting persistent disease.[64]

Haberkorn et al. performed FDG PET studies both before and after chemotherapy in 11 patients and found that the change in FDG uptake was highly correlated with tumor regression.[65] In addition, primary lesions and multiple metastatic lymph nodes in the same patient often had different baseline metabolism and different changes following therapy, a potentially interesting commentary on tumor heterogeneity even in the same patient and consistent with the known clinical finding that nodes respond less well than primary sites to radiation therapy. Reisser et al. studied 12 patients with metastatic SCC before and after the first chemotherapeutic cycle.[66] They found that one patient with a lymph node that had increasing metabolism, and three patients who had no significant metabolic changes after therapy, were clinically unresponsive and showed progressive tumor growth. However, in some patients with an excellent initial response, survival was poor. Therefore, although nonresponders certainly may be directed early to other therapies, the predictive value of an initial improvement is uncertain.

Kitagawa et al. studied the effects of combined chemotherapy and radiation therapy in 15 patients with SCC of the head and neck and found that pretreatment FDG PET is

FIGURE 45-9 A 65-year-old woman presented with a neck mass that was positive for SCC on fine needle aspiration. Head and neck examination demonstrated a mass in the right tonsillar fossa extending toward the right base of the tongue. **A**, Contrast-enhanced CT scan shows an exophytic mass emanating from the right tonsillar fossa as well as a large nodal mass. **B**, An FDG PET scan demonstrates intense uptake in the right tonsil and the right neck mass. The patient was treated with combined radiation therapy and chemotherapy, which she tolerated well. The neck mass resolved clinically, and the tonsillar fossa appeared unremarkable. **C**, A follow-up CT scan obtained with slightly different angulation shows a normal-appearing right tonsillar fossa but persistent soft tissue in the location of the conglomerate nodal mass (*arrow*). **D**, A follow-up FDG PET scan was obtained that showed minimal asymmetry of the tonsils and a small, questionable focus of activity (*arrow*) at approximately the site of the markedly decreased nodal mass. A neck dissection was performed that showed a focus of tumor only at the level that was suspicous on FDG PET, and the patient has remained well at follow-up.

useful in predicting the response to treatment, while posttreatment FDG PET can evaluate residual viable cells.[18] Lowe et al. studied 28 patients with stage III/IV head and neck cancer who were participating in organ preservation protocols.[67] FDG PET was performed before and 1 to 2 weeks after chemotherapy. The sensitivity and specificity of PET for residual cancer after therapy were 90% and 83%, respectively. This group believes that, in general, biopsy of most lesions after therapy will provide the lowest-cost approach to therapy evaluation as long as the lesion is visible and accessible. They recommend that PET be done when biopsy access is difficult (e.g., some paranasal sinus tumors), when posttherapeutic biopsy results are questionable for some reason, or when the tumor site has a normal, reepithelialized appearance after therapy (Fig. 45-10).

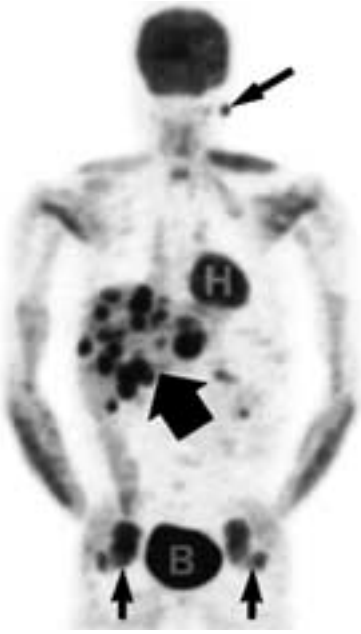
^{11}C-methionine PET (MET PET) has also been applied to evaluate the early response to radiotherapy in head and neck cancer.[68] MET uptake in tumor decreased significantly during the first 2 to 3 weeks of radiotherapy, but the rate of decrease in tracer uptake was comparable in relapsing

Copyright © 2003, Mosby, Inc. All rights reserved.

patients and those who remained locally controlled, thereby limiting the use of MET PET for prediction of the response to radiotherapy.

Evaluation of Metastases

Patients with recurrent or advanced-stage head and neck cancer are at particularly high risk of distant metastases, usually to lung and liver, but also potentially to bone and other sites. The exclusion of distant metastatic disease is important in staging and prognostication. It is also important when a major surgical procedure is contemplated, since the presence of distant metastases is a contraindication to aggressive surgical and radiotherapeutic procedures aimed at cure rather than palliation (Fig. 45-11). Patients have typically been staged with chest x-ray and liver function tests, though many clinicians selectively use CT scans of the chest and abdomen for staging. Whether the whole body is imaged during a PET scan or whether the examination is limited to the head and neck varies among institutions. Keyes et al. reported having modified their scanning protocol to include the lungs, but in only one case did PET show a significant lesion not found by routine evaluation; as a result, this approach was abandoned.[42] Manolidis et al. examined the detection of occult metastatic disease in 29 patients.[62] Ten metastases were confirmed histopathologically, and the PET scan was positive in 9/10 instances. One false positive and one false negative occurred, making the sensitivity in detecting distant metastases 90%, the specificity 94%, the positive predictive value 90%, and the negative predictive value 94% in this small cohort. With improvements in scanner technology and reconstruction methods, it is likely that whole-body screening for distant disease will become a useful adjunct when evaluating patients with head and neck cancers by PET.



VIEW IMAGE

FIGURE 45-10 A 36-year-old HIV-positive man with a history of Merkel cell carcinoma of the parotid region, was referred with locally recurrent disease for consideration of definitive therapy. A staging chest x-ray and liver function tests were normal. A whole-body FDG PET scan demonstrates focal activity in the left parotid region (*long, thin arrow*), as well as multiple foci of intense tracer accumulation in the liver (*thick arrow*). Abdominal CT scan and fine needle aspiration confirmed metastatic Merkel cell carcinoma, and the patient was treated with palliative chemotherapy. The whole-body scan shows normal activity in the heart (*H*) and bladder (*B*), as well as activity in the hands bilaterally (*short, thin arrows*) and forearm muscles related to finger clenching.

Non-SCC Malignancy

Most, but not all, of the above-referenced articles contain a mix of histologies under the rubric of ''head and neck cancer,'' including adenoid cystic carcinoma, mucoepidermoid carcinoma, mucosal melanoma, and basal cell carcinoma in addition to the dominant SCC. The numbers of these other malignancies are generally small, and it is not possible to extract separate conclusions about them. However, the general experience seems to reflect similar performance by FDG PET for these malignancies compared to SCC.

Salivary tumors have been looked at specifically to see if FDG PET could correctly differentiate benign from malignant disease.[69] Subjective PET findings correctly differentiated malignant from benign disease in 69% of cases, with 100% of malignant lesions but only 42% of benign lesions correctly classified. PET findings were false positive for malignancy in 30% of cases, and SUV analysis and ratios failed to distinguish benign from malignant disease. These authors concluded that FDG PET was not useful in distinguishing malignant from benign salivary gland tumors. FDG PET has also been shown to be useful in evaluating metastases from mucosal and nonmucosal melanoma.[70] Thyroid cancer and lymphoma have also been looked at more specifically, and these will be discussed next.

Thyroid Cancer

In the determination of management and further therapeutic options in the patient with differentiated thyroid cancer who has already undergone thyroidectomy and radioactive iodine ablative therapy, whole body ^{131}I scintigraphy (WBS) is the most important functional imaging technique. In many patients, however, thyroid cancer tissue does not concentrate ^{131}I and therefore cannot be localized by this method. The loss of ^{131}I concentrating ability results in false-negative WBS in approximately 20% of cases of metastatic thyroid cancer.[71] There is considerable evidence that FDG PET is useful in planning the treatment and follow-up of thyroid cancer patients with negative WBS (Fig. 45-12).[71–77] In patients with either papillary/follicular or medullary thyroid cancer suspected of having locally recurrent or metastatic cancer on the basis of elevated or rising blood markers, FDG PET has demonstrated the ability to identify residual or recurrent disease when conventional imaging with WBS fails to demonstrate disease. Grunwald et al. found that FDG PET had greater than 80% sensitivity for suspected recurrence and/or metastases in the setting of negative WBS, while Chung et al. found that FDG PET was 94% sensitive and 95% specific for localization of metastatic sites in 33 patients with negative ^{131}I scans.[72, 74] FDG PET may not, however, be sensitive enough to detect minimal disease in cervical lymph nodes or to reliably demonstrate pulmonary metastases smaller than 1 cm.[71, 75] As a general management issue, if the thyroglobulin level (or calcitonin level with medullary carcinoma of the thyroid) is elevated

VIEW IMAGE

FIGURE 45-11 A 49-year-old man underwent total thyroidectomy and right neck dissection for poorly differentiated papillary carcinoma of the thyroid. He was subsequently treated with radioiodine, and follow-up whole body ^{131}I scans were negative. The patient was reimaged because of rising thyroglobulin levels and concern for recurrent disease. **A**, An axial T1-weighted image from an MR scan of the neck demonstrates soft tissue in the right anterior low neck (*white arrows*), but it is unclear if this is scarring and fibrosis related to prior neck dissection or residual or recurrent tumor. Focal soft tissue in the left anterior neck (*black arrow*) may similarly represent either treatment effects or tumor. **B**, An axial image from a noncontrast CT scan of the chest demonstrates pretracheal and anteroposterior window lymph nodes, none of which are clearly pathologic. **C**, An FDG PET image through the low neck confirms focal tracer accumulation in both sites in the neck that were suspicious on MR imaging (*arrows*). **D**, Multiple mediastinal nodes also accumulate tracer. Further neck surgery and mediastinoscopy confirmed the presence of thyroid cancer at these sites.

and a WBS is negative, FDG PET can be used to detect metastases and as a complement to anatomic imaging. If intervention such as dissection of iodine-negative lymph node metastases is contemplated, then a spiral CT scan of the lungs is probably useful to assess for pulmonary metastases.[75]

Lymphoma

Early results using FDG PET to assess malignant lymphoma of the head and neck suggested that the degree of FDG uptake correlated well with proliferative activity and that FDG PET was useful in prognostication.[78, 79] Walsh et al. evaluated four patients with non-Hodgkin's lymphoma of the head and neck and found that FDG PET enabled the extent of disease to be seen.[80] FDG PET has taken on a major role in the staging of lymphoma and has been suggested as a replacement for CT scanning and bone scintigraphy.[81, 82] A residual mass after treatment of lymphoma is a clinical challenge, because it may represent vital tumor as well as tissue fibrosis. Metabolic imaging by FDG PET offers the advantage of functional tissue characterization that is largely independent of morphologic criteria.[83, 84]

One caution, however, involves the role of whole-body FDG PET in the staging of extranodal B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT) type, an increasingly recognized subtype of lymphoma affecting the head and neck (primarily the salivary and lacrimal glands). These generally low-grade malignancies do not show up well on FDG PET, leading to numerous false-negative results and poor correlation with staging by clinical and conventional anatomic imaging methods.[85]

Pitfalls

Like any test, FDG PET is subject to a number of limitations and also to certain pitfalls. In order to interpret FDG PET images accurately, one must be aware of the normal physiologic distribution of tracer, the spectrum of normal variations in uptake, and benign causes of FDG uptake that may be confused with malignancy.[27] Furthermore, one must be aware of the circumstances under which disease may be occult or very subtle on FDG PET. Knowledge of prior therapy is also important, as prior

Copyright © 2003, Mosby, Inc. All rights reserved.

surgery can result in significant tissue asymmetry that may make the normal side appear diseased in comparison with low activity on the side of prior surgery. Some of these factors have been commented on earlier but will be reviewed below, as they pertain specifically to the head and neck.

False Positives

Since FDG is taken up nonspecifically by glycolytically active cells, it accumulates in areas of inflammation as well as in tumors. In inflammation, its uptake is by macrophages and other inflammatory cells.[5, 86–88] It is possible that dynamic methods may be useful to distinguish granulation tissue from tumor tissue, but this is generally not clinically feasible using current methods.[89] Reactive or inflamed lymph nodes are a common cause of false-positive readings in the head and neck, limiting the specificity of FDG PET for detecting lymph node metastases. Ongoing inflammation at the site of a previously treated tumor may also account for false-positive readings and makes it difficult to determine whether a patient harbors residual or recurrent disease.[90] Muscular activity can also be confusing, and patients generally should lie quietly and refrain from speaking in order to avoid uptake in the cricopharyngeal area. In some cases, a muscle relaxant may be necessary to avoid muscular uptake artifacts.[33] Other potential sources of false-positive findings in the head and neck include healing bone and paranasal sinus inflammatory disease. Foreign body granuloma has also been reported to cause a false-positive result.[33]

False Negatives

A significant limitation of FDG PET scanning is its insensitivity to very small tumor deposits, on the order of 3 to 4 mm or less. Because of this, micrometastases are not reliably detected with FDG PET, and cervical nodal disease in patients with head and neck cancer may not be detected. Thus, in the N0 neck, how reliable a negative FDG PET scan of the neck is when planning a watchful waiting approach, rather than surgery or radiation therapy, remains an unanswered question. A purely cystic node with only a very thin rim of viable neoplastic tissue may also be overlooked on an FDG PET scan but would likely be detected by clinical palpation or conventional anatomic imaging. Finally, a false-negative scan may occur if FDG PET imaging is performed too soon after radiation therapy.[60]

Conclusion

FDG PET has become a powerful tool in oncologic imaging. In the field of head and neck cancer, it has proven to be useful in locating unknown primary and second primary lesions, staging nodal disease, detecting residual or recurrent disease following surgery and/or radiation therapy,

monitoring the response to organ preservation therapy, and detecting distant metastases. FDG PET may prove to be a cost-effective cancer surveillance tool in patients with a prior diagnosis of head and neck cancer. It also has a significant role in evaluation and treatment planning in patients with thyroid cancer and negative ^{131}I WBS. Both false-positive and false-negative scans do, of course, occur, and knowledge of these issues is important in the accurate interpretation of FDG PET scans.

THALLIUM-201 SINGLE PHOTON EMISSION TOMOGRAPHY

Introduction

Another technique in which initial investigations have been promising in the area of head and neck oncology is thallium-201 single photon emission tomography (Tl-201 SPECT). Initial investigations have shown that Tl-201 SPECT may be beneficial in attempting to differentiate recurrent tumor from posttreatment changes, and may be useful for both predicting and assessing the response of patients treated with nonsurgical organ preservation therapy.[90–97]

Mechanism

The primary mechanism of thallium entry into the cell is believed to be coupled to the sodium/potassium ATPase pump located in the cell membrane.[98] This system actively transports potassium into the cell in exchange for sodium, thereby creating a high intracellular potassium concentration. Thallium-201 is believed to act similarly to potassium and competes with potassium for intracellular transport across the cell membrane via the sodium/potassium ATPase system (potassium analogue).[98–101] The reason for the elevated thallium-201 uptake in tumor has not been entirely elucidated but is likely due to the increased cellular proliferation of neoplastic cells compared to adjacent normal tissue.[98, 102, 103]

Limitations

The primary disadvantage of thallium-201 imaging of the upper aerodigestive tract is the background uptake of thallium-201 by salivary and thyroid glands, as thallium-201 is normally taken up by the parotid, submandibular, and thyroid glands.[104] The uptake within the parotid and salivary glands can be especially problematic since the saliva will also have increased activity. Pooling of the saliva in the floor of the mouth may prevent accurate evaluation of lesions involving the oral cavity and may reduce the conspicuity of tumors in this area. This activity may be reduced by placing gauze in the patient's mouth and drying the oral mucosa. Another alternative in patients who have no medical contraindication to the administration of atropine is to use this drug to reduce salivary function prior to imaging.

Clinical Applications

Several studies have demonstrated that SCC is thallium avid, and previous investigators have suggested that thallium-201 may be able to detect lesions larger than 1 cc.[104] As a result, it has been suggested that thallium-201 may be useful in the evaluation of patients with unknown primary tumors in a manner similar to FDG PET scanning. Isolated cases of the successful use of thallium-201 for localizing unknown primary tumors have been reported.[97] However, larger series that have prospectively evaluated the role of thallium-201 in identifying unknown primary tumors have not yet been performed.

Initial results have shown that thallium-201 SPECT may be helpful in attempting to differentiate recurrent tumor from posttreatment changes and may be more accurate than CT or MR imaging for making this important distinction (Figs. 45-13 and 45-14). Valdes-Olmes et al. reported a higher diagnostic accuracy for thallium-201 SPECT (sensitivity = 93%, specificity = 78%) than for CT/MR imaging (sensitivity = 76%, specificity = 30%).[97] Mukherji et al. reported higher specificity for thallium-201 SPECT (sensitivity = 88%, specificity = 94%) than for CT (sensitivity = 100%, specificity = 24%) when attempting to identify recurrent tumor.[91]

Leitha et al. reported a sensitivity and a specificity of 95.3% and 78.4%, respectively, for the ability of technetium-99m-MIBI (hexakis-2-methoxyisobutyl isonitrile) SPECT to differentiate recurrent head and neck SCC from posttreatment changes.[105] If these results are substantiated, PET FDG, thallium-201, and technetium-99m-MIBI imaging all compare favorably for detecting tumors in patients with head and neck SCC.

There may be potential advantages to using thallium-201 SPECT rather than FDG PET, especially when imaging nasopharyngeal carcinoma and other skull base tumors. Unlike FDG, the background uptake of thallium-201 by normal brain is low. As a result, the conspicuity of nasopharyngeal and skull base tumors may be reduced on PET-FDG, as these tumors are directly adjacent to the normal high brain FDG activity. However, because of the low background activity in the normal brain, these tumors tend to be well delineated on thallium-201 imaging.[91]

Initial reports have suggested that thallium-201 SPECT may be useful in predicting the response to definitive radiation therapy and for assessing the response within 6 weeks after the completion of nonsurgical organ preservation therapy. Nagamachi et al. demonstrated that quantitative measurements of thallium-201 uptake may be useful in predicting the response of SCC of the upper aerodigestive tract to radiotherapy alone.[94] Mukherji et al. suggested that Tl-201 SPECT may be a reliable technique for assessing the response to treatment performed within 6 weeks after the completion of combined chemotherapy and radiation therapy (Figs. 45-15 and 45-16).[92] As previously mentioned, due to a high false-negative rate, FDG PET has been shown to be unreliable in predicting the treatment response when performed within 1 to 2 months after completion of radiation therapy.[63] Thus, initial results suggest that thallium-201 may be able to predict radioresponsiveness and assess the success of treatment earlier than can FDG-PET or cross-sectional

FIGURE 45-13 Correct exclusion of recurrent SCC by Tl-201 SPECT. **A**, Contrast-enhanced CT image in a patient with a right tonsil carcinoma previously treated with surgery and radiation therapy 14 months prior to this study. The patient presented with a right-sided nodal recurrence. This patient was a candidate for salvage surgery if no recurrent tumor was present at the primary site. Pretreatment studies were unavailable for comparison. CT shows an asymmetric soft-tissue mass involving the right tonsil (*arrows*). This is associated with asymmetry of the right glossotonsillar sulcus (*arrowhead*). Compare this to the appearance of the normal contralateral side. **B**, Axial Tl-201 SPECT image through the low oropharynx obtained in the patient in **A** shows no abnormal radiotracer uptake in the right tonsil. This patient has been followed for over 2 years after completion of treatment and has no evidence of recurrent tumor at the primary site. (From radiotracer uptake (*arrow*) in the region of the abnormality shown in **A**. Biopsy of this area revealed SCC. (From Mukherji SK, Gapany M, Phillips D, Neelon B, et al. Thallium-201 single-photon emission CT versus CT for the detection of recurrent squamous cell carconima of the head and neck. AJNR 1999;1213–1220.)

imaging. However, further studies are needed to confirm these early results.

PROTON MAGNETIC RESONANCE SPECTROSCOPY

Introduction

Recent in vitro and in vivo investigations have suggested that proton magnetic resonance spectroscopy (^{1}H-MRS) may be helpful in providing metabolic information about abnormalities in the extracranial head and neck. Several studies have found that assessment of the relative levels of choline (Cho) and creatine (Cr) can provide information that may help differentiate SCC from nonneoplastic tissue and may provide information that helps assess the response to nonsurgical organ preservation treatment protocols.[106–110] Elevation of the Cho/Cr ratio appears to be a consistent finding for SCC and has been demonstrated in cell cultures and from tissue samples from both the primary tumor site and metastatic lymph nodes (Figs. 45-17 to 45-19).[107] These in vitro findings have also been demonstrated in vivo. ^{1}H-MRS analysis of SCC performed at 1.5T has demonstrated significant elevation of the Cho/Cr ratio in patients with tumors compared with normal tongue muscle (Figs. 45-20 and 45-21). A complete review of ^{1}H-MRS is outside the scope of this discussion. The purpose of this section is to summarize the recent investigations that have been performed to evaluate ^{1}H-MRS in SCC and to comment on the potential clinical role of MRS in the extracranial head and neck.

Metabolites

The majority of ^{1}H-MRS tissue characterization in the upper aerodigestive tract has focused on two metabolites, Cho and Cr. Cho is a nutrient that is present in most foods, is absorbed from the diet, and serves as a precursor of two important molecules: acetylcholine and phosphatidylcholine.[111] Cho is also believed to be an important constituent in the phospholipid metabolism of all cell membranes.[112] The Cho molecule is transported intracellularly by a low-affinity system with its mechanism coupled to the synthesis of phosphatidylcholine.[113] Once intracellular, Cho is initially phosphorylated by Cho phosphotransferase to form phosphocholine. This latter molecule is the precursor of phosphatidylcholine, which is formed by the Kennedy pathway.[114] The *N*-methyl [$^{\pm}$N$(CH_3)_3$] group of Cho and Cho-based metabolites is detected spectroscopically at 3.2 ppm.[115] The total Cho resonance peak is believed to be composed of Cho, phosphocholine, phosphatidylcholine, and glycerophosphocholine. Elevation of this peak is not specific for SCC and has been demonstrated in several tumors. Increased levels of Cho are thought to be related to

Copyright © 2003, Mosby, Inc. All rights reserved.

increased cellular membrane phospholipid biosynthesis and are, therefore, believed to be an active marker for cellular proliferation.[116–121]

Cr is thought to play a role in the maintenance of energy metabolism. Phosphocreatine acts as a store for high-energy phosphates in the cytosol of muscles and neurons and is also believed to buffer cellular adenosine triphosphate and adenosine diphosphate.[111, 112] It may be obtained from the diet or synthesized de novo within the liver, kidneys, and pancreas by precursor molecules, which include arginine, glycine, and S-adenosylmethionine.[111, 121] Cr is converted to phosphocreatine by the enzyme creatine kinase. Because phosphocreatine is a high-energy phosphate compound, it has been suggested that it may help sustain the level of adenosine triphosphate in energy-demanding tissues such as actively proliferating tumors. Spectroscopically, the Cr

AJNR 1997;18:1057–1072.)

resonance is observed at 3.02 ppm, and it is believed to be comprised of both phosphocreatine and Cr.[121]

Clinical Applications

The importance of identifying and isolating consistent and reproducible ^{1}H-MRS metabolic markers for malignancies of the upper aerodigestive tract rests not so much in the ability of ^{1}H-MRS to initially diagnose tumor, but in its ability to identify early recurrent tumor and to monitor tumor response during therapy.[106, 109, 122–124] Because both surgery and radiotherapy result in scarring and soft-tissue edema, physical examination and CT/MR imaging often are inadequate in detecting early tumor recurrence after treatment.

Radiation therapy causes significant erythema and induration within the treated area, and this inflammatory response may be exacerbated with the addition of concomitant chemotherapy.[125] In most sites, this inflammatory response progresses to end-stage fibrosis (scar) within 3 to 4

AJNR 1997;18:1057–1072.)

months after the completion of radiation therapy.[54, 126, 127] These treatment-associated changes often prevent thorough endoscopic evaluation and reduce the ability to accurately detect persistent tumor that is unresponsive to therapy. This task is made even more difficult since persistent tumors are often situated deep to the mucosal surfaces and are not often directly visualized on physical examination. Although CT and MR imaging can be used to complement the clinical examination following treatment, their role is somewhat limited due to their inability to confidently differentiate posttreatment changes from early tumor recurrence.[125] In addition, the expected posttreatment imaging findings differ somewhat with the type of treatment given and with the location and extent of the primary tumor.[54, 126, 127]

Differentiation of Recurrent Tumor from Posttreatment Changes

Early results suggest that the ^{1}H-MRS may be used to differentiate recurrent tumor from posttreatment changes in patients with a malignancy of the upper aerodigestive tract who have undergone previous treatment.[106] Elevation of the Cho/Cr ratio in an indeterminate mass seen on CT or MR imaging is suggestive of recurrent tumor, whereas a ratio close to 1 is suggestive of posttreatment changes.[106] Despite the encouraging early ^{1}H-MRS results, it is unlikely that microscopic foci of tumor can be completely excluded by ^{1}H-MRS alone, regardless of field strength. Thus, indeterminate masses without the characteristic spectral tumor markers still warrant close clinical and radiographic follow-up, regardless of the MRS findings.

Prospective Treatment Monitoring

One of the most promising clinical applications for ^{1}H-MRS is the noninvasive treatment monitoring of patients with SCC of the upper aerodigestive tract who are treated nonsurgically. The accurate assessment of the primary tumor's response to radiation therapy and/or chemotherapy is extremely important, as early identification of an unresponsive malignancy may indicate the need for either additional therapy or surgical (salvage) resection. Previous studies have shown that cross-sectional imaging may be helpful in predicting tumor response by demonstrating a reduction in tumor size. However, these serial studies are most accurate when performed at least 3 to 4 months after completion of nonsurgical organ preservation treatment. By comparison, ^{1}H-MRS has the potential to be a much earlier indicator of tumor response, not by measuring volumetric changes but by measuring the internal chemistry of the treated tumor cells. The noninvasive nature of ^{1}H-MRS allows frequent interval studies to be performed both during and following treatment, and the utility of ^{1}H-MRS in prospective treatment monitoring for SCC is currently being investigated.

Copyright © 2003, Mosby, Inc. All rights reserved.

Preliminary investigations have shown that progressive reduction in Cho concentrations during treatment is indicative of a tumor response.[106, 128] In fact, some investigators have suggested that alterations in ^{1}H-MRS may be able to predict the response prior to changes in tumor volume.[106, 128, 129] Thus, persistent elevation of the Cho/Cr ratio suggests a nonresponsive tumor, while resolution of the Cho peak is indicative of a tumor response (Fig. 45-22). No information is available regarding the specific time interval following the initiation of treatment when one would expect to see resolution of spectral markers in tumors that are being successfully treated. Large-scale prospective studies are warranted to determine if ^{1}H-MRS can be a reliable technique for assessing the response during treatment monitoring.

Limitations and Imaging Strategies

The upper aerodigestive tract is an inherently difficult area to perform MRS. To obtain highly resolved spectra, a very homogeneous magnetic field is required in the area to be examined (i.e., ≤0.1 ppm deviation in the magnetic field). Numerous structural interfaces exist in this region that result in large magnetic field inhomogeneities. In many cases, these large field inhomogeneities cannot be corrected by the use of magnetic field shim. Susceptibility artifact from the paranasal sinuses and pharyngeal airway often prohibits analysis of low-volume tumors located adjacent to these structures. Susceptibility artifact from bone prevents spectral analysis of small to moderate-sized tumors that directly abut the skull base or mandible. Pulsations from the carotid artery result in rhythmic field inhomogeneities and may prevent spectral analysis of lesions that involve the poststyloid parapharyngeal space.[106]

Motion artifact is much more problematic in the upper aerodigestive tract than in the brain or extremities. Normal respiration usually does not interfere with analysis of primary parapharyngeal, nasopharyngeal, tonsillar, or masticator space masses. However, masses that arise in the upper airway often partially obstruct the airway and cause dyspnea. In addition, patients with upper airway tumors often have difficulty handling their secretions. This usually results in an exaggerated swallow and motion artifact. The result of these problems is increased motion that may prevent adequate shimming prior to spectral analysis. Thus, the role of ^{1}H-MRS for evaluating advanced laryngeal or hypopharyngeal carcinomas is very limited, especially if the patient is tracheostomy dependent.[106]

Fat contamination of the proton spectra is another major problem when performing one-dimensional ^{1}H-MRS in the extracranial head and neck. The fat planes surrounding the

various muscle groups are very helpful in identifying deep extension of tumor on CT or noncontrast T1-weighted MR imaging. However, these fat planes can result in contamination of proton spectra by a dominant lipid peak that prevents identification of the Cho or Cr peak.[106] When evaluating lesions that abut fat, every attempt should be made to center the voxel directly over the lesion. In these cases, it is especially important to minimize voxel size without excessively increasing acquisition time. However, despite proper placement of the voxel over a tumor, the intrinsically high fat content of the tissue may often result in sufficient fat contamination to obliterate the Cho and Cr resonances and render ^{1}H-MRS useless.[106]

Today, ^{1}H-MRS may be routinely performed on patients with nonobstructing head and neck tumors. However, because voxel size and acquisition time are competing factors, the study parameters have to be individualized, depending on the patient's clinical status and the location of the lesion in question. Thus, a smaller voxel size with a longer acquisition time could be used in a cooperative patient with a nonobstructive mass such as a masticator space lesion. However, a larger voxel size, which allows a reduction in acquisition time, may be a better strategy in a patient with a mass that extends into the airway, with resulting mild to moderate dyspnea. In the future, the best MRS results will likely be obtained by using dedicated spectroscopy coils developed solely for use in the extracranial head and neck.

Copyright © 2003, Mosby, Inc. All rights reserved.

Conclusion

Elevation of the Cho/Cr ratio has been demonstrated both in vivo and in vitro in SCC of the upper aerodigestive tract. This finding is not specific to SCC of the head and neck. It has been identified in a variety of malignant neoplasms including various brain tumors, gynecologic tumors, and lymphomas.[122–124] These findings suggest that the Cho/Cr ratio is a ubiquitous ^{1}H-MRS tumor marker that may be used to identify the presence of a variety of tumors.

ULTRASMALL SUPERPARAMAGNETIC IRON OXIDE MR CONTRAST AGENTS

Introduction

An area of active investigation is the role of new intravenous contrast agents for evaluation of metastatic disease. Over the past 15 years, superparamagnetic iron oxide compounds have been investigated primarily to detect the presence of liver metastases. However, there has been growing interest in investigating the ability of dextran-coated ultrasmall superparamagnetic iron oxide (USPIO) to detect metastatic nodal disease. This section will review the current information regarding the ability of USPIO to detect nodal metastases and evaluate primary tumors.

Mechanism

AMI 227, Combidex TM (Advanced Magnetics, Inc., Cambridge, MA), is a dextran-coated monocrystalline superparamagnetic iron oxide particle with an average particle size of 18 nm.[109, 130–132] Two major factors determine the physiologic distribution of these particles: their size and their surface properties. Iron particles with a diameter between 80 and 100 nm are trapped in liver and spleen, but not in lymph nodes and bone marrow.[133, 134] However, ultrasmall iron particles, which are less than 20 nm in diameter, can traverse the capillary walls, enter the interstitial spaces, and eventually appear in the lymphatics. These particles are then phagocytized by macrophages within lymph nodes.[130, 135, 136]

Thus, in a normally functioning lymph node, USPIO are trapped due to the normal phagocytic ability of the node. If tumor replaces portions of the node, such phagocytosis of the USPIO will not occur. Superparamagnetic iron oxide particles cause local MR field effects. Therefore, because of the functional nodal alterations caused by tumor, USPIO allows differentiation of a metastatic node from a normal or reactive node. This assessment is based on alterations of nodal signal intensities rather than on nodal morphology (size, shape, or architecture). Compared to its noncontrast signal intensities, a normally functioning node after the administration of USPIO demonstrates markedly reduced T1-weighted and T2-weighted signal intensities due to both T2 relaxation and magnetic susceptibility effects that result from the uptake of the iron particles (Fig. 45-23). By contrast, a metastatic node does not have a signal intensity loss on postcontrast images because the node's macrophages have been replaced and so fail to capture the iron particles (Fig. 45-24). Because USPIO is administered intravenously, this technique has the potential to evaluate all of the lymph nodes throughout the body. This is a significant advantage over traditional lymphography and sentinel node imaging, since these techniques only image lymph nodes in the primary drainage pathway of the injection site.

Technique

The current recommendation is to perform MR imaging from the skull base to the thoracic inlet before and after the intravenous administration of USPIO. Currently, the most commonly used MR parameters used to evaluate the distribution of USPIO are a (TR) of 500 msec, a (TE) of 20 msec, and a flip angle of 20°. The optimum time for postcontrast imaging appears to be between 24 and 36 hours after intravenous USPIO administration.[137] It is possible that future recommendations may allow the preadministration study to be omitted. This is currently under investigation.

Clinical Applications

Detection of Nodal Metastases

Identification and staging of nodal metastases is one of the most important prognostic procedures for patients with SCC of the upper aerodigestive tract, and both treatment and outcome are directly affected by information regarding the presence of nodal metastases. The diagnostic accuracy of the physical examination in detecting nodal metastasis is unsatisfactory, and the ability of cross-sectional imaging to detect metastatic disease is discussed in Chapter 36.

Several studies have been performed to evaluate the diagnostic accuracy of USPIO in detecting metastatic lymph nodes. The initial multicenter phase II trial of USPIO demonstrated a sensitivity of 84% and a specificity of 95% in detecting metastatic lymph nodes.[132] The recently completed phase III multicenter European and U.S. studies confirmed the results of the phase II studies. These trials reported similar diagnostic accuracy in detecting metastatic disease on postcontrast studies. The sensitivity and specificity of the U.S. and European trials in detecting metastases in individual lymph nodes was as follows: 96% and 87% (U.S.), 95% and 86% (European).[138, 139] If a lymph node loses virtually all of its signal intensity on the postcontrast MR imaging study, it is very likely that the node contains metastatic disease. Conversely, if there is no drop in signal intensity, the node is likely reactive. However, a problem arises when only part of the node loses signal intensity. At present, it has been suggested that if half of the node loses

Copyright © 2003, Mosby, Inc. All rights reserved.

signal intensity on the postcontrast study, there is about an 80% likelihood that the node contains tumor.[138-140, 147] These results suggest that USPIO MR contrast agents may become important adjuncts in evaluating metastatic nodal disease for SCC of the upper aerodigestive tract.

Primary Site Evaluation

Investigations are now underway to determine the ability of USPIO to evaluate the primary tumor site. Following administration of USPIO, the pituitary gland, cavernous sinuses, nasal turbinates (concha), and pharyngeal mucosa all show increased T1-weighted signal intensity. These structures appear slightly dark on T2-weighted images due to the T2 shortening effect of iron oxide particles. Early results suggest that the T2-weighted signal intensity of a primary tumor in the head and neck does not substantially change from that of precontrast T2-weighted imaging. Since the normal pharyngeal mucosa and nasal turbinates lose T2-weighted signal intensity following USPIO administration, it is possible that administration of USPIO may improve the conspicuity and margins of SCC of the upper aerodigestive tract.[138] However, further investigations are necessary to determine the utility of USPIO for evaluation of the primary site.

RADIOIMMUNOSCINTIGRAPHY IN HEAD AND NECK CANCER

Introduction

Monoclonal antibodies (MAbs) directed against tumor-specific and tumor-associated antigens can be used for selective tumor targeting. This imaging technique is called radioimmunoscintigraphy (RIS). MAbs can be produced to bind to specific targets and can be labeled with radionuclides that emit gamma rays. Thus, specific tumors can be visualized using gamma cameras. Because RIS identifies biologic antigenic targets on the tumor cell, this technique differs fundamentally from anatomic imaging modalities. The potential of RIS depends on the tumor antigen, the MAb, the radionuclide, the tumor, and the imaging technique.

The hybridoma technology introduced in 1975 by Köhler and Milstein made it possible to develop MAbs directed against specific cellular antigens[141] The ideal antigenic target for RIS is one that is expressed on the cell surface by all tumors that are to be studied. Unfortunately, such tumor-specific antigens have only been found in experimentally induced tumors and not in so-called spontaneous tumors. Most identified antigens in human tumors are tumor-associated antigens, which are present on both tumor and normal tissues. Expression of a target antigen in normal tissue is acceptable for RIS when this normal tissue is poorly accessible to MAb or when it is localized at a site outside the anatomic region of interest.

The uptake of a MAb in a tumor depends on the antigen recognized by the MAb, as well as on the molecular size of the MAb. An intact MAb is a large immunoglobulin molecule with a molecular weight of 150 kDa. Such large molecules have a limited ability to penetrate a tumor and the residence time of such an intact MAb in blood is long, resulting in low tumor/nontumor uptake ratios. For RIS, the use of smaller MAb fragments such as $F(ab')_2$ (mol. wt. ≈ 100 kDa), Fab (mol. wt. ≈ 50 kDa), and Fv (mol. wt. ≈ 25 kDa) can be advantageous. Such smaller fragments have better penetration than whole immunoglobulin and therefore have the potential for more rapid tumor targeting, a high tumor/nontumor ratio, and earlier scan times after injection (Fig. 45-25). The radionuclides most commonly used in RIS are ^{131}I (half-life: 8 days), ^{123}I (half-life: 13 hours), ^{111}In (half-life: 68 hours), and ^{99m}Tc (half-life: 6 hours).

Efforts to develop RIS for the detection of primary tumors and lymph node metastases in patients with SCC of the head and neck are currently underway. These investigations have led to the following initial conclusions: ^{131}I and ^{123}I labels are not favorable, because the detachment of ^{131}I from MAbs (dehalogenation) will result in activity uptake in the thyroid, which may disturb imaging of SCC of the head and neck in this region. Similar considerations can be made for detached ^{111}In, which can accumulate in lymphocytes present in the lymph nodes and liver. In addition, the high cost (^{111}In, ^{123}I), patient radiation exposure (^{111}In), limited availability (^{123}I), long half-life (^{131}I), and poor imaging qualities (^{131}I) are other drawbacks to these radionuclides. ^{99m}Tc appears to have the most favorable characteristics for RIS in the upper aerodigestive tract. These favorable characteristics include minimal radiation delivery to the patient (short half-life time and low gamma energy), favorable characteristic for gamma camera imaging (high

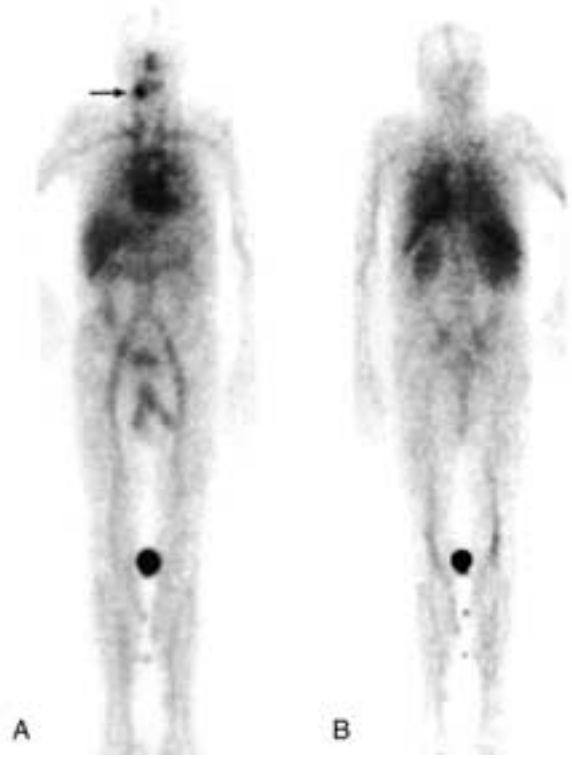

FIGURE 45-25 Anterior (**A**) and posterior (**B**) whole-body scans were performed in a patient with a right inferior alveolar ridge carcinoma 16 hours after injection of Tc-99m-labeled U36 IgG. Note the focal uptake at the site of the tumor (*arrow*) best seen on the anterior view (**A**).

photon abundance), low cost, and wide availability. Recent developments have also simplified the labeling methods for ^{99m}Tc.

Technique

The first images are usually acquired within a few minutes after injection of the radioimmunoconjugate. These early images serve as a baseline reference for subsequent images. For most intact MAbs or fragments labeled with ^{99m}Tc, the time for optimal imaging is 4 to 24 hours after injection. The later images are whole-body images and images of the head and neck region. SPECT images are often acquired in addition. Axial, coronal, and sagittal sections can be used to separate activity in the tumor from uptake in normal tissues including the blood vessels.

Early Results

It is only during the past decade that MAbs have become available with a high specificity for SCC of the head and neck and a restricted reaction pattern on normal tissues. Among the best-characterized MAbs are MAb E48 and U36, which both react with SCC of the head and neck as well as with normal squamous epithelium. These MAbs were administered to 49 patients with SCC of the head and neck who were at risk for having neck node metastases and who were scheduled to undergo neck dissection(s).[141–143] Patients received 1 to 50 mg E48 $F(ab')_2$ fragment (15 patients), E48 intact IgG (24 patients), or U36 intact IgG (10 patients) labeled with approximately 740 MBq ^{99m}Tc by intravenous injection. All 44 primary tumors in 49 patients were visualized by RIS. Thirty-two patients underwent unilateral neck dissection, and 17 patients had bilateral neck dissection. A total of 318 nodal levels were histopathologically evaluated. Fifty-one of the 66 operated sides contained metastases in a total of 77 levels. RIS detected lymph node metastases in 42 of the 77 levels (sensitivity, 55%) and in 35 of 51 sides (sensitivity, 69%). For CT and MR imaging, these figures were 60% for nodal level and 84% for neck side. Interpretation of RIS was correct in 276 of 316 levels (accuracy, 87%) and in 47 of 65 sides (accuracy, 72%). The accuracy of CT and MR imaging was, per level, 86% and 88%, respectively, and per side, 82% and 77%, respectively. The paraffin sections of the metastatic lymph nodes not detected by RIS were reexamined histopathologically.[141–143] The missed lymph nodes all were less than 2 cm in diameter and contained small tumor deposits (micrometastases) or metastases with large proportions of necrosis, keratin, or fibrin deposits. Furthermore, these examinations showed that the smallest tumor-involved lymph nodes detected by RIS had diameters of 5 mm and 9 mm in the axial plane, with a tumor burden of 50%.

In their present form, these initial studies suggest that RIS is not yet a preferred method for evaluating cervical nodal metastases. However, the immunohistochemical analyses performed during the initial RIS studies revealed that MAbs E48 and U36 had targeted all tumor-involved lymph nodes, as well as deposits that had not been visualized by RIS. Thus, MAbs were identifying lymph node metastases despite not being visualized on gamma camera imaging.

Future Trends

Investigations are now underway to improve the accuracy of RIS imaging. Ongoing investigations are aimed at reducing the time that MAbs reside in the blood pool. One concept is to use pretargeting strategies that provide rapid clearance from the bloodstream and result in high tumor/nontumor MAb ratios. Another area of active investigation is the integration of MAbs into PET technology. For this purpose, MAbs must be labeled with positron-emitting radionuclides, among which ^{124}I and ^{89}Zr are particularly suitable. Studies in tumor-bearing mice have shown that ^{89}Zr-labeled MAbs can easily be visualized with a PET camera, allowing detection of tumors as small as 50 mg.[144] On the basis of these preliminary studies, it can be anticipated that antibody-PET may eventually emerge as superior to conventional antibody-SPECT in sensitivity, resolution, and quantification.

CONCLUSIONS

The integration of new metabolic imaging techniques has led to dramatic changes in the evaluation of a variety of head and neck disorders. Because of the rapid pace of developments in the areas of metabolic and functional imaging, it is likely that currently unsuspected and unknown future applications will fall within the purview of radiologists.[145] It is imperative that our specialty continue to pursue new investigations that were once believed to be outside the realm of imaging.[146]

ACKNOWLEDGMENT

The authors appreciate the assistance of Gary Caputo, M.D., in reviewing the PET section of this chapter; the assistance of Carole Schreck, R.T., C.N.M.T., in figure preparation; and the clinical comments of Michael J. Kaplan, M.D.

A

AAO-HNS nodal classification system, 1872, 1874t–1875t
ABCs. *See* Aneurysmal bone cysts (ABCs).
Abducens nerve, 542
  branchial arches and, 1759
Aberrant fusion proteins, chromosome translocation to generate, oncogene activation by, 2277–2278
Abscesses
  Bezold, 1178f
  cerebellar, 1179f
  cerebral, nasal dermal sinus resection for, 34–35
  epidural
    in sinusitis, 582f
    with mastoiditis, 1182, 1182f
  epiglottic, 1569f
  in submandibular gland space, 1821f
  in toxoplasmosis, 778f
  intracranial, 250
  laryngeal, 1672f
  of masticator space, 1822f, 1990f
  of oral cavity, 1400, 1401f–1403f, 1402
  of pinna, 2108f
  of sphenoid sinuses, 582f
  orbital, 575, 578f
  parotid, 2027, 2027f, 2028f, 2042f, 2047f
  peritonsillar, 1504–1505, 1506f, 1565f, 1566f
  postoperative, following craniofacial resection, 435f
  retropharyngeal, 1565f, 1817f, 1820f
  septal, 380
  subperiosteal, 580f–582f, 580–581
ACCs. *See* Acinic cell carcinomas (ACCs); Adenoid cystic carcinomas (ACCs; AdCCs).
Achalasia, 2211f
Achondroplasia, 1110t, 1165f
  of skull base, 857
Acinic cell carcinomas (ACCs), 2096
Acoustic nerve, hamartomas of, 1303, 1311f
Acoustic schwannomas, 1276–1285
  bilateral, 1277–1278, 1278f
  clinical evaluation with, 1278–1279, 1279f
  imaging appearance of, 1280–1285
    on computed tomography, 1280, 1281f, 1282f, 1283
    on magnetic resonance imaging, 1280f–1284f, 1283–1284
    secondary changes and, 1284–1285, 1285f
    size, location, and configuration and, 1280, 1280f–1283f
  incidence and terms for, 1276–1277, 1277t
  intracanalicular, 1303
  pathology of, 1277
  treatment of, 1279–1280
Acquired immunodeficiency syndrome (AIDS). *See also* Human immunodeficiency virus (HIV) infections.
  coccidioidomycosis in, 1896
  neoplasia in, 2289–2290
  pharynx and, 1509, 1510f, 1511f, 1511–1512
  sinusitis in, 255
Acrocephalosyndactyly. *See* Apert's syndrome; Craniofacial dysostosis; Pfeiffer syndrome; Saethre-Chotzen syndrome.
Acromegaly, sinus enlargement in, 250f
Actinomycosis
  salivary glands and, 2037–2038
  sinonasal, 232–234
AdCCs. *See* Adenoid cystic carcinomas (ACCs; AdCCs).
Adductor paralysis, 1682, 1683f
Adelaide craniosynostosis. *See* Muenke syndrome.
Adenitis
  lacrimal, orbital pseudotumors and, 587, 590f
  retropharyngeal, 1505f
Adenoameloblastomas, 952–953, 957f
Adenocarcinomas
  basal cell, of salivary glands, 2084–2086, 2085f
  buccal, 1994f
  laryngeal, 1645
  low-grade, of salivary glands, 2096–2097, 2097f
  metastatic, lymph nodes in, 1927f, 1928f
  not otherwise specified, of salivary glands, 2104–2105, 2105f, 2106f
  ocular, 513
  of hard palate, 1444f
  of lacrimal gland, 644f
  of oral cavity, 1440, 1444f
  of parotid gland, with perineural tumor spread, 879f
  recurrent, following craniofacial resection, 435f
  sinonasal, 272, 274, 276–277, 282f
    intestinal-type, 274, 276–277
Adenoid(s)
  hypertrophic, 1509, 1510f, 1578, 1578f, 1579f
  retention cysts of, 1579f
Adenoid cystic carcinomas (ACCs; AdCCs)
  of facial nerve, 1327f
  of lacrimal gland, 645f
  of oral cavity, 1433, 1438, 1440f–1442f
  of parapharyngeal space, 1972, 1977f

Adenoid cystic carcinomas (ACCs; AdCCs) *(Continued)*
of salivary glands, 277–280, 279f, 1964f, 2090–2091, 2093f–2095f, 2093t, 2093–2096
of tongue base, 1496f
on proto magnetic resonance spectroscopy, 2314f
palatal, 851f–852f
of hard palate, with perineural tumor spread, 872f
with perineural tumor spread, 874f
perineural tumor spread of, 809f
sinonasal, 282f–284f
tracheal, 1718–1719, 1721f
Adenoidal tonsillar tissue, 1797f
Adenomas
basal cell, of salivary glands, 2084–2086, 2085f
benign, of lacrimal gland, 644f
canalicular, of salivary glands, 2086
follicular, of thyroid, 2150f
monomorphic, 1385
ocular, 513
parathyroid, 1839f, 2162–2166
on cross-sectional imaging, 2162–2163, 2163f, 2164f
on nuclear scintigraphy, 2163, 2165f, 2165–2166, 2167f
on ultrasonography, 2162, 2163f
pituitary. *See* Pituitary adenomas.
pleomorphic
of oral cavity, 1408, 1410, 1412f
of salivary glands, 280, 280f–284f, 1943, 1943f
sebaceous, of salivary gland origin, 2099
thyroid, 2150–2151
Adenomatoid hyperplasia, of mucous salivary glands, 2052
Adenomatoid odontogenic tumors, 952–953, 957f
Adenomatous tumors, of middle ear, 1342, 1346f
Adenopathy
generalized, persistent, in HIV infections, 1889
malignant, submental, 1395, 1398f
mycobacterial infections and, 1567, 1567f
Adenosis, sclerosing, of salivary glands, 2103–2104, 2104f
Adenosquamous carcinomas (ASCs), of salivary glands, 2098
Adenotonsillitis
bacterial, 1562–1564, 1564f–1567f, 1566
streptococcal, 1564f
viral, 1562
AFD Nager. *See* Nager acrofacial dysostosis syndrome (AFD Nager).
AFLNH. *See* Angiofollicular lymph node hyperplasia (AFLNH).
Agger nasi, 509
cells of, 97, 134f, 153–154
on computed tomography, 154f
Aging, oropharyngeal swallowing and, 1734–1735
AIDS. *See* Acquired immunodeficiency syndrome (AIDS).
AIDS-related cysts, of salivary glands, 2060–2063
Aileron, 1822
Air
humidification of, as nasal function, 93
in nasopharynx and oropharynx, on plain films, 121
in retropharyngeal space, 1820f
warming of, as nasal function, 93
Air cells
apical, giant, 1147
of temporal bone, 1061
Air-fluid levels, 196–198, 197f–199f, 200
on computed tomography, 197f–199f
on plain films, 197f–199f
Airway disorders, pediatric, 1525–1588
clinical evaluation in, 1525–1526
of obstructive sleep apnea, 1525–1526
of stridor, 1525
congenital, 1538–1561
craniofacial malformations, 1543–1544, 1544f, 1545f
laryngeal obstruction and, 1551–1553
nasal obstruction and, 1538–1543
oropharyngeal obstruction and, 1544, 1546–1550
subglottic obstruction and, 1553–1554
tracheal obstruction and, 1554–1556
vascular, 1556–1561
compression due to, 1555–1556, 1557f, 1558f
foreign bodies, 1575–1577, 1577f
infectious and inflammatory, 1562–1570
radiographic techniques for, 1526–1528
computed tomography, 1528
fluoroscopy, 1527–1528
magnetic resonance imaging, 1528
plain films, 1526f, 1526–1527, 1527f
traumatic, 1570–1578
tumors and tumor-like conditions
benign, 1578–1583
malignant, 1583–1588
AJCC. *See* American Joint Commission on Cancer (AJCC).

Tumor-reactive lymphadenopathy, 1903
Turbinates. *See* Nasal turbinates.
Turbinectomy, middle, postoperative findings with, 187, 187f
Turricephaly, 67
TWIST transcription factor, craniofacial dysostoses and, 73f, 74
Two-hit hypothesis of Knudsen, 2281
Tympanic cavity, parts of, 1066
Tympanic membrane
anatomy of, 1066
calcification of, 1199, 1199f, 1200f
Tympanoplasty, 1221–1222
Tympanosclerosis, 1199, 1199f, 1200f
Tympanostomy tubes, 1184, 1185f, 1219f
Tympanum, pneumatization of, 1061

U

Ultrasmall superparamagnetic iron oxide (USPIO) MR contrast agents, 2315–2317
clinical applications for, 2316–2317
notal metastasis detection, 2316–2317
primary site evaluation, 2317
mechanism of, 2315, 2316f
technique for, 2316
Ultrasound. *See specific regions.*
of neck. *See* Neck, ultrasound of.
Uncibullous groove, 101
Uncinate bulla, 161, 164f
Uncinate process, 92f, 97, 98, 101, 102, 140f, 144f
anatomy of, 155, 157f
attachment of, 160–161, 164f
deviation of, 160, 163f
pneumatization of, 161, 164f
Uncinatectomy, 170
Uncinectomy, postoperative findings with, 187
Undifferentiated carcinomas
large cell, of salivary glands, 2101–2102
of mastoid, 1347f
of salivary glands, 2101–2102
sinonasal, 285, 287–289
small cell
cutaneous. *See* Merkel cell tumors.
of salivary glands, 2101
Usher's syndrome, 1113t
USPIO. *See* Ultrasmall superparamagnetic iron oxide (USPIO) MR contrast agents.
Utricle, 1074
Utriculosaccular anomalies, 1121f, 1127, 1130f
Uvea, 453
anatomy of, 455f, 455–456
hemangiomas of, 509
lymphoid hyperplasia of, 473
lymphomas of, 511–512, 512f
melanomas of, 469f
malignant, 500–506
clinical diagnosis of, 500
diagnostic imaging in, 500–501, 501f–505f, 503–505
differential diagnosis of, 505–506, 506f, 506t
on computed tomography, 500f
on magnetic resonance imaging, 501f–506f
retinal detachment and, 514
metastatic disease of, 507, 508f
Uveal nevus, 508
Uveitis, 475, 478f
anterior, in sarcoidosis, 747
in sarcoiditis, 597, 597f
Uveoparotid fever, 600
Uvula, 1798f
on plain films, 121

V

Vaccinia, lymphadenitis in, 1888
Vagus nerve, 96, 1601, 1702, 2231–2235, 2234f–2236f, 2234t
anatomy of, 1785f, 1785–1786
branchial arches and, 1759, 1769
on magnetic resonance imaging, 1100f
pharyngeal branch of, 2231–2232
schwannomas of, 1292, 1299f
Vallecula, 1800f
Vallecular cyst, 1661, 1844f
Valsalva DCR bubble test, 670–671
Valves of Krause, 699
Van Buchem's disease. *See* Endosteal hyperostosis.
van der Hoeve's syndrome. *See* Osteogenesis imperfecta.
Vanishing bone disease, 837–838, 841f
Varicella zoster virus (VZV) infections
labyrinthitis due to, 1207, 1207f
lymphadenitis in, 1888
Varix, orbital, 569, 617, 619–620, 621f, 624f
Vascular disorders. *See also specific disorders.*
congenital, 1556–1561
neoplastic
of lymph nodes, 1909
of skull base, 836
tinnitus due to, 1367
of oral cavity, 1387, 1387f
